HORSELESS VEHICLE JOURNAL

A RECORD AND REVIEW OF APPLIED AUTOMATIC LOCOMOTION.

Circulates amongst Makers and Users of Autocars, Cycles, etc., in the United Kingdom, the Colonies and the Continent.

VOL. I. No. 2. NOVEMBER 17TH, 1896. PRICE SIXPENCE.

CONTENTS.

THE NEW MOTOR-CAR REGULATIONS.

THE Local Government Board have issued the following Regulations to the county councils and certain other local authorities in England and Wales with respect to the use of light locomotives on highways, and their construction, and the conditions under which they may be used, and have directed that the same shall have effect on and after November 14th:—

ARTICLE I.

In this Order:—

The expression "carriage" includes a wagon, cart, or other vehicle.

The expression "horse" includes a mule or other beast of draught or burden, and the expression "cattle" includes sheep.

The expression "light locomotive" means a vehicle propelled by mechanical power which is under three tons in weight unladen, and is not used for the purpose of drawing more than one vehicle (such vehicle with its locomotive not exceeding in weight unladen four tons), and is so constructed that no smoke or visible vapour is emitted therefrom except from any temporary or accidental cause.

In calculating for the purposes of this Order the weight of a vehicle unladen, the weight of any water, fuel, or accumulators used for the purpose of propulsion shall not be included.

ARTICLE II.

No person shall cause or permit a light locomotive to be used on any highway, or shall drive or have charge of a light locomotive when so used, unless the conditions hereinafter set forth shall be satisfied, namely:—

(1.) The light locomotive, if it exceeds in weight unladen five hundredweight, shall be capable of being so worked that it may travel either forwards or backwards.

(2.) The light locomotive shall not exceed six and a half feet in width, such width to be measured between its extreme projecting points.

(3.) The tyre of each wheel of the light locomotive shall be smooth, and shall, where the same touches the ground, be flat and of the width following, namely:—

(*a*) If the weight of the light locomotive unladen exceeds fifteen hundredweight, but does not exceed one ton, not less than two and a half inches;

(*b*) If such weight exceeds one ton, but does not exceed two tons, not less than three inches;

(*c*) If such weight exceeds two tons, not less than four inches.

Provided that where a pneumatic tyre, or other tyre of a soft and elastic material is used, the tyre may be round or curved, and there may be upon the same projections or bosses rising above the surface of the tyre if such projections or bosses are of the same material as that of the tyre itself, or of some other soft and elastic material. The width of the tyre shall, for the purpose of this proviso, mean the extreme width of the soft and elastic material on the rim of the wheel when not subject to pressure.

(4.) The light locomotive shall have two independent brakes in good working order, and of such efficiency that the application of either to such locomotive shall cause two of its wheels on the same axle to be so held that the wheels shall be effectually prevented from revolving, or shall have the same effect in stopping the light locomotive as if such wheels were so held.

Provided that in the case of a bicycle this Regulation shall apply as if, instead of two wheels on the same axle, one wheel was therein referred to.

(5.) The light locomotive shall be so constructed as to admit of its being at all times under such control as not to cause undue interference with passenger or other traffic on any highway.

(6.) In the case of a light locomotive drawing or constructed to draw another vehicle or constructed or used for the carriage of goods, the name of the owner and the place of his abode or business, and in every such case and in the case of every light locomotive weighing unladen one ton and a half or upwards, the weight of the light locomotive unladen shall be painted in one or more straight lines upon some conspicuous part of the right or off side of the light locomotive in large legible letters in white upon black or black upon white, not less than one inch in height.

(7.) The light locomotive and all the fittings thereof shall be in such a condition as not to cause, or to be likely to cause, danger to any person on the light locomotive or on any highway.

(8.) There shall be in charge of the light locomotive when used on any highway a person competent to control and direct its use and movement.

(9.) The lamp to be carried attached to the light locomotive in pursuance of Section 2 of the Act shall be so constructed and placed as to exhibit, during the period between one hour after sunset and one hour before sunrise, a white light visible within a reasonable distance in the direction towards which the light locomotive is proceeding or is intended to proceed, and to exhibit a red light so visible in the reverse direction. The lamp shall be placed on the extreme right or off side of the light locomotive in such a position as to be free from all obstruction to the light.

Provided that this Regulation shall not extend to any bicycle, tricycle, or other machine to which Section 85 of the Local Government Act, 1888, applies.

Article III.

No person shall cause or permit a light locomotive to be used on any highway for the purpose of drawing any vehicle, or shall drive or have charge of a light locomotive when used for such purpose, unless the conditions hereinafter set forth shall be satisfied, namely :—

(1.) Regulations (2), (3), (5), and (7), of Article II of this Order shall apply as if the vehicle drawn by the light locomotive was therein referred to, instead of the light locomotive itself, and Regulation (6) of the Article shall apply as if such vehicle was a light locomotive constructed for the carriage of goods.

(2.) The vehicle drawn by the light locomotive, except where the light locomotive travels at a rate not exceeding four miles an hour, shall have a brake in good working order of such efficiency that its application to the vehicle shall cause two of the wheels of the vehicle on the same axle to be so held that the wheels shall be effectually prevented from revolving, or shall have the same effect in stopping the vehicle as if such wheels were so held.

(3.) The vehicle drawn by the light locomotive shall, when under the last preceding regulation a brake is required to be attached thereto, carry upon the vehicle a person competent to apply efficiently the brake: Provided that it shall not be necessary to comply with this Regulation if the brakes upon the light locomotive by which the vehicle is drawn are so constructed and arranged that neither of such brakes can be used without bringing into action simultaneously the brake attached to the vehicle drawn, or if the brake of the vehicle drawn can be applied from the light locomotive independently of the brakes of the latter.

Article IV.

Every person driving or in charge of a light locomotive when used on any highway shall comply with the Regulations hereinafter set forth, namely :—

(1.) He shall not drive the light locomotive at any speed greater than is reasonable and proper, having regard to the traffic on the highway, or so as to endanger the life or limb of any person, or to the common danger of passengers.

(2.) He shall not under any circumstances drive the light locomotive at a greater speed than 12 miles an hour. If the weight unladen of the light locomotive is one ton and a half and does not exceed two tons, he shall not drive the same at a greater speed than eight miles an hour, or if such weight exceeds two tons, at a greater speed than five miles an hour.

Provided that whatever may be the weight of the light locomotive, if it is used on any highway to draw any vehicle, he shall not, under any circumstances, drive it at a greater speed than six miles an hour.

Provided also that this Regulation shall only have effect during six months from the date of this Order, and thereafter until We otherwise direct.

(3.) He shall not cause the light locomotive to travel backwards for a greater distance or time than may be requisite for purposes of safety.

(4.) He shall not negligently or wilfully cause any hurt or damage to any person, carriage, horse, or cattle, or to any goods conveyed in any carriage on any highway, or, when on the light locomotive, be in such a position that he cannot have control over the same, or quit the light locomotive without having taken due precautions against its being started in his absence, or allow the light locomotive or a vehicle drawn thereby to stand on such highway so as to cause any unnecessary obstruction thereof.

(5.) He shall when meeting any carriage, horse, or cattle keep the light locomotive on the left or near side of the road, and when passing any carriage, horse, or cattle proceeding in the same direction keep the light locomotive on the right or off side of the same.

(6.) He shall not negligently or wilfully prevent, hinder, or interrupt the free passage of any person, carriage, horse, or cattle on any highway, and shall keep the light locomotive and any vehicle drawn thereby on the left or near side of the road for the purpose of allowing such passage.

(7.) He shall, whenever necessary, by sounding the bell or other instrument required by Section 3 of the Act, give audible and sufficient warning of the approach or position of the light locomotive.

(8.) He shall on the request of any police constable, or of any person having charge of a restive horse, or on any such constable or person putting up his hand as a signal for that purpose, cause the light locomotive to stop and to remain stationary so long as may be reasonably necessary.

Article V.

If the light locomotive is one to which Regulation (6) of Article II applies, and the particulars required by that Regulation are not duly painted thereon, or if the light locomotive is one to which that Regulation does not apply, the person driving or in charge thereof shall, on the request of any constable, or on the reasonable request of any other person, truly state his name and place of abode, and the name of the owner, and the place of his abode or business.

This Order may be cited as "The Light Locomotives on Highways Order, 1896."

In a letter addressed to the County Councils Sir Hugh Owen, the Secretary of the Local Government Board, draws attention to the provisions of the Locomotives on Highways Act, 1896. He refers to the exemption of light locomotives from certain enactments, and points out that the duties imposed by Section 4 of the Customs and Inland Revenue Act, 1888, will be payable for light locomotives which are carriages or hackney carriages as defined by the Act, and that such light locomotives will pay on and after January 1st next an additional excise duty at the following rate :—£2 2s. if the weight of the locomotive exceeds 1 ton but does not exceed 2 tons unladen, and £3 3s. if the weight exceeds 2 tons unladen. A summary of the above Order issued by the Local Government Board is given, and on the subject of speed Sir Hugh Owen states :—"Section 4 of the Act directs that no light locomotive shall travel along a public highway at a greater speed than 14 miles an hour, or than any less speed that may be prescribed by regulations of the Board. There is considerable difficulty in laying down definite rules as to the speed of light locomotives at the present time, as no experience has been obtained of their use in this country; but the Board have been strongly urged to make some general regulations on the subject, and they have dealt with it by Article IV of the Order."

The Carriage of Petroleum.

Sir Matthew White Ridley, the Home Secretary, in issuing the regulations as to petroleum for motor-cars, states:—

In promulgating the following regulations relating to the keeping, conveyance, and use of petroleum in connection with light locomotives, the Secretary of State for the Home Department desires to call public attention to the dangers that may arise from the careless use of those more volatile descriptions of petroleum to which these rules apply, being petroleum to which the Petroleum Act, 1871, applies, and commonly known as "mineral spirit."

Not only is the vapour therefrom, which is given off at ordinary temperature, capable of being easily ignited, but also, when mixed with air, of forming an explosive mixture. Hence the necessity for strict precautions in dealing with and handling the same, and for the employment of thoroughly sound and properly closed vessels to contain the same, the importance of avoiding the use of naked lights in dangerous proximity to the same or to any places where such petroleum may be kept, and generally of taking precautions to prevent contact of the highly inflammable vapour of this very volatile liquid with any form of artificial light.

Regulations.

1. Petroleum shall not be kept, used, or conveyed, except in tanks or cases of metal so made and closed that no leakage, whether of liquid or vapour, can take place therefrom, and so substantially constructed as not to be liable, except under circumstances of gross negligence or extraordinary accident to be broken or become defective or insecure in course of conveyance or use; and every air-inlet in any such tank or case shall be at all times, except when the valve, if any, is required to be removed for immediate use or repair, protected by securely affixed wire gauze, the openings in which shall not be less in number than 400 to the square inch.

2. Every such tank or case shall be clearly stamped or securely labelled with a legible metallic or enamelled label with the words "mineral spirit, highly inflammable, for use with light locomotives."

3. The amount of petroleum to be in any one such tank or case at one time shall not exceed 20 gallons.

4. There shall not be at the same time on or in any one light locomotive, more than two of such tanks as aforesaid.

5. Before repairs are done to any such tank or case, that tank or case shall, as far as practicable, be cleaned by the removal of all petroleum and of all dangerous vapours derived from the same.

6. When petroleum for use in, or in connection with any light locomotive is not being so used, it shall be kept either in accordance with the provisions of the Petroleum Acts, or in such tanks or cases as aforesaid; provided that the amount of petroleum which may be so kept in tanks or cases as aforesaid shall not exceed the amount of petroleum which may be kept on or in any one light locomotive at the same time, and that the tanks or cases shall be kept in the open air, or in some suitably ventilated place.

7. The filling or replenishing of a tank with petroleum shall not be carried on, nor shall the contents of any such tank be exposed by artificial light, except a light of such construction, position, or character as not to be liable to cause danger, and no artificial light shall be brought within dangerous proximity of the place where any tank containing petroleum is being kept.

8. In the case of all petroleum kept or conveyed for the purpose of or in connection with any light locomotive (*a*) all due precautions shall be taken for the prevention of accidents by fire or explosion, and for the prevention of unauthorised persons having access to any petroleum kept or conveyed, and to the vessels containing or intended to contain, or having actually contained the same; and (*b*) every person managing or employed on or in connection with any light locomotive shall abstain from every act whatever which tends to cause fire or explosion, and which is not reasonably necessary, and shall prevent any other person from committing such act.

9. These regulations shall come into operation on the 14th day of November, 1896, and be in force until further notice.

AGRICULTURISTS AND THE SPEED OF AUTOMOTORS.

The monthly meeting of the Council of the Central and Associated Chambers of Agriculture was held at the Society of Arts, Adelphi, London, on the 3rd inst., under the presidency of Mr. J. Lloyd Wharton, M.P. The delegates considered, as a matter of urgency, the rate of speed to be permitted by the regulations of the Local Government Board for light locomotives on the roads.

Mr. Muntz, of Warwickshire, moved: "That in the opinion of this Council the maximum rate of speed at which light locomotives should travel along public highways for 12 months at least should be fixed at not exceeding 10 miles per hour, and representations to this effect be forwarded to the Local Government Board." He drew attention to the fact that under the Act the speed was to be not exceeding 14 miles an hour. They thought that rate was excessive. The Act further asserted that the machines were to be pulled up within 50 feet. The stoppage within such a short distance from a high rate of speed would seriously damage the roads.

Mr. H. Williams, Monmouth, seconded, and thought that eight miles per hour was sufficient. Agriculturists ran a great risk from their horses being frightened by cyclists. Of this class "the scorchers" were the worst. He regretted they did not postpone their scorching till they got to the next world. (Laughter.)

Mr. A. D. Wells (Berks and Oxon) opposed the resolution, and Mr. Corbett mentioned that in Switzerland electric cars ran along the roads at a speed of over 14 miles an hour without to any extent inconveniencing the traffic.

Mr. Lipscomb said that in his district (the West Riding) a year or two since traction engines had, through using the roads in frosty weather, damaged them to the extent of £1,000 per mile. The rate of speed, he thought, should be moderated. They were in danger of being overridden. He dissented from the view taken by one of the speakers, that the proposal to moderate the speed of road locomotives was grandmotherly. Restrictions in this direction were as necessary now, in the light of experience, as ever they were.

The Chairman said the minimum distance for pulling up light locomotives was 50 feet, and this he thought was much too short a distance. With heavy engines he thought this would result in serious injury to the roads. Fast travelling was all very well in the fen district, where a driver could often see two miles or more in front of him, but in districts where the roads had sharp curves and high hedges, he regarded swift travelling as extremely dangerous. He should like to see the maximum rate of speed reduced.

The motion was adopted.

The Indestructible Ignition Tube Syndicate, of 100c, Queen Victoria Street, E.C., have made arrangements for repairing and storing autocars in Queen Victoria Street. They have their showrooms, 110 feet long by 25 feet wide, fitted with machine tools for repair work, and dynamos for electric charging.

TYPES OF HORSELESS VEHICLES.

The Thornycroft Steam Motor-Carriage.

Mr. Thornycroft, whose name is identified throughout the world with high class torpedo-boat machinery, has identified himself with the new self-propelled traffic, and designed a steam-carriage which will carry a load of one ton, and weighs about 35 cwt. when in full working order—including the weight of the coke used as fuel, the driver, and water necessary for a run of 20 miles.

Tho boiler is of the Thornycroft water-tube launch type with water fire-bars, steam being raised in about 15 minutes. The engine is double compound, the cylinders being respectively of 2 and 4 inches diameter, with a stroko of 3 inches. The engine speed is geared in the ratio of 9 to 1 to the road driving wheels. The condenser is placed on the roof, and is of sufficient cooling surface to condense all the steam at ordinary rates of working.

The van can climb an incline of 1 in 10 when fully loaded. The ordinary speed of working is about six or seven miles per hour, but a speed of nine miles per hour can easily be sustained on level roads. The floor space available for carrying goods is about 25 square feet.

Several trials have been made of this carriage with excellent results, while the name of Thornycroft is sufficient guarantee of the admirable quality of the workmanship and material which is used throughout. For developing this new branch of work an establishment has been founded under the title of the Steam Carriage and Wagon Company, Homefield, Chiswick Mall.

THE THORNYCROFT STEAM MOTOR-CARRIAGE.

An American Motor-Carriage.

From our representative in the United States we learn that a carriage capable of attaining a speed of from three to 18 miles an hour has been invented by a Springfield man, and an extensive factory will be erected for the manufacture of the vehicle. The promoter of the new carriage is Henry W. Clapp, and the inventor is Charles E. Duryea, both of Springfield, Ohio. A company is now being formed, and nearly one-half of the required capital of £60,000 has been secured. The new carriage has been given repeated tests, all of which have been successful. A trip was made to Hartford and return recently, insido of three hours. In appearance the machine resembles an ordinary side-bar four-wheel carriage. The wheels are rubber-tyred and run on ball bearings. Each of the front wheels instead of turning on a central bolt, as is the case with ordinary carriages, revolves on its own pivot located in the hub, thereby making each turn in a much smaller radius, and, consequently, being easier to operate in steering. The vehicle is easily manipulated by a lever located in front of the driver. A lateral motion of the lever turns the wheel while the vertical motion controls the speed. One of the advantages of the carriage is that by pressing a button connected with a brake drum the vehicle can be stopped almost instantly, thus lessening the danger of travelling in the streets. The motor is compactly located under the seat, and is stated to weigh about one cwt. for an output of four horse-power. Near this is a dynamo. To start the wagon a crank is revolved once on the side of the wagon. This turns the motor which starts the dynamo, which generates the necessary sparks to explode the oil-gas contained in the combustion end of the cylinder. Since the experimental machine has been completed it has been run over 1,000 miles, and is reported to have established its practicability on country as well as city roads.

Roots and Venables' Three-wheeled Carriage.

THIS vehicle, which we illustrate as manufactured by Messrs. Roots and Venables, of 100, Westminster Bridge Road, is built with a strong angle steel frame, carrying the oil motor of 2½ horse-power at the back, together with the exhaust box and small water-tank. The power is transmitted from the crank-shaft of the engine to a counter-shaft by means of belts working on various-sized pulleys, which counter-shaft again transmits the power to the axle of the carriage by a pinion and toothed wheel.

ROOTS AND VENABLES' THREE-WHEELED CARRIAGE.

This two-speed gear runs the carriage at ten or four miles an hour as desired. In the front of the carriage the larger water-tank is fixed out of sight beneath the feet of the riders. The carriage steers remarkably easy, and is fitted with two brakes, one on the front wheel and the other on a drum on the main axle. Sufficient oil is carried for a run of 27 miles in the tank, but more can be easily placed under the seat.

The tyres are of solid indiarubber dovetailed into steel rims.

The oil used is common American Tea Rose or Royal Daylight, price 5½*d.* per gallon.

The specific gravity of this oil is from ·8 upwards. Consequently it is quite safe to use, and must be distinguished from the gasoline or benzoline used by most other carriages, particularly those at present running in France.

The Benz Motor-Carriage.

A BRADFORD correspondent writing of this vehicle—which is the invention of Mr. Benz, of Mannheim, and is being introduced into this country by the Arnold Motor-Car Company, of East Peckham—gives an interesting account of a ride which he recently enjoyed. He states that "by the courtesy of the local agent, Mr. James E. Tuke, Aldermanbury, he was initiated into the mysteries of the horseless carriage, riding with Mr. Tuke in a small car of 1½ horse-power from Otley to Bradford, the time occupied being an hour and twenty minutes exactly. The day was very unsuitable owing to the heavy condition of the roads, and the success of the ride under such adverse circumstances showed how great the scope of the invention must be. At present the machine is hardly out of the experimental stage; but on the flat a good speed was attained. One fine feature of the machine is the ease with which the speed is regulated, without having recourse to the brake. Hollings Hill can be descended, either fast or slow, by simply setting the indicator, or, if economy be aimed at, the gearing may be shifted, and the wheels allowed to revolve down hill under the control of the brake. It appears that a car of 1½ horse-power is not quite equal to carrying two people up the Yorkshire hills in bad weather, but an addition of "½ horse-power" would probably be ample. The little carriage now in Mr. Tuke's possession is one of the smallest made, and its value is about £130. No particular mechanical knowledge is required to understand the working of the car, and when once charged with oil and electricity it will run for 150 miles. The sensation of travelling by this new and convenient method is precisely that of cycling, with the exception of the labour involved by the latter. All that is needed for motor-car riding is a hand for steering and a head to restrain one's natural inclination for racing on the public road. Of the utility and general merit of the horseless carriage there cannot be any doubt. For doctors the novelty appears to offer immediate advantages, but a general adoption of the vehicle by tradespeople and others will naturally be a work of time, and must depend upon the further development of the invention itself." These motors have found much favour in France and Germany, and will doubtless obtain a fair measure of success in this country.

THE BENZ MOTOR-CARRIAGE.

HINT TO INVENTORS.—In connection with the show of cycles which is to be held in Belgium in the new year, prizes of £40 are being offered: (1) For the best wrench which will not cut or disfigure the nut; (2) for a motor for machines, weight not to exceed 21 lbs., capable of giving one horse-power, and inexplosive. Smaller prizes are offered for the following: (1) A machine for transmission, whereby an even amount of power is obtained on both sides of the machine; (2) the best kind of frame, in which solidity and weight are carefully and advantageously combined.

A WELCOME reminder of the advent of Christmastide is to hand in the shape of a package of the marvellous cards and books issued by Messrs. Raphael Tuck and Co. The firm has so long held and deserved the highest reputation for artistic design and perfect printing, that it is almost impossible to write anything new in their favour. For the children there are wondrous books of fairy lore, of kindly goblins, and nursery rhymes illustrated with beautiful children and dolls, while whimsically-designed elfins and Puck-like creatures hover about the pages in such alluring ways that the little ones cannot fail to be attracted and amused by the apt illustrations and tasteful dialogue. For older folk the Christmas cards are designed in perfect taste; while such work as that shown in Raphael Tuck's series of platino panels has, perhaps, never been equalled by any other publisher. Perhaps next year they may give us an idealised automotor carriage, with appropriate occupants and motor (we apologise—motto).

THE LONDON COUNTY COUNCIL AND MOTORS.

THE Highways Committee of the Council presented a report to the Council on the 3rd inst. regarding the Locomotives on Highways Act, 1896, and motor-cars in London. The committee stated that they had considered a letter from the Local Government Board, forwarding a copy of general regulations which it is proposed to make under the Act. It appeared to the committee that, having regard to the crowded condition of many of the London thoroughfares, it is important that a regulation limiting the speed of such vehicles when travelling in London to a maximum of eight miles an hour instead of 14 should be made and issued before the Act comes into operation. There is little doubt, the committee stated, that if light locomotives were to be allowed to run at the rate of 14 miles an hour they would seriously interfere with the other traffic. The Board asked that observations upon the proposed general regulations might be submitted not later than October 31st, and the committee had accordingly, on behalf of the Council, made a representation to the Board of the necessity for such a regulation. The action of the committee was approved by the Council.

LIGHT RAILWAYS.

THE Commission appointed by the Act of Parliament last Session to give assistance to promoters of light railways throughout Great Britain has acquired temporary offices at 23, Great George Street, Westminster, where all plans of light railways must be considered before the end of December. Every application going before the Commissioners must be accompanied by a full statement of the proposed light railway, gauge, motive power, county and parish where proposed, advance of money requisition, and a certificate that a fee of £50 has been paid to the Board of Trade. The Commissioners are quite ready to advise applicants having the desire of constructing light railways in the procedure necessary. The Commissioners are the Earl of Jersey, Col. G. F. O. Boughey, R.E., and Mr. Gerald FitzGerald. Mr. Bret Ince is the secretary. A full account of the provisions of this important measure appeared in our last issue.

An interesting exhibition of light railway plant was recently shown at Newlay, near Leeds. It was all the more noteworthy by reason of the fact that the plant is intended for the first light railway which the Government of India has sanctioned. The Barsi light railway, for which the present equipment is intended, will be laid along the side of an ordinary country road, the gauge being 2 feet 6 inches. The rails weigh 30 lbs. per yard, and as there is no land to purchase, it is estimated that the cost of construction will not exceed £600 per mile of single track. The locomotives are of the eight-wheeled coupled type, capable of hauling 276 tons on a gradient of 1 in 100, and of 150 tons on a gradient of 1 in 57. Both the goods wagons and the passenger coaches are of the bogie type. The object of the demonstration was to show that heavy loads can be carried over a narrow-gauge line, and that the permanent way and plant in an average country district are simple and inexpensive.

THE SELF-PROPELLED TRAFFIC ASSOCIATION.

FORMATION OF A LIVERPOOL BRANCH.

The vice-president of the Liverpool branch of the Self-Propelled Traffic Association, Mr. Alfred L. Jones, on Monday, the 26th ult., gave a luncheon in the Exchange Station Hotel for the purpose of welcoming Sir David Salomons, Bart., president of the Association, on the occasion of his visit to that city to deliver an address before the members of the newly-formed local branch of the Self-Propelled Traffic Association. About 50 gentlemen assembled besides the principal guest, Sir David Salomons.

Invitations had been extended to the following :—The Earl of Derby, Prince Bhanuganger, of Siam ; Colonel A. H. Holme, Sir W. B. Forwood, Captain Wilson Wilson, Professor Hele-Shaw, Messrs. A. Bromley Holmes, A. J. Lyster, J. A. Brodie, A. Musker, G. F. Ransome, H. H. West, J. Wilson, J. F. Wood, E. Shrapnell Smith (local hon. sec.), G. H. Cox, M. Bannister, H. P. Boulnois (city engineer), C. M'Arthur, L. Jones, A. Sinclair, W. J. Davey, F. C. Danson (president), T. H. Barker (secretary Liverpool Chamber of Commerce), A. Cook, A. Elder, J. Dempster, Ellis Edwards, John Holt, J. Thorburn, E. Bindloss, W. J. Stewart, D. Jones, J. Pinnock, S. B. Cottrell, H. G. Clarke, &c. Public engagements prevented the Lord Mayor attending, and the Prince of Siam had left the city.

After luncheon, Mr. Jones, in his introductory remarks, said that much of the agitation and many of the facilities offered in improved road locomotion were due to Sir David Salomons's energy, foresight, and ability, both inside the House of Commons and out (hear, hear). He (the speaker) had attached himself to the society for the sole purpose of obtaining improved means of getting cargo to and from Liverpool and adjacent places. One of the most wicked expenditures of money had been the making of the Manchester Canal, which would not secure the object the Manchester people had in view—viz., taking steamships to Manchester, because the steamship of the future would be altogether unable to enter the canal.

Sir David Salomons acknowledged the cordial expressions of Mr. Jones concerning himself. Proceeding, he said if those who were going to start a system of transferring passengers or goods from one point to another could evade the purchase of land and the necessity of capital for the laying of the permanent way and its up-keep, they could do the work of transit very much cheaper than a railway company which started with those disadvantages at its back. Under the system he referred to they had the advantage of roads kept up and repaired by the ratepayers, and with it they ought to compete most favourably with the railways in the cost of conveying goods. A penny per ton per mile was an exceedingly reasonable figure to place on transit by road with any known form of locomotor. The chairman had a scheme before him of carrying goods at even a lower rate. The scheme was that of road trains not under the new Act, but under the old Act, to go at a speed not exceeding four miles an hour, carrying goods for less than a penny a mile between Liverpool and Manchester. It appeared to him if that scheme were going to be such an exceedingly profitable one—to say nothing of what the railways might do in consequence—they would have road trains innumerable between Liverpool and Manchester, sufficient almost to make the roads themselves impassable in a very short time. A question which arose was, would the county councils or other local authorities keep and repair the roads under those conditions without extra contributions from those who used them ? It would not be fair to ask the authorities to do so. There was a solution, however, for that. Those who benefited by that form of traction should, under the special clause of extra wear and tear, help the other unfortunate ratepayers in paying their rates (applause).

Mr. G. F. Ransome, a Liverpool engineer, believed the scheme mentioned by Mr. Jones to be thoroughly practicable. It was, he said, working in some parts of the country.

Sir David Salomons proposed the health of Mr. Jones, who, in responding, said his great object was to make Liverpool more successful than she had ever been.

The company then separated.

Address by Sir David Salomons on the Motor-Carriage Industry.

In the evening, Sir David Salomons delivered the inaugural address in connection with the Liverpool branch of the Self-Propelled Traffic Association, in the Royal Institution, Colquitt Street. In the unavoidable absence of the Lord Mayor, the president of the Liverpool centre of the Association, the chair was occupied by Mr. A. L. Jones, who was supported by a number of leading engineers, members of the Liverpool Chamber of Commerce, and others. It should be mentioned that the local vice-presidents are Mr. H. Percy Boulnois, Mr. Alfred Holt, and Mr. Alfred L. Jones. The Council consists of Mr. Maunsell Bannister, Mr. John A. Brodie, Mr. E. R. Calthrop, Mr. George H. Cox, Mr. A. Bromley Holmes, Mr. A. G. Lyster, Mr. Arthur Musker, Mr. G. F. Ransome, Mr. H. H. West, Mr. John Wilson, and Mr. J. T. Wood. Mr. E. Shrapnell Smith is the energetic honorary secretary of the centre. The number present exceeded 400, and amongst those who attended were :--Alfred Holt, H. Percy Boulnois (city engineer), F. C. Danson (president Liverpool Chamber of Commerce), W. J. Stewart (Stipendiary Magistrate), Professor H. S. Hele-Shaw (University College), E. Hallon Cookson, C.C., W. H. Williams, C.C., Thomas Menlove, C.C., Charles H. Giles, C.C., Louis S. Cohen, C.C., George H. Ball, C.C., W. J. Carmichael (Lancashire and Yorkshire Railway), J. Shaw (London and North-Western Railway), John Macaulay (Mersey Tunnel Railway), J. Audley F. Aspinall (chief engineer Lancashire and Yorkshire Railway, Horwich), M. C. Bannister, John A. Brodie, E. R. Calthrop, Geo. H. Cox, A. Bromley Holmes, Arthur Musker, G. Frederick Ransome, Henry H. West, John Wilson, C.C., J. T. Wood, C.C., Laurence Jones (solicitor to the local branch), T. H. Barker (secretary Liverpool Chamber of Commerce), Dr. Francis Melach, Dr. Proctor, Dr. Percy Marsh, Colonel Gamble, C.B., Colonel A. Hill Holme, J.P., Eustace Carey, Alexander Wall, Dr. J. W. Hayward, Dr. C. W. Hayward, A. R. Marshall, M. Zagury, Chas. H. Beloe, C.C., Major W. A. Pride, Dr. Henry O. Forbes, A. J. Pilkington, R. J. Glasgow, J.P., S. B. Cotterell (Liverpool Overhead Railway), C. H. Darbyshire, J.P., Geo. S. Hazelhurst, J.P., D. de Ybarrondo, Alex. Dalrymple, Percy Bateson, H. L. Higgins, R. E. Warren (Midland Railway), and E. Shrapnell Smith. Amongst the audience there were some 40 ladies.

The Chairman, at the outset, said he did not know any town in the country where the use of the self-propelled vehicle was likely to be more beneficial than Liverpool (hear, hear).

Sir David Salomons, who was very cordially received, after paying a graceful compliment to the energy and intelligence of the citizens of Liverpool, said :—The place I have occupied in regard to self-propelled traffic is so exceptional, that it is difficult for many to believe that I have not some ultimate interest in the movement. Business men cannot always appreciate the position of those who are devoted to the application of science, and whose pleasure it is to work and expend money in this direction, without the expectation or desire to receive interest in return. It is my good fortune that, by devotion to practical science, I can hope to influence others, for, with an engineer's training, and having studied the question to be dealt with to-night very closely for a number of years, I am able to speak freely, and without fear or favour. I should not refer to myself in such terms, but for the reason that I am anxious to assure my hearers that all I say is honestly what I believe ; and further, that it is not my desire to give offence in any direction. My object is simply to put the whole case fairly before you, without paying compliments to anyone.

The Doubtful Value of Patents.

One opinion from which I have never swerved upon this question is that no patent connected with self-propelled traffic is worth the paper it is written upon, whether the patents will bear the test of the Law Courts or not. All fresh capital required for the production of the new vehicles should be utilised by enlarging existing workshops, or for the erection of additional factories as well as for working capital. There is no reason for locking up large sums of money in patent rights except for the benefit of company promoters and their companies. Any industrial concern heavily loaded with unproductive capital, must necessarily either charge the public an undue profit on their goods or fail, and since there is no impediment in the way of producing the best possible self-propelled vehicle (the question of patents not arising, except in some cases to an inappreciable extent), it would be unjust that any attempt should be made to compel the English public to pay an unfair price for an article, only to benefit the few who are feathering their nests. It must not be supposed from these remarks that I grudge the inventor a portion of the profits which might arise from the article which he has devised or improved, but I object to the trading in patents by sale outright, which so often acts unfairly to the public as well as to the inventor himself. I have always contended that the equitable way of dealing with such property is for the patentee to accept deferred interest and, if required, a moderate sum paid down in money or shares according to the nature of the circumstances, the transaction being such that in the case of the manufacture (which all patents *must* be) the patentee, should his invention prove of value, would derive the benefit jointly with those who hold his rights, and *vice versâ*. As a natural consequence the patentee and the manufacturer, in regard to the article produced, would stand or fall together. Self-propelled traffic, although it has in recent years been hampered in this country, is so old, so well known, and has been worked out by such able men in the past, that every form of engine, and every type of gearing which has a value, is public property. Further, every patent of any value in connection with gas and oil engines has expired, so that to the Englishman the world is now open for the production of self-propelled vehicles without let or hindrance, whatever may be said by interested parties to the contrary.

Steam the Motive Power of the Future.

I have expressed myself very strongly, that steam and steam alone will be the future power of self-propelled traffic. You must not understand me to mean that there is absolutely no place for other forms of motors. This I fully recognise, yet I feel confident that within a short period, in nine out of every ten motor vehicles constructed, steam will assert its supremacy. You will see the point more forcibly when I deal with the subject in detail.

The Initiation of Recent Legislation.

The celebrated 1881 Appeal in the Court of Queen's Bench decided till November 14th, 1896, the fate of motor locomotion on the highways, for the decision placed every vehicle self-propelled within the narrow limitations of the Locomotives Acts, which were created to deal with heavy traction. The definition of a locomotive in one of these Acts is such that the lawyer's well-known "coach and four" could not drive through it. Although many gentlemen, including myself, have been given the credit of helping forward the new Act, it is only fair to point out that the first credit is always due to Mr. Shaw-Lefevre, who introduced a Bill in the final Session of the last Parliament, and that he did so without public agitation is a proof that he is a man ready to recognise the wants of modern society. His Bill, however, was faulty in regard to one point. Had this Bill become an Act without considerable amendment, the question would have been left in the hands of the local authorities, and once more there would have been an Act, which would probably have been unworkable, in consequence of different districts adopting dissimilar regulations. The manufacturer might have had to consult the requirements of a hundred or more local authorities, whose demands might have been constantly varied. The user of the carriage would also have been hampered quite as much as the manufacturer.

Advantages of the New Law.

The present Act is free from this blemish, and the high roads of England are made continuous under one system of regulations. The manufacturer, by the study of two sets of rules to be issued, one by the Local Government Board, and the other by the Home Office, will be able to conform to the requirements of the State. These rules will be framed in the interests of public safety, and therefore an advantage to all concerned.

The Paris-Marseilles Contest.

From time to time I have published pamphlets and articles dealing with the subject of horseless traffic. I will, therefore, not weary you with a recapitulation of all that can be said on the matter, but leave the past and go straight to my recent visit to Paris on the occasion of the Thousand Miles Race, and from its results draw deductions according to my own judgment. About 50 carriages were entered, but on the day of the start 32 only appeared. So few, out of the total entered, arriving at the starting point was due to many manufacturers having found that their vehicles were not sufficiently perfect, or could not be prepared in time. The fact that steam was only represented by two carriages, and that these failed to make any headway, will by many be taken as an argument against this agency. On one point the French differ from the English, in not being so practical. The Englishman would finish his carriage long before the day of the race, and experiment with it. Our neighbours, however, leave matters to the last moment, although there are, of course, exceptions to this rule. I saw the two steam carriages 48 hours before the start, and at that time the wheels were not completed! These carriages, so far as their build and system are concerned, were good, though heavy. The wheels, in consequence, formed an important element in the success of their running. My own opinion, from the first, was, that accidents apart, the race would lie between M. Levassor and M. Peugeot. The result was in accordance with my expectations. M. Levassor was successful in one class, and M. Peugeot in the other.

The Works of MM. Panhard et Levassor.

The first mentioned gentleman very recently showed me over his works, and I cannot do better than pay him the compliment that his factory is organised on the best English lines, with the most modern machinery. The whole of the engineering portion of his carriage is as well and accurately made as a piece of watchwork. The engine employed is a modified Daimler, called the Pygmé, and is a great improvement on the Daimler engine. M. Levassor did not use any special carriage in the race. He employed the benzine motor and gearing which he has for some time past adopted, and was consequently well prepared when the day arrived.

The Peugeot Motor.

A year ago M. Peugeot purchased his engines from MM. Panhard and Levassor. He then decided to make one of his own type, and after much experimenting, only reached a successful result a very short time before the race. Indeed, the carriages sent in from his manufactory only reached Paris a day or two before the start, and the "bodies" were in an unfinished condition. It is truly remarkable how well these carriages have run, seeing that there was no time to make the necessary experiments. In the Peugeot engine there are two cylinders, and they are horizontal instead of vertical, as in the Levassor type. The time was too short to make anything beyond a cursory examination of the Peugeot motor, but it appears to remove the objectionable points existing in the Daimler engine.

The Daimler Engine.

To describe briefly the construction of the Daimler engine, of which so much has been heard. It consists of three parts:—

1. A double-cylinder Otto gas-engine pure and simple, the patent of which has run out some years.

2. A cam arrangement for working the valves, which is similar to a method previously used in connection with gas and steam-engines.
3. A governing device which is an absolute copy of the Corliss trip gear.

This latter adaptation is the weak point of the engine. The Corliss gear is perfect for a steam-engine, but too delicate for these quick-running, small engines on account of the numerous springs necessary. Yet, although there is absolutely nothing novel in the Daimler engine, great credit is due to the designer for having made one of the first attempts to construct a very small, light, and quick-running oil motor suitable for a carriage or any other purpose. From what I observed in the Peugeot motor, the disadvantages of the "Daimler" have been overcome. The working parts are more accessible, and the multiplicity of springs has disappeared.

Sir David's Opinion of the Result.

The difference in running between the Levassor and Peugeot carriages in the race has been so small, that, when allowances are made—for in the case of M. Levassor he was ready long before anyone else, and M. Peugeot was only prepared on the eve of the race—it is evident there is not much to choose between the two. Knowing M. Levassor personally, I am quite prepared to believe that he will still further modify the governor to simplify his engine. Of the other carriages which competed, those of M. Delahaye ran well, but there is nothing very novel in them beyond the general assemblage of the parts. Carriages of the type of the Benz were run by the Maison Parissienne, but notwithstanding the French name of the Company it was curious to observe that the conductors spoke in German. M. Bollée entered a carriage and two of his tandem cycles, which have been so well advertised. These latter I regard as dangerous from every point of view. They are complicated, and first engineering principles are disregarded. The single driving wheel at the back gives an insufficient grip on the road, with a tendency to throw the man out in consequence of the back wheel "dancing."

The Time occupied in the Contest.

In consequence of the great storm which occurred the day after the start, and owing to various little accidents which happened, considerable delays were experienced, which brought down the average rate of running in the race. But there is one point I would call your attention to. It must not be imagined that because the whole distance was traversed in a given time, at the average rate of approximately 25·5 kilometres per hour, that if you purchased one of these carriages you could do anything approaching the same record. In the first place, endless quantities of duplicates were carried in case of need. Secondly, a perfect army of workmen, the best that France could produce in this trade, accompanied the carriages. Thirdly, the speed attained down the hills was tremendous, to make up for the slow speed uphill. It would be impossible for anyone to perform the distance in the race time if he complied with the law of France as to a maximum speed of 20 kilometres (14 miles) an hour, carried only a reasonable quantity of duplicate material, and travelled with one conductor, who would naturally be a mechanician, unless the owner was one himself. In this case the time occupied would be double or treble that taken in the race.

Increase of Power found to be Necessary.

Technically, in regard to the carriages which entered, there was absolutely nothing new of engineering interest, beyond the fact that makers have learnt that more careful work is required, and that the horse-power found to be necessary has been raised from three or four to six. This power is still insufficient for a hilly district such as is found in parts of Kent and elsewhere. Anything less than 8-horse power is not of much service for an average speed of 12 miles an hour, if the legal maximum is not at any time to be exceeded. The vibration produced when the carriages were standing has not been remedied, nor has any fresh arrangement been devised for stopping and starting the engines in the traffic.

The Steering of Motor-carriages.

Much surprise was caused by the recent appearance of an article on the self-propelled traffic question in one of our leading engineering papers, condemning both the steering properties of the present motor vehicles as well as the new Act. The writer of the article must either have been biassed or have been ignorant of the subject. A proposal is therein mentioned to attach ponies to motor-driven carriages to give the direction whilst employing the motor to do the work! Now, anyone who has the smallest experience of motor traffic knows perfectly well that it is far easier to guide such carriages than any horse, and I was able to prove this to the complete satisfaction of Major Tullock, C.B., who visited Paris officially at the instance of the Local Government Board.

Various Types of Motors—The Oil-engine.

I will now deal briefly with the various types of carriages, that you may judge of the advantages and disadvantages of each form. The ideal heavy oil motor for light work has not yet appeared on the market. To volatilize or to spray the oil, a special form of carburetter, or some equivalent, is necessary, less simple in form than that required with the lighter spirits like benzine. Besides this, the exhaust gases have a very disagreeable smell. Many attempts have been made to scent the oil, but the success met with is somewhat doubtful. That a suitable heavy oil motor will eventually be made, no reasonable man can doubt. Petroleum motors using mineral spirit such as benzine are the favourites at the present time. A large number of engines of this type are on the market. In every single instance they are ordinary gas-engines. The carburetters are very simple. Water is necessary to cool the cylinder, except in those cases where the power is small, and in these the heat is dissipated by means of metal webbs cast on the cylinder, or by making the cylinders exceedingly thin, so that no large mass of metal is required to be cooled. I do not consider that any engine of this type is satisfactory when the power exceeds ½ horse, unless water for cooling is used. Many engines of a larger size have been shown without a water jacket, but an expert would be very sceptical in regard to their performances if put to real work. Such engines may run round in a room or yard very well, but if placed on a hilly road on a hot day the chances are that they would come to grief, or give off very little power. Only those who have had considerable experience with a carriage driven by a benzine-engine can realise the little difficulties which arise. All the working parts are placed so closely together, that should any slight accident occur when on the road, and the engine pull up, it is, in most instances, impossible to remedy the defect, because all the working parts are so hot, that even with thick gloves, the hands cannot be inserted between the machinery. It is absolutely necessary to grind the valves periodically. Otherwise, in a comparatively short space of time the engine will give off little or no power. The grinding process is by no means easy, except for a mechanic. The best form of benzine motors have two or more cylinders, and the working parts generally are fairly complicated; consequently there are a large number of screws, nuts, bolts, stuffing boxes and connections, which the rattle of the road is liable to loosen. Should this occur, as it does pretty frequently, and tightening up is not at once resorted to, portions of the engine may be lost, and the occupants of the carriage landed high and dry miles away from home. It is absolutely essential that the owner, or his man, should be a mechanician, and anyone purchasing a carriage on an assurance to the contrary, will soon discover his error, though after many sad experiences, the owner or his man will, by force of circumstances, become a workman, unless totally devoid of mechanical sense. This experience will also have to be paid for, because, at the beginning, a practical man will have to be called in from time to time to put matters right. In regard to benzine, the difficulty of storage enters, which will always be a source of trouble in large towns. To sum up the foregoing remarks, I would never advise a friend to purchase a benzine-driven carriage, unless he was made well aware of the disadvantages.

Advantages of Oil.

The advantages may be summed up in the following manner:—If the vehicle is supplied with a powerful motor, is constructed by a good maker and the driver is a mechanician, he will be able to travel immense distances at a good average rate of speed—an advantage which is not possible with the horse. Further, in the winter, he need not fear slippery roads, and he could drive his carriage from within a glass canopy. When calling anywhere he would have no qualm as to keeping his horse standing. If he has a suitable arrangement, something like a condenser, for cooling the water, there is no reason why the carriage should not travel 24 hours and more at a stretch without taking in supplies of any kind.

Benzine Troubles.

To give an idea of one of the troubles least anticipated, which may arise with a benzine motor-carriage, I may mention that I was stopped last month on my road to Paris, in consequence of a tube leading from the reservoir to the engine becoming blocked up with deposit from the benzine. Accidents, similar in character, have been reported to me by friends. The consequence is that I am now changing the pipes for others of larger section, and so connected that they can be cleaned from end to end at a moment's notice. It has been supposed that the deposit in the tubes is due to the use of inferior benzine, but this is not the case. About 23 years ago a Company was formed to enrich coal gas by passing it through benzine. It was intended to place in every house a cistern of benzine, which liquid would be changed from time to time by the Company, an annual charge being made for this purpose. I declined to place the apparatus in my house, until I was convinced that the pipes could not become incrustated, and after making some experiments I soon discovered that a deposit was formed in the shape of crystals, in appearance like cotton wool, as well as a condensation. From these experiments and my recent experience, it is quite clear that all pipes employed for benzine should be large, and so arranged that they can be cleaned from time to time, quickly and with ease.

Igniting the Explosive.

Some makers use the well known gas-engine ignition tube, and others the electric spark, to ignite the gas in the cylinder. The lamps have the disadvantage of being troublesome in very windy weather. No doubt, in time, this will be remedied, though it is not so easy as anyone would be led to believe, in consequence of the large amount of air necessary to keep them burning. I have myself been stopped on one or two occasions, owing to the lamps blowing out, and great difficulty is experienced in re-lighting them, because the lights are generally extinguished at an exposed place, and they must be heated first before they will burn. When an electric spark is employed there is the risk of the accumulator or primary battery becoming exhausted when far away from any place where a fresh store can be taken on board. For a long journey a duplicate source of electric energy should be carried, and in a strange land, where renewal is impossible, lamps are preferable, because primary batteries are always troublesome, and, as a rule, are not fit for use until they have stood several hours after being charged.

The Dion-Bouton Tricycle.

There is one type of benzine carriage which is worthy of special attention. It is the De Dion and Bouton tricycle. This carries a little engine of about ½ horse-power. The ignition is electric, and the pedals are employed as an auxiliary force. Both muscular and engine power are necessary on hills, and on fairly level country there is no fault to be found with these tricycles, but in hilly districts they are tiring. The machines are good and well made. I have two of them myself, and they answer the purposes for which they are required in an admirable manner.

The Power required to Drive a Motor Vehicle.

It has often been asked, Why should the horse-power required to be carried by a carriage be greater than that necessary when the horse occupies his place in front? This is due to the position of the motive power. When it is placed without the carriage, as in the case of the horse-drawn vehicle, the wheels are lifted over the various impediments existing on the road. When the power comes from within, the tendency is to push the wheels into the ground when an obstruction is met with. This disadvantage may be partly overcome by the employment of very large wheels, but, no doubt, in course of time, our present notions of design in regard to these carriages will become modified. In theory, to obtain double the speed, four times the power is necessary, yet with the motor-propelled carriage, within the limits of the speed permitted on the highway, the increase of power for a given increase of speed is almost in an arithmetical instead of in a geometrical proportion. In other words, to obtain double the speed, instead of four times the power, very little over twice is needed. It must not be inferred that in practice the theory is upset. The reason is that at a greater speed the obstacles on the road are overcome in a different manner, and therefore offer less resistance to the advance of the vehicle, than when travelling at a slower rate.

Electric Carriages.

Carriages driven by electric energy have not yet come within practical range for general purposes. The weight of the accumulators and the necessity of charging stations are the stumbling blocks. The comparatively light accumulator, capable of being charged and discharged rapidly, must require frequent renewal, and this expense few are willing to face. Electrically-driven carriages may yet have a limited use.

The Serpollet Steam Motor.

My faith is more than ever pinned on steam, after seeing the recent carriage of M. Serpollet in Paris. When writing about his carriage, and of steam generally, I had pointed out that complete success could only be obtained when a good heavy oil burner appeared, and M. Serpollet accepting this view, set to work assiduously, and his labours have been crowned with success. The carriage I rode in is a light voiturette for two persons, with the boiler placed behind and out of sight. One large heavy oil petroleum burner serves for the fire. The engine of this little carriage can give off 10 horse-power with ease. The carriage is on three wheels, but I understand that four will be employed in the new ones. It runs up the steepest hills as if on level ground. The ride from Paris to Versailles is very hilly, and with my carriage I required an hour and twenty minutes to make the journey, but the little Serpollet carriage covered the distance in somewhat over half an hour, and on the long steep inclines it rushed in front of every other vehicle, whether motor or horse drawn. The only fuel necessary to be taken in upon a long journey is water, and this is required but every three hours. A sufficient store of heavy petroleum can be carried for a very long journey. In the new carriages, which will be made after the model of the experimental one, a condenser will be added capable of condensing a portion of the steam, and thus enabling a longer journey to be made before obtaining fresh water. The carriage requires a few minutes' preparation, say four or five, before it is ready to start. The time is occupied in the combustion of a small quantity of methylated spirit to warm up the burner that it can be lighted. The speed is regulated by a pedal, and the price is so reasonable, viz., £120, that this vehicle must have an enormous future. There is not the slightest doubt that the steam-carriage, as solved by M. Serpollet, is the coming one. The machinery is simplicity itself, and of a character known to almost every village smith—the ordinary steam-engine. The boiler is small, non-explosive, and self-cleansing.

The burner has nothing in it to get out of order, and the power given off is enormous compared with the size and weight of the vehicle. Larger types will be made on the same lines as soon as the numerous orders, which are pouring in, can be got off hand. The weight of the carriage described is between 8 and 9 cwt. It is unfortunate that the experimental carriage was not completed some months ago, instead of but one week before the race. Had this been the case steam would probably have competed successfully with benzine-driven carriages. I think it may be fair to point out that many boilers of this type are in existence; indeed the principle of only admitting sufficient water into the boiler to supply the steam needed is much older than M. Serpollet. The chief credit which attaches to this gentleman consists in the fact, that after experiments extending over many years, and after repeated failures, he has, by his persevering efforts, probably attained a better knowledge of this class of boiler than anyone living, and his advice, guided by his experience, therefore, has far greater value than his patents, whether they be good or bad. Three weeks ago M. Serpollet left Etretat at 8 a.m. in his experimental steam-carriage, and arrived in Paris at 6 p.m., thus covering the distance of 240 kils. in 10 hours, at an average rate of 24 kils. the hour, which speed is equivalent to nearly 16 English miles per hour. The actual rate of running must have been greater, but the times of the various stoppages are not given.

Steam v. *Petroleum.*

Those who have read what I have from time to time published on the Self-Propelled Traffic question may think that my views have somewhat changed, and that having been in favour of petroleum motors I now prefer those actuated by steam. This is by no means the case, because steam has always been my favourite, but I have simply discussed vehicles as they existed, and until recently the difficulties in the way of applying steam to this class of light traffic on highways had not been overcome. I still believe that motors employing light or heavy petroleum will have a considerable future, although eventually steam is likely to supersede them. For the moment electricity is out of the running, but it is quite possible that improvements will be forthcoming which will place this agency on an equality with steam, or even before it.

Trade the Ruling Factor in Great Britain.

In France, motor-carriages have been taken up as a kind of sport, and in general the class of men who purchase them care little whether they throw away £100 or not, but the great and immediate future of self-propelled traffic in England will undoubtedly be in connection with trade. The sporting element of society will never be induced to give up their horses, and the poorer gentry and small tradesmen cannot afford to purchase motor-carriages until they are assured that a really satisfactory vehicle can be obtained. There will undoubtedly soon be seen on the roads a very large number of motor delivery vans for railways, factories, shops, and other business houses, for the simple reason that they will not wait for the little refinements required in a private carriage, and the cost of replacing their vans at a later period will not be an important matter. The reason for this is that every motor-wagon or cart will be doing the work of from four to six horses per day at a far lower cost. The rent of stabling for horses will also be saved, and these economies will cover the cost of the van in a comparatively short time—say two or three years. The trader will not only reduce his expenses but add to his profits, because his circle of delivery will be much increased, since his vans will travel greater distances. Each van could accomplish a fifty mile run from the shop or warehouse in the course of an afternoon—a journey which no one would dream of attempting with horses. One other advantage, a motor-van can be left standing in an open yard, and at the end of a day's work may easily be sent to the outskirts of the town for shelter, where the rent is low. This point does not exist in the case of horse-drawn vehicles, since the horse cannot be left standing in the open and in all weathers. In winter especially, heavy traffic will be relieved of a great deal of the cruelty to horses which accompanies it at the present time, when on a slippery day we see horses losing their foothold in all directions.

Condition of the Roads.

England is possessed of splendid roads as compared with France, although it is true that in the latter country fine roads are to be found, but in village districts they are paved with stone in the roughest manner. Whatever our local authorities may say in regard to economy of expenditure in road-making, it is a benefit to a district that the roads should be good. Anything which will induce people to travel through a locality, must be an advantage, since it leads to more money being spent there; and even where this is not the case, good roads must lead to increased business and a general reduction in the rates and taxes.

A Forecast.

I can picture to myself that in the next ten or perhaps five years, the whole of the heavy traffic, as well as the public conveyances of this country will be propelled by motors, probably steam, instead of by living horse power. Tradesmen and country doctors will also have called in this method of locomotion to their aid, and those whose occupation requires them to go to daily business by rail, will be able to live at greater distances from a railway station, thus paying a lower rent, which will more than compensate the expense of the motor vehicle.

The Speed Question.

One of the most difficult points with which the Local Government Board will have to deal, is that of speed. My contention is that since "furious driving," and "driving to the public danger," apply to all light locomotives, whether bicycle, tricycle, carriage, or wagon, the police have complete power, in accordance with the Act, to control the traffic for the public safety. Consequently, when dealing with speed, only one other condition is required, which the new rules will probably, in some form, provide for. It is, that the speed of any vehicle, at any time, shall not be greater than that the brake may bring it to a standstill within a given distance, say 50 feet, which is about twice the length of a horse and carriage.

Conclusion.

I can only conclude by expressing the hope that all those engaged in trade will give motor traffic a fair chance—not by rushing into the subject as enthusiasts who spend money without regard to profits—but as business men who exercise their judgment, and prove by a true balance sheet, that motor traffic is the right thing in the interest of the community, adding not only to the prosperity of the manufacturing classes, but extending also a helping hand to the working population. (Loud applause.)

At the close of the address several questions were asked and answered, and a vote of thanks was passed to Sir David Salomons, on the motion of Mr. F. C. DANSON, seconded by Professor HELE-SHAW, and supported by Mr. W. J. STEWART.

On the following day Sir David Salomons left Liverpool for London. Prior to departing he paid a visit to the Town Hall, and was introduced to the Lord Mayor. The Earl of Derby expressed his regret that municipal engagements prevented his presence at the meeting of the Self-Propelled Traffic Association. Sir David Salomons afterwards visited the Overhead Railway and docks, and was accompanied by Colonel A. H. Holme, Professor Hele-Shaw, Messrs. S. B Cotterill, W. J. Stewart, and E. Shrapnell Smith. It may be mentioned that Mr. Lawrence Jones has been appointed solicitor to the Liverpool branch of the Association.

The proceedings throughout were most successful, and the reception accorded to Sir David Salomons was very cordial. Not content with the official luncheon, which we have reported.

some of the members entertained him to a quiet dinner at the Palatine Club, prior to the delivery of the address, and many necessary details of organisation were discussed and to some extent settled in this pleasant fashion.

The local branch intends to practically disseminate all the information it can amongst its members, and various papers will be read before them during the session of 1896-7. The first of these (illustrated by experiments) will be by Professor H. S. Hele-Shaw, M. Inst. C.E., &c., and will be delivered on Tuesday, December 1st.

All interested in Self-Propelled Traffic, who live within a convenient radius of Liverpool, should make it a point to join the branch, which bids fair to being a stalwart offspring of the parent Association.

NOTICE.

The Self-Propelled Traffic Association have decided that in future all communications to their members shall be conveyed to them through the columns of the Automotor and Horseless Vehicle Journal. *We have made arrangements to enable this to be carried out.*

MOTOR-CAR versus LIGHT RAILWAY.

At the annual general meeting of the Royal Scottish Society of Art held in Edinburgh, Professor Armstrong, who presided, referred to the passing of the Light Locomotive and Light Railways Acts. These in relation to the powers they respectively conferred could not well be otherwise than rivals in public estimation, and it would obviously depend upon the manner in which each was administered which of them would achieve the greatest popularity and success. The cars would do less damage to the roads than the present traffic, and, moreover, they would be able to run on the roads as they were. The motor-cars would be able to enter fields and farmyards, and run alongside the loading station and upon the quays, so that the farmer would be able, not only to deliver, but to receive his commodities direct and at first hand. He anticipated that in their day they were destined to witness a struggle for supremacy between the motor-car and the light railway, and whichever way the battle might turn, the outcome would be the same—the opening up of a new and extensive field for the exercise of that inborn mechanical genius and constructive skill which were the peculiar heritage of the British nation. (Applause.)

PROPOSED CYCLE SHOW FOR NOTTINGHAM.

It has now been decided by the members of the Nottingham Bicycle Club to hold a Cycle, Cycle Accessories, and Motor-Car Exhibition in Nottingham early in the new year, providing a suitable hall can be secured, a point which a sub-committee is at present investigating. The matter was thoroughly discussed at a meeting of the members of the N.B.C., several members connected with the trade expressing the opinion that the exhibition was bound to be a great success. An influential committee was appointed, with Mr. Ben Richards as hon. sec., and they are going into the scheme thoroughly. There is no doubt that the many local manufacturers who do not care to go to the expense of showing in London will warmly embrace the opportunity which the N.B.C. are placing before them, and that if a hall suitable for the purpose can be engaged the exhibition will be a great success.

MOTOR-CAR INSURANCE.

With business-like promptitude the National Cycle and Motor-Car Insurance Company has come forward to meet the danger which may arise from the use of motor vehicles, and is prepared to insure the owners against damage to person or property. The offices of the Company are situated at 33, King William Street, London, E.C., and, with the object of obtaining some information as to its work, we recently sought and obtained an interview with Mr. Edward Willson, its able secretary.

The task of organising an insurance company is an arduous one, involving, as it does, nearly as much work outside as it does in, and we were, therefore, not surprised to hear from Mr. Willson that he had recently visited the principal towns of England, Scotland, and Ireland, arranging branches of the

Mr. Edward Willson,
Secretary of the National Cycle and Motor-Car Insurance Company.

Company's business, inducting district officials, and interviewing agents, and contemplated a trip to Paris for the same purpose.

The difficulties in establishing a new insurance company are always very great, in consequence of the cost of initiating a successful opposition to the old-established and often conservative concerns which have the ear of the public; but the great possibilities which are in store for the automotor industry have been alluring to Mr. Willson from the first, and suggested to him that a Company established for the purpose of insuring this traffic on the lines upon which existing companies insured ordinary horsed traffic would, by making it a special feature, attract to itself a volume of business concurrently with the extended use of the new vehicles. The idea was not an easy one to carry out. There were those who derided the notion of the motor-car being for another decade anything more than a phantasm.

It became necessary, therefore, to expand the scheme so as to include all the ordinary branches of accident insurance. Hence the title of the Company, which was the ultimate outcome of his efforts, viz., the National Cycle and Motor-car Insurance Company. At this stage Mr. Willson entered into an alliance with Mr. James Jeffries, the *alter ego* of the undertaking, who occupies the position of the Company's manager. The title of the Company is certainly felicitous, but has a drawback in not sufficiently covering the various branches of the business, which also include insurance against personal accidents, sickness, ordinary traffic liabilities, employers' liability, burglary, plate glass, traction engines, sailing barges, and steam-tugs.

Naturally a new comer in the insurance world has difficulties to encounter, but the Company, by a judicious selection of its officials, has made great headway, assisted as they have been by a board of directors constituted as follows:—Colonel C. W. Wilson, D.L., J.P. (chairman, the Brewers and General Fire Insurance and Guarantee Corporation, Limited); Mr. Clement A. Ravenscroft (director, Birkbeck Bank); Mr. David F. Carmichael (director, the Madras Railway Company); Sir Edward Lee; Mr. C. H. Tindal, director, Walkers, Parker, and Co.; and Mr. Sidney Lee (editor *Cycle Trade Journal*, and director of the Dunlop-Truffeult Company).

The board is composed of business men, who, in dealing with claims, have adopted a broad and liberal policy which can alone ultimately succeed in insurance matters. They avoid legal quibbles, and construe their liabilities to their clients in a generous spirit.

The National Cycle and Motor-Car Insurance Company will exhibit, on the 20th instant, at the Stanley Show, at the Agricultural Hall, and on the 4th December, at the National Show at the Crystal Palace, their stand numbers being 6 and 117 respectively. It may be mentioned that they have secured a large amount of the insurance work amongst the exhibitors at both establishments.

BRISTOL ENGINEERS AND MOTOR-CARRIAGES.

THE first meeting this session of the Bristol Association of Engineers was held on Saturday evening, the 24th ult., at the Queen's Hotel, Clifton, the President, Mr. John M. McCurrich, in the chair. There were present: Messrs. J. R. Bennett, H. A. Chattock, F. J. De Soyres, C. Cooper, W. Fiddes, J. H. Fiddes, T. J. Moss Flower, R. Fenton, G. E. Ford, G. Garrard, D. L. Harris, J. W. J. Harvey, F. W. Hudson, H. J. Jacques, A. W. Metcalfe, T. Morgans, J. A. McPherson, P. Munro, A. Peckett, T. L. Perkins, H. C. Parkinson, E. M. Rees, J. Ryan, W. Stagg, D. Stuart, W. Thomson, N. Watts, T. H. Yabbicom; visitors, Messrs. Morgan and Brownlow.

The PRESIDENT having thanked the members of the Association for the honour they had done him in electing him their President, and the ordinary business of the meeting having been completed, he called upon

Dr. J. RYAN to read his paper upon "Motor-cars." Commencing with the early history of the subject, the speaker referred to the steam-carriages of Cugnot, of Symington, and of Trevethick. He dwelt upon the very considerable progress that was made with steam omnibuses and coaches in the early part of the century by James, Gurney, Dance, and Hancock, as well as Maceroni and Squire, Hill, and others. The era of the traction and agricultural engine was next dealt with. The modern aspect of the question and the recent developments in motor-cars were finally treated and illustrated with numerous views. The results and lessons of the various French competitions were discussed. Paris-Rouen, 1894; Paris-Bordeaux, 1895; Paris-Marseilles, 1896; and the Chicago competitions of 1895 were considered. The paper was illustrated throughout by interesting oxy-hydrogen views.

An interesting discussion took place on the conclusion of the paper, and the meeting was brought to a close by the President proposing a vote of thanks to Dr. Ryan for his interesting paper.

CORRESPONDENCE.

*** *We do not hold ourselves responsible for opinions expressed by our Correspondents.*

*** *The name and address of the writer (not necessarily for publication)* MUST *in all cases accompany letters intended for insertion, or containing queries.*

A MEMBER OF PARLIAMENT ON AUTOMOTORS.

To the Editor of THE AUTOMOTOR AND HORSELESS VEHICLE JOURNAL.

SIR,—The AUTOMOTOR has made a brilliant *début*. The editor, publisher, and everyone connected with it deserves the thanks and appreciation of the public for the very excellent publication they have so successfully started. The far reaching and enormous issues connected with, and incidental to, the introduction of horseless carriages, it is impossible to estimate. The historian of the future will look back upon November 14th, 1896, as an epoch to be marked for all time as one that effected one of the most revolutionary, yet at the same time useful, changes of a very changing century.

Foremost among the few who called the attention of our Parliament to the startling and novel mode of travelling, the Right Hon. Shaw-Lefevre takes first place. Sir David Salomons, outside Parliament, both here and in France, has done giant's work in popularising this most modern mode of moving from place to place. Perhaps you will kindly allow me to take an humble share with my worthy colleagues in my just claim to be the first person who in this present House of Commons had the honour of bringing the matter of motor-cars before the notice of the House, and directing Mr. Chaplin's attention to it, who at once gave it his most cordial support, and with the able assistance of his Under-Secretary, Mr. T. W. Russell, brought the Bill to a most triumphant issue, and pushed it through all its stages in the Commons and the Lords in a remarkably short time on August 14th last, when it had the Royal Assent. The general good sense of both Houses seemed to give an almost unanimous approval of the principle of the Bill, and sent forth this British-born bantling of foreign parentage, bred from an iron race of strong giants, to run on roads without rails—hither, thither, and everywhere—not merely from John o'Groats to Land's End, but, if necessary, from Chester to Calcutta, or Manchester to Moscow, when carried across the Channel.

The recent races held in France from Paris to Bordeaux, and Paris to Marseilles and back, the latter being held under most unexampled difficulties of storm and tempest, have uncontestably proved to a critical and yet appreciative public what enormous strides have been made in mechanical locomotion by these most modern discoveries of a century that first heard the screech of a railway whistle in our land, and gave birth to the wonders of electricity in motion, speed, sound, sight, and light, as instanced in the miracles of the electrophone, microphone, and kinetoscope, &c. When we think with what marvellous speed these wonders have been developed within the last few years, what great expectations may we not anticipate in the near future! Looking back but a very few years we compare Stephenson's "Rocket" with our latest 90 miles an hour express steam-engine—we compare the old "bone-shaker" of 20 or 30 years ago with the sylph-like "safety" of to-day. All this tends to indicate, but faintly, what great advancement the engineering instinct and inventive genius of our people is bound to achieve in a very short time from the present small and crude beginning of the best even of our present motor-cars. Go on, great giant of genius—go on your great career till this old century of cycles dies of old age to renew its youth in the ever-increasing progress of science through succeeding generations of centuries till "time is no more."

I am, Sir,
Your obedient servant and well-wisher,
Carlton Club, London. CUMMING MACDONA.

REPORTED ACCIDENT TO SIR DAVID SALOMONS.

To the Editor of The Automotor and Horseless Vehicle Journal.

Sir,—The following is a copy of a letter I have sent to a contemporary for publication. Will you oblige me by also inserting it in your columns?

"My attention has just been called to a note in a prominent part of your issue stating that there is a 'rumour' that I have met with an accident in a Serpollet steam-carriage. Since I have not one in my possession, it is clear that such a rumour is unfounded, and I take the opportunity to contradict it, because it might injure the prospects of what is probably one of the best and cheapest motor-carriages of the day."

I would point out that the editor of your contemporary is a director of the Daimler Motor Company, and therefore leave my readers to form their own conclusions as to the reason of inserting such a note, when it is remembered that he might have inquired of me by letter or telegram as to the truth of the report.

Yours very faithfully,
David Salomons.

Broomhill, Tunbridge Wells,
November 7th, 1896.

AUTOMOTOR FIRE ENGINES.

To the Editor of The Automotor and Horseless Vehicle Journal.

Sir,—The new Act should be of service in introducing a new method of propelling steam fire engines. Although few complaints can ever be made against the Fire Brigade for not being prompt at fire calls, yet there is a certain amount of delay in getting the horses from the stables, and then attaching them to the fire engines; and all this hindrance will be avoided if the engines are to be worked by the new motor power, for as soon as an alarm is given the engines can dash out of the station, and be at the scene of the fire in a very short time. The use of motor power instead of horse power to the engines will also be very advantageous in twisting in and out the traffic, and bringing the engines to a standstill much quicker than heretofore, and with very much less exertion, and it is perfectly clear that the expense will be materially reduced. It would be a happy idea if the Fire Brigade could manœuvre some scheme so as to do away with that shouting, or, perhaps more correct, yelling, when a fire engine is going to a fire. I should think that a steam whistle, a bell, or some kind of horn would be a more appropriate instrument for clearing the road. I suppose, however, we must await events.—I am, yours sincerely, Watling Street.

THE OPPOSITION TO MOTOR-CARS.

To the Editor of The Automotor and Horseless Vehicle Journal.

Sir,—The report of the meeting of the Warwickshire County Council and the speeches made by some of the members, if not very edifying, are at any rate somewhat amusing to read at the end of the nineteenth century, and would almost lead us to believe that we were living a couple of hundred years back, when, if anyone had been caught riding on a conveyance without any apparent motive power, he would probably have been burnt at the stake as being a magician. Alderman Flavel was very strong indeed in his denunciation of motor-cars, and gave it as his belief that they were "diabolical machines." Lord Willoughby de Broke, of course, was also very energetic in his wrath at the introduction of "these things" into an agricultural district, where no one has any right to be considered but landlords and farmers. It is an extraordinary thing that these people cannot see the necessity that exists for advancing with the times, and taking advantage of every new scientific discovery which tends to benefit the people generally.—I am, &c., Go Ahead.

OLD-TIME STEAM COACHES.

To the Editor of The Automotor and Horseless Vehicle Journal.

Sir,—By the enclosed extract you will see that in the year 1832 an attempt was made to introduce steam vehicles for the roads, and the first trip was to Birmingham. I hope that now the idea has been started again of introducing "motor-cars," it may be successful, and may be productive of good. Surely, omnibus and tram drivers and conductors, together with horses, will hail the day with joy when those who now go to church, chapel, Sunday lectures, and for pleasure, in public conveyances, will have their own vehicles, and leave the overworked a Sunday free from labour.—I am, &c., Antiquary.

[Extract from *Ladies' Magazine*, November, 1832.]

"Steam Coaches.—From Liverpool we learn that the steam coach of Messrs. Ogle and Summers, which has lately been making a trip to Birmingham, entered the former town on Monday, amidst the acclamations of a crowded populace. Among the party brought by her were the Messrs. Brotherton, the late extensive coach proprietors between that place and Manchester. Thus has been accomplished by steam power, on our common roads, a journey from Southampton, through Oxford and Birmingham, to Liverpool, over as irregular a surface of country as perhaps could have been selected for the purpose of the experiment. The objects sought, and of which there is a proof of accomplishment by these gentlemen, are, in the first place, a safe method of generating steam, in convenient space, in sufficient quantity to enable them at all times to propel vehicles on common roads, at any desired speed, and with such command of power as will overcome increased resistance from occasional obstacles, fresh gravelled, soft, or hilly roads. Secondly, the safe application of this power to vehicles of such construction, as will ensure action and progress on any description of ground, and, nevertheless, be under the immediate control and certain guidance of the conductor."

MOTOR-CAR SPEEDS.

To the Editor of The Automotor and Horseless Vehicle Journal.

Sir,—It seems to me that the authorities would be unwise in going outside the Government regulations to place a limit on the speed of automobiles. By so doing there is, on the one hand, the risk of giving the reckless an excuse for too fast driving, inasmuch as they would urge that they were not exceeding the authorised speed; on the other hand, there might and would occur, on roads where there was plenty of room and but little traffic, the absurdity of fast-driven horses passing an automobile which was proceeding at the reduced rate laid down by the local authority. In any case, an automobile is easier and more speedily controlled and stopped than a horse. Surely the wiser plan would be to leave automobile drivers to accommodate their speed to that of other traffic, and to proceed under the same responsibilities and risks as the drivers of all other vehicles, whether they be in charge of cycles, vans, carriages, omnibuses, &c.—Faithfully yours, Miles.

November 4th, 1896.

"What shall we call our motor-cars when we get them?" asks a correspondent. "We call our bicycles 'bikes.' On the same principle we might call our motor-cars 'mokes.' Imagine the delight of being requested by a charming young lady to 'stop that moke' for her. Mocar is not bad, but it sounds too much like 'Go-car.' I have a final suggestion to make, and I offer it to 'The Great Horseless Carriage Company, Limited,' free, gratis, and for nothing. Why should they not alter the name of their Company into the London General Pluribus Company, Limited? Their conveyance could be called a plus to distinguish it from bus."

REVIEWS OF BOOKS.

"Motor Carriages: The Vehicles of the Future." By "VAGABOND," the Cycling Editor of the *Newcastle Daily Chronicle*. (London: Messrs. Walter Scott, Limited.) Price 6*d*.

THIS is a reprint of a series of well written and carefully compiled articles which appeared in our Northern contemporary at the end of last year. The author, who wields a graceful pen, has put together some old facts in a manner which renders them easy of refereuce, and the little book is in every way worthy of perusal by all iuterested in the subject. Doubtless in view of the great impetus which the events of the past few months have given to automotor work, the publishers will make it the basis of a more ambitious volume in the near future.

"The Principles of the Transformer." By FREDERICK BEDELL, Ph.D. (London: Macmillan and Co., Limited.)

THE author of this work, from his position as assistant professor of physics at Cornell University, aud his deservedly high reputation in the mathematical field of electric science, is entitled to speak with authority on the abstruse and somewhat complicated problems involved in the construction of transformers. The growth of this particular branch of electrical research has been rapid. Ten years ago, the idea of generating a current of high tension and low quantity, and then transforming it into a current of comparatively low voltage and high ampèreage had hardly been thought of, but in the bare decade which has elapsed, the dream of the student has become the commonplace of the manufacturer. Only those who are intimately acquainted with the subject cau attempt to estimate the great practical economies in distribution of current which have been rendered possible by the transformer, aud the most expert cannot venture to prophesy as to its future value in electric lighting and the transmission of power. In the time which has elapsed since the initiation of the subject to the present day much valuable information and literary matter has been contributed in a scattered way to the learned societies and to technical papers. To gather all this into oue book, and to formulate a definite and intelligible scheme out of the multifarious and often contradictory material at hand, was not an easy task, but the author has entirely succeeded. To the student and to the practical maker of transformers the work will be invaluable.

"The Inventor's Adviser on Patents, Designs, aud Trade Marks." By REGINALD HADDAN. (London: Harrison and Sons.) Price 3*s*. 6*d*.

ALL who desire a reliable, concise, and cheap guide to the patent laws and customs of the world, should obtain this book. It is alike useful to the inventor, the manufacturer, and the commercial man who desires to invest in patents. The favour with which it has been received ou all hands is testified to by the issue of this—the third edition. The author treats in comprehensive and clear language of the English patent laws and rules, cases being cited to enforce the points laid down; while, in the latter portion of the book, the laws aud customs of all foreign countries are given, great care having been bestowed in making necessary alterations up to date. Another valuable feature of the work is contained in the chapters devoted to the commercial valuation of a patent; under this comprehensive heading, the questions connected with the sale, purchase, and licensing of a patent are fully discussed, and a basis is laid down which cannot fail to be of use to those who wish to deal in patents, but are too often prevented from doing so by the wide diversity which usually prevails between two interested parties in their attempts to establish the present value of a share in a probably untried patent. The work is well got up, and, with 440 pages of technical matter of this description, it is marvellously cheap.

"Notes on Motor Carriages." By J. H. KNIGHT. (London: Messrs. Hazell, Watson, and Viney.)

THE author of this little book is well kuown for the lengthened interest which he has taken in motor carriages on common roads. He is, therefore, fully competent to write a handbook which may be of service to those who take up the matter for the first time, while some of his hints will be useful to users of these vehicles. He discourses pleasantly aud correctly enough upou the historical portion of his subject. The chapter on oil and other engines—while purely elementary—will be a means of introducing the subject to those who approach it for the first time. The weakest chapter in the book is that devoted to electricity. It is so fragmentary in its character as to be useless iu its present form. Should another edition be issued, it would be better to omit it altogether, unless it is re-written in a much more comprehensive manner. The chapters relating to the French and American motor-car contests will be found useful for reference, as will also a brief but reliable list of books and articles, which may be consulted by those who wish to go deeper iuto the matter. The illustrations are sufficient for the purposes of the text, and the work may be safely recommended to the amateur.

THE *Leisure Hour* for October has a very readable article, with a reproduction of a quaint old print, on Mr. Goldsworth Gurney's steam carriage.

WE are in receipt of the report of the Institute of British Carriage Manufacturers, edited by Mr. Andrew Barr; it contains much interesting matter on carriages, and may be consulted with advantage by all interested in the allied automobile industry.

THE *Cosmopolitan* for October gives an illustrated account of the result of the competition for motor-cars which they recently organised, the prizes which they offered being 3,000 dollars. It is worthy of note that the prizes were awarded on the following points, the maximum being 100:—

Speed	35
Simplicity of construction and durability	30
Ease iu operating and safety	25
Cost	10

These, without being by any means ideal conditions, are considerably more satisfactory than any mere speed test.

THE *Referee* has devoted much space to the automotor question. The inimitable "Dagonet" has discoursed in his pleasant fashion of the dangers and changes which will follow in the wake of the new vehicle. Now the writer of "Our Handbook" has taken the matter in hand, and with that all-round mechanical and scientific knowledge which enables him to write sound aud intelligible matter upon almost any conceivable subject, has imparted much good advice to the makers and users of the new carriages. Whatever other fate may await the automobile world, the public Press of this country are determined that it shall not die of neglect.

MESSRS. REEVES and TURNER, of Chancery Lane, will publish immediately a book on the "Law of the Motor-Car," by Mr. E. Grimwood Mears, Barrister-at-Law. The work contains an introductory chapter giving *inter alia* an account of the motor-cycle invented in 1881 by Sir Thomas Parkyns, and the subsequent litigation. A full text of the Act is given with explanatory notes, and the Petroleum Acts and the general law relating to carriages are therein embodied, together with the partially repealed enactments. There is an important chapter on Negligence and Contributory Negligence, in which the rights and liabilities of persons in collision cases are carefully defined. Space is devoted to Employers' Liability, to Nuisance Obstruction, and kindred topics. A review will appear in our next issue.

LUTZMANN MOTOR-CARRIAGES.

We have the pleasure of giving an illustration of the Lutzmann Patent Motor-Van which has been imported by Messrs. Julius Harvey and Co., of 11, Queen Victoria Street, E.C., for Messrs. Lever Brothers, Limited, of

Sunlight Soap fame. We have ourselves inspected this van and find the motor is very powerful and strongly made, in fact the van throughout is a first-class piece of workmanship, and is likely to prove a most serviceable vehicle for all trade purposes. Messrs. Harvey have wisely had the final painting and lettering done in London by Messrs. Mulliner, of 28, Brook Street, W., who have a high reputation for carriages of every description, and

Messrs. Harvey's van is certainly one of the best finished motor vehicles we have yet seen. In addition to the van, Messrs. Harvey were able to show us a Lutzmann motor-carriage, which is extremely elegant in design and well got up in every respect. We also illustrate this carriage, which, with the van, took part in the run from London to Brighton.

BUSINESS NOTES.

We have received from Messrs. Julius Harvey and Co., of 11, Queen Victoria Street, London, an extremely well got up catalogue of motor-carriages—some of the best types of Continental makes being illustrated. A reprint of the Locomotives on Highways Act, 1896, is added for the convenience of users. The motto of the firm is very apt, Shakespeare, as is usual in all difficult cases, being the source of the quotation, which runs: "And here an engine fit for my proceeding." Messrs. Harvey and Co. are to be congratulated on their enterprise, as one of the first pioneers in this new field.

Mr. J. H. Paterson has been appointed manager of the Caledonian Motor-Car and Cycle Company, Limited, his business address being 265, Union Street, Aberdeen.

Messrs. T. B. Barker and Co., of Schofield Street, Birmingham, write to a local paper which stated that it was unable to ascertain that any motor-carriages were being made in the district, as follows:—"Allow us to say that the motor-car, of which we send a large photograph for your inspection, was made on our premises here, and that it has, during the last three months, travelled some hundreds of miles through the streets and suburbs of this city, carrying from one to seven passengers; its normal complement, as you will see by the photograph, being five passengers. We thought it would be of interest to you to know that Birmingham is, as usual, abreast of, if not ahead of, other centres in this new industry. The motor is a petroleum engine with electrical ignition."

The silver medal of the Highland and Agricultural Society has been awarded to the Daimler Motor Company for their exhibit at Perth.

PRIZES FOR MOTOR-CAR DESIGNS.

The expectation of the motor-car is obviously abroad in the land, for the Worshipful Company of Coachmakers and Coach-harness Makers of London is offering, in its next series of prizes, a competition, open to British subjects generally, for designs of a self-propelled light-motor pleasure carriage, to convey two or more persons. The first prize will be the Company's silver medal and £20, and the second the Company's bronze medal and £10, given by its Master (Colonel John William Lee); while the copyright of any new design for which a prize is awarded will remain the property of the winner. The other competitions are restricted to British subjects engaged in the trade of coach-making, and resident in the United Kingdom, and they embrace working drawings for a single brougham, a single-horse Stanhope phaeton, and other kinds of carriages; these having to be delivered before April 30th of next year. Previous competitions of the kind have resulted in some original designs, and much, therefore, is hoped from the present one.

A scheme of considerable magnitude is in contemplation, having for its object the connection of Southport and Lytham by means of an electric tramway. It involves the formation of an entirely new carriage drive 30 feet in width, which will run parallel with the tram lines. Ultimately it is desired to continue the tramway to Blackpool.

THE BOLLÉE TRICYCLE.

Fig. 1.

Herewith we give three illustrations of this machine, which, since its performance in the Paris-Mantes contest, has been a theme of much discussion in automotor circles.

Fig. 1 is a photograph of the actual tricycle.

Fig. 2.—A front elevation, partly in section.

Fig. 3.—A plan of steering details.

Owing to the great pressure on our space we reserve a detailed description of the various parts, but the drawings will doubtless give all the requisite information. The owners of the patents in this country are the British Motor Company (Limited).

Fig. 3.

E

NOTICES.

Contributions and articles likely to prove of interest to our readers will receive due attention, but in all cases the name and address of the writer must be given, not necessarily for publication.

All matter intended for publication should reach us not later than the 10th of each month. Stamped envelope must be sent if the manuscript is required to be returned.

All Advertisements should be sent to the Advertising Department. F. KING AND CO., LIMITED, 62, *St. Martin's Lane, London, W.C., where Advertising Rates may be had on application.*

The Annual Subscription is 7s., including prepaid postage to any part of the world.

Cheques and Post Office Orders should be made payable to F. KING AND CO., LIMITED, *and crossed London and County Bank; otherwise no responsibility will be accepted.*

THE AUTOMOTOR AND HORSELESS VEHICLE JOURNAL *can be obtained through* MESSRS. W. H. SMITH AND SON, *at* WILLING AND CO.'s *bookstalls, and wholesale of* MESSRS. HORACE MARSHALL AND SONS, *Temple House, Temple Avenue, London.*

When any difficulty is experienced in procuring the Journal from local newsvendors, intending subscribers can obtain each issue direct from the Publishing Office, by filling up and forwarding, with remittance, the Subscription Form accompanying the Paper.

The Automotor and Horseless Vehicle Journal.

A RECORD AND REVIEW OF APPLIED AUTOMATIC LOCOMOTION.

NOVEMBER 17TH, 1896.

THE NEW REGULATIONS AS TO MOTOR-CARRIAGES.

IN drafting the regulations under the Locomotives on Highways Act, 1896, we have to thank the Local Government Board for having tried to do its best in the interests of the new-comer on the streets. In the original circular which they sent out to the Local Authorities they shadowed out the following as the chief points to be insisted upon :—

A motor-carriage to come within the protection of the Act of last Session must not weigh more than 3 tons unladen; and must not be used for the purpose of drawing more than one other vehicle, such vehicle and locomotive not to exceed an unladen weight of 4 tons.

A motor-carriage must be constructed in such a manner that no smoke or visible vapour is emitted, except under temporary or exceptional circumstances.

If a motor-carriage exceeds 336 lbs. in weight unladen, it shall be capable of working either backwards or forwards.

No motor-carriage must exceed a width of 7½ feet between its extreme projecting points. (*Now amended to 6½ feet.*)

The tyres must be proportioned as follows :—

Between ¾ ton and 1 ton,	not less than 2½	inches wide.
„ 1 ton „ 2 tons,	„ 3	„
„ 2 tons „ 3 tons,	„ 4	„

No bosses or projections will be allowed, except in the case of pneumatic tyres, when the projections must be of the same material as the tyres.

Every motor-carriage must be provided with two independent brakes of such a power that when the carriage is travelling at the rate of 14 miles an hour, the carriage can be stopped within a distance of 50 feet.

The name and address of the owner must be painted on the side of the vehicle.

The driver must be competent.

Lamps must be carried at night.

The driver must give notice of his position to the public by sounding a bell or by other sufficient signal.

The vehicle must be brought to a standstill at the request of the driver of a restive horse or at the demand of any police constable. The putting up of a hand shall be a sufficient signal to bring this order into operation.

The maximum speed allowed is 14 miles per hour. (*Amended.*)

The various County Councils have mainly fallen foul of the speed allowed, altogether forgetting that it would have been a maximum rate, and was safeguarded by the brake power insisted upon, while both drivers and owners are, of course, subject to the Common Law of the land. The consequence has been that a minimum of 12 miles an hour for the lightest vehicles, diminishing down to six miles for the heaviest types, has been insisted upon. This will doubtless satisfy the critics who imagined that a three-ton vehicle, driven by an incompetent amateur, who had never before seen a piece of mechanism, would be permitted to run amuck in a crowded thoroughfare at the greatest legal speed permitted originally by the Act. The regulation as drawn is almost prohibitive to motor omnibuses, and will doubtless be amended at the earliest opportunity.

The chief point, however, is that the Local Government Board have done wisely in restricting the new rules to an operative period of six months. No great harm can be done in the interregnum by the small difficulties which have been thrown in the path of the owners and makers of the vehicles by the deviations which have been made from the original intentions of the Central Board. In the meantime, the drivers must show, by their consideration for the public interest, that restrictions are not justified. What is reckless and unlawful on the part of the owner of a vehicle drawn by a horse should be the test applied to the conduct of the driver of a motor-carriage, and if an owner employs bad workmen or purchases inferior vehicles as propelling power, the punishment which will ensue will soon act as the most effectual deterrent.

We have dealt at length only with the question of speed, because we believe that the experiences of the next few months will demonstrate more fully the inutility of the present regulations than reams of argument could at the present moment. One final remark and we have done. The regulations provide a scheme for the compulsory display of lamps by the horseless vehicles, and the sooner this is applied to the whole of the carriage traffic the safer will our streets become.

LIVERPOOL TO THE FORE.

FOLLOWING the admirable example set by Glasgow, a local branch of the Self-Propelled Traffic Association has been instituted in the great seaport which may be said to be the connecting link between Great Britain and the United States. The Western city, which has commenced so well with a president of the standing of Lord Derby, and with such an influential backing of celebrities as those which assembled to listen to and applaud the interesting address delivered to them by Sir David Salomons, cannot fail to help to mould the future of the great industry which dates its new birth from the 14th of the month.

In the course of his remarks, Sir David said much that was of invaluable use at the present stage of matters—he has had unique opportunities of testing the vehicles which our French friends have constructed, and from his independent and fortunate position can freely express his opinions. His views on the present position of the various motive powers will therefore be read with the keen interest which they deserve—for he has the courage of his convictions, and an adequate technical training and knowledge to back up his opinions when they are questioned.

One item in his address strikes us as capable of much modification. He is doubtless correct when he states that the main principles of explosive engines are well known; but we cannot follow him in his seeming depreciation of the value of patents in automotor work. Doubtless many of the so-called inventions which have been introduced are valueless; but before a motor-carriage free from vibration and using an engine propelled by a safe and heavy oil has been perfected, much inventive skill will be necessary—especially if other essential points, such as ease of management and economy, are to be secured. In such a case the labourer will be worthy of his hire, and will receive it ungrudgingly from all interested in the subject.

This, however, is only incidental to the congratulations which may be addressed to the new branch. By adopting the principle of an extended course of lectures on all subjects of interest to the users of automotors, the Liverpool Society is doing well—for discussion and a liberal interchange of enlightened views must benefit the users and makers of the new carriages.

WANTED—A WORD.

In a considerable portion of the bulky correspondence which has come to hand as a consequence of the first issue of this Journal, complaint has, *inter alia*, been made that none of the terms hitherto employed neatly describe the vehicles which come within the provisions of the Locomotives on Highways Act, 1896. On one point at least all our friends are united, viz., that the Parliamentary phraseology is not worth imitation, while in the many suggestions which have been made we have not yet received, at least in our opinion, a better word than Automotor. It is convenient to remember, does not outrageously violate scientific principles, and does not jar on a sensitive ear as does the word "bike," which we hear so often in a kindred trade.

The fact is that we want a coined phrase which must be apt and yet not too flippant—"horseless vehicle" and "self-propelled carriage" are too lengthy and not distinctive or exact enough—so, for the moment at least, we must be content to accept a compromise between those who would frame a word built on German chemistry lines, having some forty letters in it describing in brief all the complex operations which are required to propel a carriage by power, and the Ishmaels of philology who would be simply content to dub the new carriages as "mo-cars."

We have, as we have stated, received many views on this interesting subject, but as they occur, in the main, in the course of private congratulory letters to the Editor, we have not published them, not caring to do so without the express permission of the writers. The matter, however, is well worthy of ventilation, and we invite correspondence upon it. We can hardly offer a prize for the best title, because the public will ultimately judge what word shall be the survival of the fittest; but the correspondent who succeeds in hitting upon the term which the "man in the street" will adopt, will have at least the satisfaction of adding another word to the thousands which haunt our end-of-the-century dictionaries.

"ENGINEERING" AND AUTOMOTORS.

We have received several letters from correspondents complaining of the apparently hostile attitude taken up by *Engineering* against the self-propelled vehicle. Most of these communications are of a private nature, while those sent for publication did not—either through inexperience in the use of the pen for journalistic purposes, or in consequence of the writer's wrath—treat our able contemporary with the courtesy which is due to its high standing as a trade journal.

We think that *Engineering* has altogether failed to grasp the position taken up by those who are seeking to introduce the new industry into the country. No one—least of all the owners and makers of the machinery—wishes to place vehicles of from one to three tons in charge of incompetent men to drive through crowded streets at the rate of some 14 miles an hour, with the certain result of dealing out death and destruction all round. This is the fear which seems to haunt our usually level-headed contemporary; but every interest is opposed to the adoption of any such idiotic and suicidal tactics. The keynote of the advice given by all concerned in automotor work is to go slowly at first; to avoid the slightest suspicion of fear at any cost; and to win public support by accomplished facts of safety and convenience. If we attempted to traverse some of the comments of

E 2

Engineering our remarks might be discounted, as emanating from a newspaper identified with this particular industry, so we prefer to quote from an article which appears in an independent journal—the *County Council Times*—some remarks with which we cordially agree. They are as follows:—

"The motor-car is not to be made as useful as it should be just yet, for there are evidently still many old and foolish prejudices to be broken down. There is an idea in some quarters that the object of the inventors of motor-cars has been solely to produce a machine which shall personate the 'raging lion' on every road in the country, and shall seek not only whom, but what it may devour. The motor-car is not a dangerous machine, any more than an ordinary carriage and pair is dangerous; and on country roads, where it will be most frequently met with, it will be far less dangerous than a horse-drawn vehicle, which travels faster there than in a city. The motor-car, from the fact of its being machine-driven, is better under the control of its driver than a horse-drawn vehicle can possibly be, and both the steering and the brake-power are so much more perfect that danger is greatly reduced by them. Nevertheless, although the man with the red flag will cease to be necessary at the end of next week, the speed at which motor-cars are to be allowed to travel is being ridiculously restricted. The Local Government Board thinks that 10 miles an hour is a more suitable speed than 14 miles; and some people prefer 8 miles to 10. But, since 10 miles an hour will probably be the limit imposed, let us consider what that means. The mail-coaches which still leave London at night for Guildford and Brighton travel, when they get out of the suburbs, quite 14 miles an hour. The coaches which run during the season are not much slower. An ordinary carriage and pair travels more than 10 miles an hour; and a cyclist is never 'hauled up' for furious riding unless he is going at a rate of 15 or 16 miles per hour. In Warwickshire the Council has declined to sanction a higher speed than 10 miles an hour for what one member, Mr. Flavel, calls these 'diabolical' machines. But even in Warwickshire opinions are divided, for another member, Mr. Vero, means to try a motor-car and 'go as hard as ever he can'; so perhaps we shall have an agitation for greater freedom when the cars become better knowo."

In all friendliness we would ask the editor of *Engineering* to look a little more kindly towards the new industry, the legal birth of which only dates from the 14th of the present month.

Forthcoming Exhibition.—One of the special attractions next year to mark the sixtieth year of her Majesty's reign will be an electrical and engineering exhibition to be held at Newcastle on-Tyne. There being no permanent building in that city adapted for showing heavy machinery and machinery in motion, a site on Pandon Dene has been secured, on which special temporary buildings will be erected, and will be so arranged as to meet the requirements of the exhibits referred to. It is intended to be strictly an exhibition, and in no way an organisation for the sale of goods. Exhibitors, however, will be allowed to book or take orders for the various specialities. What are known as bazaar goods will be absolutely excluded from the exhibition. The importance of Newcastle as an electrical and general engineering centre will naturally create special interest in an exhibition of the articles described. It is intended to make a special feature of cars and cycles propelled by electric or other motor power. Exhibitors in these lines will find it to their advantage to be adequately represented at the exhibition. Mr. H. Engel has the matter in hand, and intends making substantial provision out of the proceeds for the Royal Infirmary, which will take the form of "a donation from the exhibition to the new building fund."

THE BRITANNIA COMPANY'S ELECTRIC SYSTEM.

We herewith illustrate a couple of carriages fitted with motors on the well-known Britannia electric system, the rights of which in this country have been purchased by the British Motor Syndicate. One great feature of this motor is the ease with which it can be adapted to existing carriages in case the owner desires to substitute motive power for the horse. The photograph of a Victoria is taken from a carriage which was taken out of the ordinary stock of a coachbuilder, and converted into a motor-carriage by the addition of a box under the seat to hold the battery, the Britannia motor and axle being substituted for the ordinary axle box, and these, with the addition of a simple and effective form of steering gear, being all that was required for the conversion. The dog-cart was altered in an equally simple manner, the battery in this case being placed at the driver's feet. The carriages are extremely smooth and easy in running, and are very fast; the amount of power provided and the general efficiency of the motor renders them capable of attaining a good speed on gradients. Mr. J. Vaughan-Sherrin is the inventor of the motor. Both of these vehicles took part in the procession to Brighton.

THE MOTOR-CAR IN THE LORD MAYOR'S SHOW.

PERHAPS the most striking feature in the Lord Mayor's Show, on the 9th, was the appearance of the motor-car. It was certainly the item which was received with the greatest amount of cheering in such crowded thoroughfares as Moorgate Street, Cheapside, Fleet Street, and the Strand. The past and the present were admirably and pictorially contrasted. Immediately preceding the horseless carriage, moving with grace and freedom, and adapting itself, under the alternate steering of Mr. Henry J. Lawson and Mr. Charles McRobie Turrell, to all the exigencies of the narrow lane through the closely-packed and swaying crowds in the thoroughfares, and to the frequent halts and irregular pace of the snake-like procession, was the ancient stage coach, with passengers in the picturesque costumes of the last century, and the quaint guard, armed against highwaymen with a huge blunderbus. The motor-car was dubbed "New Times," and there could be no question of its "up-to-date" type. The property of Mr. Henry J. Lawson, its dexterous driver, the "New Times" (which we illustrate herewith) is to outward appearance an elegantly-modelled enlarged landau, capable of holding four inside (which is beautifully upholstered in dark-green cloth and leather) and two in front. On the right of the front seat is the steering-wheel, more easily manipulated than horses' reins, to which the car is more instantly obedient than ever horses could be under the guidance of the most expert whip. The driving power is petroleum, and the propelling engine, the Daimler motor, which is stowed away behind and beneath the body of the car, so as to be hardly noticeable. Vibration has been reduced to a minimum, and the rattle and whirr of the gearing has been obviated by the employment of leather belting, instead of cogs, on the driving wheels. All the wheels are also furnished with rubber tyres. The car, which, by the way, had as an inside passenger a representative of the *Daily Telegraph*, moved with great ease and silence, and the success of this official introduction of the "New Times" carriage to the streets of the Metropolis was beyond question.

"NEW TIMES" MOTOR-CAR.

LONDON TRAMWAYS PURCHASE.

Electric or Mechanical Haulage Considered.

NOTHING has been heard for some time of the scheme for the transfer of the Metropolitan tramway systems to the County Council. When the question was last discussed by the Council, the offer of a syndicate to lease from the Council, after that body had purchased them, the undertakings of the North Metropolitan and the London Street Tramways Companies was rejected. Since then the Highways Committee have had several schemes under consideration, and the result of their investigations is contained in a voluminous report. The committee have come to the conclusion that an arrangement should be made with the companies mentioned for the purchase by the Council of their lines and depôts, and for leasing them to the North Metropolitan Company for a comparatively short time.

The proposal is that the companies shall sell their tramways to the Council at £10,000 per mile for double and £5,000 per mile for single lines. Without entering into details of the two systems, it may be stated that, at this rate, the purchase-money for $43\frac{1}{2}$ miles of double lines—single lines included as half the length of double—will amount to about £437,000. To this sum, however, must be added £101,798 paid for about five miles of the London Street Company's undertaking already purchased by the Council and leased to that company. This brings the total capital expenditure up to about £540,000. The Council will receive £45,000 fixed rent, which is equal to $8\frac{1}{2}$ per cent. per annum on the capital outlay, and which will be further augmented by the rent of freehold and leasehold buildings, and 5 per cent. of the increase of the gross receipts over those of 1895. This, moreover, leaves out of account any profit that may be made from new extensions or connections. At the expiration of the lease to the company, in 1910, the Council will, it is estimated, have received by way of fixed rent and percentage of receipts a sum of £903,630, of which £187,854 will have been applied to the reduction of debt, £251,869 to payment of interest on loan, and £463,907 in relief of rates. The relief to rates during the first year will be £25,875, after payment of £32,295 for interest and repayment of capital, which the committee consider "an exceedingly good return on the capital invested by the Council."

In addition to preparing this scheme for the transfer of the tramway systems, the Highways Committee have discussed the advisability of adopting some system of electrical or other mechanical haulage in substitution for horse traction; and have arranged with the company that, if at any time during the continuance of the lease, the Council should consider it desirable that some form of traction, other than horses, should be adopted, the leasing company will be prepared either to carry out the necessary works on terms to be arranged, or, should the Council execute the works, to pay a fixed rent and a share of the extra profits which may accrue in this way. If future developments in the system of traction by electricity or otherwise should promise a very largely increased return, by reason of saving in working expenses and increase in number of passengers carried, the bulk of such profit should, the committee state, accrue to the Council and the ratepayers rather than to any private corporation. The ultimate decision as to the proposals of the Committee has been adjourned pending further negociations on the subject.

NORTH COUNTRY FARMERS AND MOTOR-CARS.

A meeting of the members of the Newcastle-on-Tyne Farmers' Club was held on the 7th inst. in the Club Rooms, Town Hall Buildings, Newcastle, Mr. E. J. Browell occupying the chair.

Mr. John Morrison, F.C.S., read a lengthy paper on "English Roads and Road Transit of the Present and the Future, from an Agricultural Point of View"; and in his introduction said his statements and conclusions must be regarded as those of a critic rather than an expert. There could be no question, the writer proceeded, that cheap transit is the true key to the whole position as regards foreign competition in agricultural produce, and only by fighting it could British agriculture keep its head above water. There was the unfortunate peculiarity about agriculture, that its operations for a given volume of results are diffused over an enormous area The quantities per acre to be moved in one direction or another were comparatively small. He went on to point out that road haulage by means of horses had long been regarded as a comparatively extravagant method, and reviewed at considerable length the history of the movement of mechanical cars on roads, and the difficulties placed in the way of their development. Having touched upon the various restraints put by Act of Parliament upon road locomotion by steam, Mr. Morrison said the new Locomotives on Highways Act inaugurates an entirely new *régime*. After commenting adversely as to the great speed allowed, Mr. Morrison said the probabilities were that no such speed would be required for commercial purposes, and regretted that the framers of the new Act seemed to have been influenced in the interest of vehicles of a non-commercial class. He then discussed the merits and demerits of the various kinds of motive power, and said that one of the weak points in the new Act was that—owing to its 3-ton weight limit—it gave very little fairplay to steam, which presented more possibilities of usefulness than oil, and was the only source of road motor power which up to the present possessed the slightest economical importance, while a really successful and practical oil road-engine had not yet been exhibited. He then proceeded to deal at length with the Light Railways Act of last Session, and stated that his own experience was that what agriculture really wanted was a four or five ton locomotive, capable of hauling five to 10 tons load at a six or eight mile speed, with but a man and a boy in attendance.

In the course of the discussion which followed the reading of the paper, Mr. W. Trotter said good roads were undoubtedly necessary. He was of opinion that the cost of repairing should be divided, as in Scotland, between the occupier and the owner of the land. He complained of the imperfect way in which roads were made.

Mr. Forster Coull thought the roads should be maintained by the nation.

Mr. John Philipson, speaking as a carriage manufacturer, said he believed the vehicle of the future would be the steam-carriage. He did not think the petroleum-carriage, with all its complications, would ever be reliable, at any rate for the agriculturist. The electric-carriage would be the carriage of the future, however, so far as regarded large towns, where they could have storage stations. He did not think there was yet one reliable vehicle in the market. There was still wonderful scope for development, and he looked forward to the English engineer giving that attention to the subject, which would surmount the difficulties that had shown themselves both in Paris and America, and to their producing a vehicle superior to any of them. Englishmen had been handicapped by legal restrictions, but these having been removed to a very great extent, a stimulus was given to the younger generation of engineers to produce a vehicle suited not only to carrying purposes, but also to the conveyance of passengers. These new carriages should be protected back and front with lights. He was inclined to think that something like eight or ten miles an hour would be the average speed. With good roads and proper vehicles to bring agricultural produce to the centres of population, they would constitute one of the greatest boons, and at the same time do much to alleviate agricultural depression.

Mr. Knox-Lyal said light railways would not do agriculturists as much good as one of those steam-cars, which could go from one place to another to collect the produce. He believed the speed ought to be restricted.

The Secretary said the committee of the club were in communication with a company in London who were desirous of obtaining information with a view to the construction of light railways in various parts of the country. If particulars could be laid before them to show that such a railway was desirable and would pay in some particular locality, they were prepared to send someone down. He (the secretary) would be glad to hear from any member of the club on the subject.

The Chairman agreed with Mr. Knox-Lyal that light railways did not promise so much for a part of the country like theirs as a carriage to travel independently over the existing roads. He also was of opinion that very stringent regulations were necessary in connection with the management of the new vehicles in order that pedestrian and horse traffic might be protected.

On the motion of Mr. Potts, a vote of thanks was accorded to Mr. Morrison for his paper.

Dr. Seelig, of 11, Ludgate Hill, who is well known as an organiser of Continental trips, is arranging a series of Motor-Carriage Journeys at home and abroad.

A Sign of the Times.—Messrs. Chadwick and Sons, the old-established and well-known auctioneers, of St. Martin's Lane, are, we believe, the first firm of repute to announce their special facilities for dealing with the new automotor vehicles, whether by auction or valuation. The firm's reputation and experience should secure them a goodly portion of the business likely to come forward with the introduction of this new and important industry.

In our last issue a couple of mistakes occurred, for which the difficulties incidental to the production of a first number can only be offered as an excuse. In thanking our contemporary, the *Kent and Sussex Courier*, for the courtesy extended to us, we inadvertently described that paper as the *Kent and Sussex Chronicle*; while the heading to Mr. C. Harrington Moore's letter *re* the "Motor-Car *Run* to Brighton" was interpreted by the printers as a "Motor-Car *Race* to Brighton." The context of the letter sufficiently explained what was really intended; but we presume our friends, the printers, were too sportsman-like to imagine that the rival vehicles could be sent on their way without an effort being made to determine which could cover the distance in the shortest time

DOINGS OF PUBLIC COMPANIES.

The Aberdeen Motor-Car and Cycle Company.

The shares of this new Motor-Car and Cycle Company are reported to have been practically all taken up. Originally it had been intended that the Company should be a private one, but now it has been decided to make it public. When all preliminaries have been adjusted, the Company propose to at once proceed to organise a factory for the manufacture and sale of the machines specified in their prospectus. The premises No. 414, Union Street, Aberdeen, vacated by Messrs. Gifford and Son, have been secured for this purpose, the shop being by situation specially adapted for show purposes. The Company propose manufacturing a special cycle of their own, and will likewise hold agencies for a number of leading firms in the south. They will also be agents for a new motor which has been devised for the propelling of any cycle. Also they will hold an agency for the Great Horseless Carriage Company. In order to spread the business, agencies on behalf of the Company will be established throughout the north. The manager appointed by the Company is Mr. J. H. Paterson, and it is expected that the business will be under way by Christmas.

Midland Cycle and Motor-Car Exhibition.

The statutory meeting of shareholders of this Company was held at the Grand Hotel, Birmingham, on the 11th instant. Mr. J. B. Burman presided, and there was a large attendance of shareholders.

The Chairman explained that the Company had now been duly registered, and the capital considerably over applied for. The allotments had been made, and the preliminary arrangements decided upon for the holding of the exhibition at Bingley Hall from January 22nd to 30th inclusive. A number of applications for space had already been received, and everything was progressing in the most satisfactory manner.

The election of the Board of Directors was then proceeded with, and resulted as follows:—J. B. Burman (chairman), W. Calcott (Coventry), R. F. Hall (Birmingham), F. H. Parkin (Wolverhampton), F. Westwood (Birmingham), J. H. Price (Birmingham), J. Urry (*Bicycling News*), and C. Wheelwright (*Bicycling News*). The registered offices of the Company are at 174, Corporation Street. Mr. C. Wheelwright, of Lucifer House, Lionel Street, Birmingham, was elected secretary.

A vote of thanks to the chairman closed the proceedings.

New Companies.

The number of new companies registered at Somerset House during October was 382, with capital amounting to £23,665,740, as against 280 in September, with an aggregate capital of £15,695,774. The following are more particularly related to horseless vehicles:—

	Capital.
British Electric Traction Company (Limited)	£600,000
British Pure Acetylene Gas Syndicate (Limited)	50,000
Beeston Wheel Company (Limited)	10,000
Coventry Wheel Company (Limited)	12,000
Coventry Motor Company (Limited)	10,000
King and Rool's Starting Gear Syndicate (Limited)	3,000
Midland Cycle and Motor-Car Exhibition Company (Limited)	1,000
Rosser Cycle and Vehicle Brake Company (Limited)	50,000
Starley Bros. and Westwood Manufacturing Company (Limited)	110,000
Savage's Engineering Works (Limited)	120,000
Steam Carriage and Wagon Company (Limited)	1,500

Ramsay's Horse, Carriage, Cycle, and Autocar Repository (Limited).

This is a new Company, formed with a share capital of £60,000, for the purpose of erecting an extensive repository in the Hammersmith main road, for auction sales, &c. The directors are Sir Edward Lee, Messrs. Charles Fox, Robert Johnson, and W. D. Ramsay, and the offices 223, Hammersmith Road, W. A dividend of 10 per cent. per annum is anticipated; and provided the proposals of the Company are efficiently carried out, there is no reason why the shareholders should not receive all the advantages the directors foreshadow.

New Issue.

With a capital of £150,000, in £1 shares, the London Electrical Cab Company (Limited) has been formed to place on the streets of London electrically-propelled cabs (British Motor Syndicate patents), to supersede the present hansoms and four-wheeled cabs. The cabs will ply for hire in London in the same manner as the present hansoms, and at the same rates. Two sets of accumulators will be supplied to every cab, each set, it is claimed, being capable of propelling the vehicle 40 miles with one charging. It is intended to open depôts in different parts of London, so that the driver will be able to change accumulators without always having to return to his own station. The Company will acquire for the price of 50,000 shares, or cash in lieu thereof, the license from the British Motor Syndicate (Limited), subject also to the payment of a royalty of £4 per cab per annum. The said price has been fixed by the Traffic Syndicate (Limited), who are the vendors to the Company. The whole of the shares are offered for subscription, £100,000 being for use as working capital.

Walter C. Bersey, A.I.E.E., M.I.C. and M.E., the engineer to the Company, also represents the following kindred organisations:—The Great Horseless Carriage Company (Limited), the British Motor Company (Limited), the Motor-Car Club.

Mr. Bersey's two carriages in Saturday's procession were pronounced a success. The large landau was driven by Mr. Bersey himself. This gentleman has constructed several carriages—omnibus, vans, cabs, phaeton, and landaus—which have run an aggregate of considerably over 10,000 miles during the last four years. These vehicles are covered by several patents, which are now owned by the British Motor Company (Limited); and the Great Horseless and London Electrical Cab Companies are working under licenses from the British Motor Company.

A practical demonstration of the capabilities of the new cabs was made on Monday in the presence of a large number of people, when one started from the Royal Hotel, Blackfriars, at 12.30 for the City. In the carriage were the Earl of Fingall, Mr. Frank Gardner, Mr. Davison Dalziel, Mr. H. Mulliner, while Mr. Bersey was on the box. The carriage was driven down Queen Victoria Street, past the Mansion House, and round the Bank, into Throgmorton Street, the ease and facility with which it was guided through the crowded streets and the entire absence of any vibration proving that the introducers of this new form of locomotion for the public are justified in their anticipation of a successful future.

Capital of Cycle Companies.—The popularity of bicycling is demonstrated in some measure by the fact that since the first of the year over £11,000,000 has been invested in new cycle companies. Up to the end of last year the capital of the cycle companies was less than £6,000,000. It has thus been nearly trebled since January. This figure does not include capital invested in the numerous private concerns in different parts of the country. Nearly 2,000 patents for inventions connected with bicycles or accessories were applied for during 1895. The value of the bicycles made in a year in Great Britain, at the present rate of production, is £12,000,000.

NOTES OF THE MONTH.

An agitation has been set on foot in Manchester with the object of compelling the owners of omnibuses and tramway cars to provide covers for outside seats to protect them from rain in wet weather. The movement deserves to succeed. "If you don't like to sit on a wet seat, walk," is not good policy for either the public or the omnibus and tram proprietors.

An electric tramway is proposed to be constructed at Bray; the agents for the promoters are Messrs. Molloy and Molloy, 18, Eustace Street, Bray. The company which they represent is called the Electric Pioneering Company, with a capital of £100,000, and they propose to expend from £30,000 to £40,000 on the scheme. At the annual meeting of the Bray Township Commissioners held recently the matter was very favourably received.

The Dublin United Tramways Company intend to promote an Order in Council to authorise their making considerable extensions in the city and townships.

Penny rides on tramcars are popular, but when a passenger is compelled to take three separate tickets and pay for them in the three instalments at different stages of the journey, the process is apt to be somewhat irritating. In Leeds, on the Corporation tramways, tickets are only issued of one value, viz., one penny, and when a rider has exhausted the potentiality of one ticket, he has to take another, and so on to the end of the journey. It is little wonder, therefore, that we learn, on the authority of the *Leeds Mercury*, that the system is causing a good deal of dissatisfaction. Tickets of various values should be at once adopted; it is easy for an intelligent conductor to prevent any attempted fraud on the part of those who would ride a long journey with a short-distance ticket.

The men employed on the Manchester Tramways have been dissatisfied with their hours of work, and at one time a strike was imminent. This has been obviated by an arrangement, commencing on the 1st of this month, by which the hours of the drivers and conductors are reduced to 11 per day, and the wages of the horse-keepers are increased.

Either the local opinion of Bradford is not favourable to electricity, or the terms offered by the tenderers were not considered satisfactory, as we find that last month the offer of the Simplex Electric Tramway Conduit Syndicate to work the proposed tramway line to Great Horton was declined by the Bradford Town Council.

In Nottingham there has recently been a battle—not of gauges—but of the particular power to be applied to the tramway systems of the Corporation. For the moment the advocates of cable lines seem to be in the ascendant, but probably those interested in other methods will make their views heard. In Nottingham the cost of running the cable system, when in full working order, is estimated at about 6*d*. per car mile.

The Swansea Improvement and Tramway Company have agreed to sell their tramways to the Swansea Corporation for a nominal purchase price of £32,000, but as this amount is contingent upon certain conditions it is subject to modification. The Company in return get a 21 years' lease of the line at a rental which will fluctuate between £5,000 and £6,000 per annum. The Corporation intend to substitute electric traction for horse power, and this they will do in connection with an extensive scheme of electric lighting which they have in contemplation.

A cycle which "can easily be driven at the rate of 35 miles an hour," is one of the wonders promised us by the chairman of the Company owning the patents. The surprise one feels at the announcement is certainly not lessened when we are told that the word "'easily' means that only one-tenth of the power required to drive an ordinary cycle will be needed for getting the enormous speed out of the new machine." This is all delightfully vague, and is not rendered any clearer by the chairman's explanation that the cycle is to be "driven neither by chain, gearing rods, nor mechanical contrivance, but by a wonderful adaptation of an old principle in use in our chief public buildings to-day." The Belfast *Northern Whig*, which appears to be in the secret, prophesies that the power is hydraulic.

The Blackburn Corporation have applied through their town clerk, Mr. R. E. Fox, for power to raise a loan, £10,000 of which is to be devoted to electric traction, and £18,000 to the extension of the very successful electric lighting plant which has already been laid down, but which is not equal to all the demands made upon it. The price to be paid by the Tramway Company for electric power has been fixed at 3*d*. per car mile, and both the Corporation and the Company are stated to be satisfied with the agreement. As no opposition has been made to the loan, there is no doubt that the Local Government Board will sanction it.

A large scheme for the extension of the tramway system of Liverpool has been prepared, and is now under the consideration of the Health Committee.

It is proposed to apply for powers to construct an electric tramway next year from Laxey to Ramsey, Isle of Man.

A Company is shortly to put 24 motor-omnibuses on the road between Birmingham and Warwick, which will convey passengers the whole distance at a return fare of 1*s*. 6*d*., or half the third-class railway fare. To give another example of the cheapness of the new traction, a motor-car containing four passengers was lately run for 80 miles in Warwickshire at an expenditure in oil of 3*s*., or 9*d*. a head. It would be curious indeed if the railways at the end of the century were to find themselves once more face to face with their earliest competitor, traction by road.

The Clontarf and Hill of Howth Tramways Company, Limited, have presented a memorial to the Lord Lieutenant, praying for an Order in Council to authorise the construction of a tramway between Clontarf and the Hill of Howth.

IN Tokio electric tramways are only to be permitted as a municipal concern, and progress has been retarded by a recent refusal of the City Council to allow the utilisation of the head-waters of the Tamagawa for the generation of the necessary motive power on the plea that the town water supply, which is drawn from a lower reach of that river, might suffer contamination.

BIRMINGHAM being so much interested, there is no doubt that a representative exhibition of cycles and motor-cars held in that city would prove to be of great benefit to the two industries concerned, and we are therefore not surprised to learn that a Company is being formed for the purpose of making a demonstration of this kind. The proposed Company, which is to be called the Midland Cycle and Motor-Car Company, Limited, has received so much support that more than the total capital required has been promised. The exhibition, which is to be held in Birmingham early in January, should act as a great stimulus to the cycle and motor-car industries. The promoters hope and believe that the Right Hon. Mr. J. Chamberlain, M.P., will consent to open the exhibition.

MR. H. W. STANER, of Coventry, in a letter to the *Western Morning News*, takes to task some correspondents in that journal who have attempted to somewhat belittle the results which have been attained in the recent contests. As he truly observes, our Continental friends have been the modern pioneers in this matter, and the greatest credit is justly due to them for what they have achieved. He concludes an interesting communication as follows:—"As a matter of fact, the reason for abstention of the Anglo-French vehicles was found in the fact that the English-made carriages were not ready, and it is to be hoped that when the great British contest takes place next year the home-made productions will have passed the experimental stages, and be in a condition to compete in a hard and protracted trial under the eyes of mechanical experts, with proper regulations and tests, to ascertain power, fuel consumed, weight, and all-round efficiency. Finally, I would like to emphasise the fact that every autocar contest which has been held up to now has provided all intelligent autocar designers and builders with many invaluable object-lessons and useful hints, the practical results of which can be seen in numerous improvements, both in design and construction, of the later pattern of horseless vehicles."

THE directors of the Dublin Bread Company (Limited) deserve notice as perhaps the first public concern in this country to advertise for tenders for a motor-van. We trust that these requirements have been met; if not, their consulting engineer, Mr. F. J. Warden-Stevens, 34, Victoria Street, Westminster, may doubtless be pleased to hear from those who can meet his requirements.

HERE is "A Sign of the Times." Mr. Jas. Cooper, the well-known auctioneer of Newcastle-on-Tyne, recently sold at his Crown and Thistle Mart, in that city, a number of heavy draught horses and carts and chain gears. His instructions were from Messrs. Nimmo and Sons, brewers, of Castle Eden, and the reason assigned for the sale is "owing to their having purchased a traction-engine."

THE municipality of Buenos Ayres must do pretty well out of the local tramways. It levies a tax of 6 per cent. on their gross receipts, and the amount collected by this means last year was £91,113.

EVIDENCE of the wide disparity which would have prevailed in various districts had the various local authorities been empowered to fix the speed at which motor-cars could travel in different parts of the country, has been amply given during the last few weeks. Members of a large number of County Councils, under the erroneous impression that with them, and not the Local Government Board, rested the fixing of the maximum speed, gave notices of motion to deal with the subject, but were, of course, ruled out of order. The speed actually proposed to be allowed varied between four miles per hour and the actual maximum of 14. The first-named retrograde step was proposed in Scotland, while the Midlands and the South were generally in favour of a liberal welcome to the new comer on the roads. The mean average of the various proposals made worked out at 9½ miles per hour. We have, indeed, reason to be thankful that we have only one body to deal with in this matter, otherwise the resulting chaos would have been terrible.

BIRMINGHAM, always a model Corporation, is about to effect some very great improvements in its at present very excellent tramway service, and an interesting report on the subject may be expected at an early date. At present the tramway system extends 14½ miles outside the city, and these connections will, in all probability, be taken even further.

IN West Hartlepool the electric tramway system has, after a six months' trial, been found to give general satisfaction to the inhabitants. Although overhead wires are used, they are not regarded locally as unsightly, while the smoothness of running leaves little to be desired. The members of the Middlesborough Town Council have recently inspected the line, and will report at an early date whether they recommend the example to be followed in Ironopolis. In the course of a speech made after a luncheon at Hartlepool, Alderman Bulmer, responding for the Middlesborough Corporation, said he and his colleagues were well pleased with what they had seen.

THE Tonge Parish Council have decided in favour of electric tramways, and intend to use their influence with the Bolton authorities to get them constructed.

THE Bolton Corporation have succeeded in persuading the Horwich Urban District Council to adopt electric tramways. The cost of laying the line is estimated at about £4,000 a mile, or a total of £12,000; the electric equipment will cost £2,000 per mile, bringing the total cost of the rolling plant and line up to about £19,000. If the Horwich Council generated its own current, a further capital expenditure of some £15,000 would be necessary, but this is to be obviated by the Corporation furnishing the supply from their own station at a rent to be agreed. Powers to carry out the scheme are to be applied for at once.

STIRLING tramways are to be extended by the Bridge of Allan Tramways Company (Limited).

A NEW Company has taken over the Highgate Hill Tramways, London, and are busy with necessary repairs to plant and roadway.

MR. J. H. WILKINSON, of Chancery Lane, London, presided over a meeting held in the Hoghton Chambers, Hoghton Street, Southport, on the 22nd ult., when a provisional committee was appointed for the purpose of putting into due form, prior to the formation of a limited company, the scheme of Mr. Stewart Speddy, Southport, for constructing a roadway and electric tramway from Southport to Lytham. The estimated cost was put at from £450,000 to £500,000.

THE Dundalk Town Commissioners have resolved to apply for a Provisional Order enabling them to light the streets of the town by electricity, and to run their trams by the same power.

A DAIMLER motor-carriage was recently on view at Ashford, and caused considerable interest in the vicinity of the "Saracen's Head," the headquarters of its driver. It had travelled from Margate to Ashford in about three hours—leisurely progress being made on a Sunday afternoon under the old Act. The weight of the carriage was about 28 cwt.

WE understand the Gorleston and Southtown Tramway Company are seeking Corporate sanction to extend their line from Pier Walk to the vicinity of the South Pier, and to apply electricity as a motive power.

THE Manchester City Council have discussed the speed of motor vehicles under the new Act, and have recommended the Local Government Board to restrict the maximum to six miles per hour within a given radius of the Manchester Town Hall.

THE Gloucestershire County Council have contented themselves with suggesting that there should be two new bye-laws, the first providing that any motor exceeding one ton in weight should not exceed the rate of four miles an hour in crossing any bridge exceeding a 12-foot span, and a second forbidding two motors crossing any bridge at the same time.

THE Coventry Electric Tramways Company propose to apply for Parliamentary powers to extend their present system by about six miles and a half.

THE opposition which magisterial minds can bring to bear on suggested improvements was voiced by Mr. Hopkins, the stipendiary magistrate at Lambeth Police Court, who recently fined a cyclist 10s. and costs for furious riding, and then went out of his way to remark: "It's a horrible thing to think that in another fortnight we shall have the auto-cars doing the same kind of thing. What will then happen I don't know." To presuppose that the owners of the new vehicles intend to break the law is neither impartial nor judicial.

THE Warwickshire County Council, in considering the proposals of the Local Government Board with regard to the regulation of motor-carriages, ultimately adopted the report of a committee recommending that the speed should be 10 miles an hour, instead of 14, and the maximum width of a vehicle $6\frac{1}{2}$ feet, instead of $7\frac{1}{2}$ feet. This was carried by 33 votes to 24, but not before Lord Willoughby de Broke had made an earnest effort to get the speed reduced to eight miles. He held that, as the representatives of an agricultural district, they should encourage horse-breeding, and put all the obstacles they could in the path of what another worthy member described as "diabolical machines." His Lordship and his supporters are at least half a century behind the times.

THE London cabby has assuredly fallen on evil days. Threatened by the rivalry of the motor-car in the future. and railway monopoly in the present, he may well be at his grumpiest and surliest. Everything has gone wrong with him. Embarked by his union on a strike which everyone realised from the first must end in disaster, he fails to comprehend even now that he is beaten. His union, too, landed him still deeper in the mire. Their proposal to carry the war into the enemy's camp by boycotting the railway stations, and putting down passengers with their bag and baggage outside, was certainly one of the most audacious suggestions ever entertained, but they alienated any little public sympathy with their cause which might have been felt. Besides, it placed the drivers absolutely at the mercy of their fares, who were, of course, quite justified in refusing to pay should the men refuse to drive them to their destination. That such a proposal should ever have been entertained shows to what desperate straits the men were brought; but, thanks to the vigorous utterances of at least two of the London magistrates, the boycott was as short in its duration as the sentences upon the drivers would have been long had the mad scheme been persisted with.

MR. WOLFE BARRY's inaugural address as the President for the year of the Institution of Civil Engineers, on the 3rd inst., largely took the form of a review of the progress made in engineering science during the 60 years of the Queen's reign. Perhaps the most attractive part of Mr. Barry's address was that in which he dealt with the appearance of the automotor as a factor in our everyday life. In his opinion we are now on the eve of a development in automotor carriages and wagons which will be as remarkable and far-reaching as that of the bicycle. He thinks it will probably prove that the automotor will accommodate much of the traffic to be served by light railways, and render to a large extent nugatory the legislation of last Session on this subject, more especially if provision is not made in the construction of such lines against the evils of break of gauge.

A DECIDED novelty was seen in the course of the November municipal elections at Coventry. Voters were conveyed to poll in motor-cars. This is the first time the new vehicles have been brought into such use in England. The motor-cars are the earliest to be made in this country, having just been produced at the Coventry works.

As a contribution towards solving the problem of locomotion in London, Mr. J. Allen Baker, a member of the County Council, has prepared an elaborate memorandum dealing with the question in various aspects, and discussing incidentally the scheme now under consideration for the purchase of the two metropolitan tramway systems. He has drawn up a statement based upon information collected by himself at Blackpool, Huddersfield, Leeds, Glasgow, Edinburgh, and other cities where mechanical traction or the municipal working of tramways is in vogue. The result of his inquiries is summed up in the statement that he is "more than ever confident that the Council will not obtain full value for their property, either in the sense of giving an efficient service to the travelling public of London or an adequate profit to the ratepayers, until they adopt a suitable system of electric traction and have the full benefit of the very great advantages that are to be derived therefrom." Experience, he adds, is universally in favour of municipal as against company working of tramways, and he opposes the scheme now before the Council on the ground that it would delay municipalisation for a period of 14 years.

It is announced that there is to be an auto-car race on the Riviera early next year. It is being organised at Nice by a number of amateurs, but it will be open to makers as well as amateurs. The race will probably be from Nice to Marseilles and back, a distance of 450 kilomètres. It will most likely take place in February.

It is stated that, in view of the electric omnibuses which will be placed on the London streets, the London United Tramways Company contemplates a second attempt to obtain Parliamentary powers for the substitution of electric for horse traction on its lines from Hammersmith to Kew and Richmond, and from Uxbridge Road Station to Acton.

The automotor drivers of Hamburg have established a strike record. Five-sixths of them went out, leaving the public without the indispensable horseless carriage, and in one day the terms of the men were conceded, and the Hamburg citizens again enjoy their usual facilities of locomotion.

Motors for horseless sleighs are among the latest novelties. They are light, powerful affairs, and can be run by an amateur as easily as those attached to horseless carriages. The sleighs are designed to be run either on snow or ice.

The City of Belfast has, by a majority of 24 to 9, resolved to adopt the overhead system of electric tramways.

London is charged £75 per horse per annum for the hire of 137 horses for Fire Brigade work. Any practical proposal, therefore, which would have for its object the reducing of this big item of £10,275 is sure to receive careful attention at the hands of the authorities. America, as usual, is leading the way in such matters. A big self-propelling steam fire-engine is already in use at Hartford, and Fire Commissioner Russel, of Boston, is about to order two of the same kind for his city.

A correspondent suggests that while the County Council is asking the Local Government Board to reduce the speed of motor-cars it might also devote some attention to the size and weight of traction engines. His house, he says, which is in one of the nearer London suburbs, suffered a veritable earthquake from the passage of one of these gigantic machines past its doors. The whole house seemed to sway, and small articles of crockery and furniture clattered as if there had been a genuine earthquake.

Hull seems likely to be amongst the leaders of the automobile movement. A motor-carriage belonging to Messrs. Thornton, Varley, and Co., a well-known firm of drapers in Prospect Street, Hull, has been perambulating the streets for a month past; now comes the news that a local Company for manufacturing automotors will be launched shortly, and that already there is a large demand for the shares.

The Lancashire County Council have adopted a stupid recommendation of their Main Roads Committee, to the effect that the speed of the new motors should not exceed six miles per hour. This decision was come to after a vigorous protest from the Chairman of the Board, who pointed out that it was expected, and no doubt would be the case, that half the motor-carriages would be really private carriages, which would not be more liable to injure the bridges than any other ~~private~~ carriage which went over them now. In France a light kind of motor-carriage was much in use on the roads, and it was to be remembered that if a bicycle had motor power it would come under the rule. He suggested that the proposed rate of six miles an hour should only refer to heavy traffic. To apply it to light vehicles would be, in his opinion, objectionable. He did not think the Council should do anything to limit the use of the new carriage when it came into operation, and on that ground he appealed to them to reconsider their recommendation. The Board, however, would not listen to reason, and, as a body, rendered themselves ridiculous by their resolution.

The North Riding County Council were not much better, as they resolved to recommend that the rate of speed at which light locomotives shall travel on public highways shall be, for 12 months at least, not more than 10 miles an hour.

The Works Committee of the Acton District Council have instructed the clerk to the Council to write to the secretary of one of the motor-car companies, asking for an estimate of the cost of a scavenger's cart fitted with motors. It has not yet been decided to dispense with the horses now in use, but it is thought that motor scavenging carts will be a more economical means of road-cleaning.

From far-distant Rangoon we hear that the ladies have taken the automotor under their protection and made it popular—as a practical protest against the cruel manner in which horses are treated there. The engineer drivers are smartly dressed in a sort of Spanish costume of dark blue velvet, and the "turn-outs" are reported to present an extremely taking appearance.

EMANCIPATION DAY.

(*See Pages 64, 65, and 66 for Illustrations.*)

On Saturday last, the long looked for and much discussed date on which motor-carriages could be legally driven through our streets without absurd restrictions arrived. Those of us who have in the past indulged in stolen rides in out of the way places, undertaken with a due fear of the police ever present to the mind, naturally took the earliest opportunity of making use of our new-found liberty. Without incurring the expense of a Continental trip, we were on the stroke of that midnight which ushered in a dismal 14th of November, at liberty to career at will through the streets of London, hampered only by thoughts of Local Government Board regulations, which will doubtless be modified at the end of the six months for which they have been officially promulgated.

Personally, we celebrated the occasion by taking a phaeton out of its quarters at about ten minutes to twelve, being duly guarded by a policeman, who exercised solemn care that we did not start a moment before the "grim clutches of the law" were released by statute. Once the clock had really chimed the man in blue had lost his terrors, and with a vigorous cheer from the crowd which had gathered round, we started on our way through the traffic, encountering in our progress the good-humoured chaff and comments of the omnibus and cab drivers, who were conveying belated theatre-goers and diners-out to their homes. About an hour or so of this on a bad November night, with the prospect of a heavy day before us, was enough for amusement, and after comparing notes with a few others who had similarly celebrated the occasion, we gladly adopted Pepys's phrase of "then to bed."

Fig. 13.

Fig. 14.

The early morning—say between eight or nine—might have pleased a Mark Tapley, but with the prospect of a run to Brighton on vehicles which had never before been legally tried in England, the outlook was about as bad as it could well be. A drenching rain had fallen heavily for hours, the roads were soft and muddy, while a mist—heavy enough to be almost described as a London fog—hung about the streets in the vicinity of the river with a chilling depression which might have well checked any enthusiasm on the part of those who might otherwise have been expected to be interested in the new vehicles. The inhabitants of the Metropolis and the surrounding suburbs soon showed, however, that climatic conditions would hardly prove to be any check at all upon their curiosity to see the new carriages, and to celebrate the day on which they might be used in their streets. The procession to Brighton, which had been organised by Mr. H. J. Lawson and his *confreres* of the Motor-Car Club, was in the mouths of the multitude; fabulous sums were on offer for a seat in one of the carriages; crowds of more or less known people vied with each other for the possession of tickets to the Hotel Métropole to view the start in comfort, while outside the great British public took possession of every available inch of Northumberland Avenue, its adjacent streets, and the roomy Thames Embankment.

Writing with an intimate knowledge of the crowds which have been seen in the streets on great occasions, we unhesitatingly assert that never before have so many thousands of people been gathered in a given space as those which congregated in the immediate vicinity of the Hotel Métropole to see the start of the motor-carriages. The throng came at last not in hundreds but thousands, and in the end the streets were absolutely impassable. The first carriages to take up their position in the vicinity of the Whitehall entrance of the hotel arrived at about 9 o'clock, and from thence onward until the start at 10.30, the police force, both on foot and on horseback, waged one continual war with the crowd to get the vehicles into position, and to make such arrangements as would enable them to get a fair chance of starting when the time arrived.

While all this was going on outside of the hotel, the interior presented a very animated appearance as the numerous guests invited to an inaugural breakfast by the Motor-Car Club put in an appearance. In addition to the representatives of most of the important newspapers in the kingdom, and the members of the Club, many notable persons were present at the repast, which was presided over by the Earl of Winchilsea, among his supporters being Lord Fingall, Lord Cardross, Lord Trimlestown, Lord H. Fitzgerald, Col. Sir V. Majendie, Col. Fitzgeorge, Sir J. Ewart, Mr. B. Barnato, Mr. H. J. Lawson, Mr. Jerome K. Jerome, and many others equally well known. Mr. Chas. McRobie Turrell and the Secretary of the Club, Mr. Harrington Moore, were here and everywhere throughout the day, indefatigable in their efforts to ensure the comfort of the guests. The Chairman, in the course of some well-chosen remarks, pleaded for consideration on behalf of the drivers who had undertaken that day to pilot down to Brighton carriages with which they had but little acquaintance under circumstances of unusual difficulty, their task being rendered the harder by the crowds which they would meet, and the weather which was to be faced. To this would have to be added the fact that many of the carriages starting were comparatively old types of Continental makes, which had covered considerable distances and had sustained much wear and hard usage, so that they could not fairly be taken as being at all representative of the motor-carriages which may be reasonably expected to be ultimately produced by the English companies and firms engaged in this industry. The noble Chairman's remarks were well received, and at the conclusion of the breakfast a dramatic "drop curtain" was effected when the Earl of Winchilsea tore into tatters one of the red flags which have hitherto been compulsorily carried in front of traction-engine and motor-bicycle alike, and thus symbolically emphasised the fact that the day of freedom in this matter had at length arrived. All those who were not bound for Reigate and Brighton by train to watch the arrival of the carriages at those places then repaired to the windows of the hotel to witness the start, and amongst the crowd of special sightseers who occupied prominent positions in the principal rooms we noticed the Duke of Teck and the Saxe-Weimar family.

Punctually to time the vehicles were ready to start, the official programme and order being as follows:—

1. Panhard dog phaeton.
2. Mr. Lawson's private landau.
3. Panhard and Levassor, the winning carriage at the "Paris-Marseilles" race.
4. The Hon. Evelyn Ellis's private carriage, Daimler type.
5. Daimler phaeton.
6. Daimler phaeton.
7. Daimler carriage, second in "Paris-Marseilles" race.
8. Panhard and Levassor wagonette.

9 and 10. Daimler dog cart.

11. Panhard and Levassor omnibus.
12. Daimler dog-cart, Mulliner's limited body
13. Daimler's two-seat carriage.
14. Peugeot Frères omnibus.
15. Bersey landau, electrical.
16. Bersey phaeton, electrical.
17. Bersey hansom, electrical.
18. Britannia Victoria, electrical.

19 and 20. Britannia dog-cart, electrical.

21. Britannia Victoria, electrical.
22. Britannia Bath chair, electrical.

23, 24, 25, and 26. Anglo-French phaeton.

27, 28, and 29. Arnold sociable, Bentz motor.

30. Arnold Sunlight Soap van, Bentz motor.
31. Arnold Victoria, Bentz motor.
32. Pennington tandem.
33. Pennington tricycle.
34. Pennington cycle safety.

35, 36, 37, and 38. Bollée motor-cycle, Bollée motor-car.

39. De Dion tricycle.
40. De Dion racing tricycle.
41. Barrie Bersey, private carriage.
42. Lutzmann phaeton.

43 and 44. Duryea carriage, American.

45 and 46. Rüb tricycle.

47. Three-wheel dog-cart, New and Mayne, oil.
48. Hunt's Panhard and Levassor omnibus.
49. Bucknall private carriage.
50. L'Hollier tricycle.
51. Lormont Paris steam bicycle.
52. Lutzmann van, Sunlight Soap.
53. Petter's oil motor-carriage.
54. Messrs. Penn's steam-carriage.

The route taken was by way of the Victoria Embankment, Westminster Bridge, Lambeth Palace Road, Albert Embankment, Harleyford Road, Kennington Oval, Brixton, Streatham, Thornton Heath, Croydon, Purley, Merstham, Reigate, Crawley, Hand Cross, Bolney, Albourne, Pyecombe, Patcham, and Preston Park.

The carriages with their drivers had been in readiness for more than an hour before Mr. H. J. Lawson, as pilot, gave the signal to start; but when progress had to be made then came the troubles of the police. A solid wall of people in front and an all too narrow lane at the sides of the drivers seemed to arrest all attempts to proceed. However, by a judicious admixture of force and persuasion, coupled with the good humour of the crowd, a commencement was at length made, the onlookers being vigorous with their cheers and ready with their comments. The feelings of the "man in the street" towards the newcomer are somewhat difficult to ascertain. We told off one of our representatives to specially advise us on this point, but he failed to give us much help. His testimony was to the effect that the trade unionists had somehow got it into their heads that the whole procession was an organised opposition to the cabdrivers on strike; while the mothers were of opinion that from henceforth the streets would not be safe for women or children; and the City men thought that "no fellow would ride behind a 'bus horse while he could glide along like that." All were unanimous, however, on one point—that the show was the most novel which London has seen for years. Perhaps when our contributor has had time to analyse the result of his investigations, he will see that the public—like all of us—cannot yet attempt to fathom what will be the ultimate result of the new method of transport which has been introduced into our midst.

Coming to the actual start of the procession, such inspection as could be obtained from even the most advantageous stand in the hotel, was an imperfect and obscure one, but it could be seen that in the forefront of the procession was the pilot car, displaying the violet and gold banner of the Motor-Car Club, the President of which, in yachting costume and wearing an armlet of blue and crimson, steered the machine—a dog-cart with a hood—which was propelled by a Panhard motor. Next to it in the order of starting—which, however, was soon disarranged by the vicissitudes of the journey—was the Daimler "Present Times" closed landau—the same which took part in the Lord Mayor's Show. Then came the winner of the Paris-Marseilles race, having two places in front, with a protecting hood, and two places behind, the passengers being seated back to back. Colonel Sir Vivian Majendie was on this car. Next in order was the Daimler private carriage, owned and driven by the Hon. Evelyn Ellis—a vehicle which has already travelled 2,000 miles. It holds four people, dog-cart fashion. All these were provided with petroleum motors. Three tricycles, tandems, constructed on the Bollée system—cumbrous-looking machines, with huge rubber tyres, but having powerful 1¼ horse-power oil-motors — followed, together with a Kane-Pennington bicycle. In their rear was a phaeton giving room for four travellers, who were assured of some protection from inclement weather by a roof and a glass screen. An advertising delivery van (Messrs. Peter Robinson's) preceded another of the yellow-wheeled cars which appeared in the Paris-Marseilles race, in which it actually proved the fastest. Mr. Turrell was in charge, and his sole companion held aloft a red, white, and blue flag, intended to commingle the French and English colours, with a tattered and besmirched red traction-engine flag also attached to the pole. After this, in order of starting, was another of the French automobiles, the winner of the second prize. It was a wagonette, with room for a driver and three passengers, the Earl of Winchilsea taking the box seat. Other vehicles, also driven by Panhard and other motors, built according to patents owned by the British Motor Syndicate, followed, one of them being a neat bus (Harrod's), with accommodation for four inside, and another being the Panhard-Mulliner dog-cart.

It was altogether a matter of hazard on the part of those who started for Brighton by motor-car whether they would ever reach their destination. A Press representative who was fortunate in having the opportunity of travelling by a car which completed the journey satisfactorily supplies the following record of the run:—

Our car was No. 15. It was the one which actually came in first in the Paris-Marseilles race, but was placed second in order of merit. M. Merckel, who steered it on that occasion, and whose portrait appears in Fig. 4 of this number, was our driver, and his coolness and discretion, with daring and nerve at ticklish moments, were much to be admired. Lord Winchilsea sat on the box of this conveyance, which carried four persons in all, two in front and two in wagonette seats, facing each other, behind. The six horse-power motor, built by Panhard, an improved Daimler, was driven by petroleum, and it made 690 revolutions per minute, the gearing permitting four rates of speed—the fastest, I understood, being 25 miles an hour. Reversing gear enabled us to go backwards or forwards at will, and, instead of bands and rubber pulleys, which, if too soft, are liable to lengthen and burn, creating an horrible odour, the power from the motor was transmitted from the shafting by a chain travelling over a cogged wheel attached to the axle. Two brakes were fitted, and the machine was under splendid control, as the incidents of the trip will show.

We had to forge our own way through the huge crowd which filled the Thames Embankment, the temporary stoppage of a parcel van in front of us having led the spectators to close up their ranks, but following in the wake of Mr. Turrell's "flier" —its record speed is 32 miles an hour—we presently crossed Westminster Bridge, cheered by tens of thousands. The pavements, the housetops, the range of hospital buildings belonging to St. Thomas's, the river craft, and every inch of foothold on the ground, or high above it, were black with people. From Vauxhall—where the first car fell out—we steered through the crowd there assembled, and through Kennington to Brixton the concourse of spectators was immense. The red parcel van again indulged in vagaries, but before the police could deal with it as an obstruction it again went merrily onwards. Not so a motor-cycle, whose owner I saw despondently wheeling it back along the edge of the crowd, until, as I afterwards learned, he could find a hansom to carry off the disabled machine. Cabmen were just a little incredulous, and 'bus drivers were sarcastic as to the capabilities of the new machines. "I don't think much on 'em," said one; but the tram drivers—who have been accustomed to the cable trams on Brixton Hill—were more tolerant.

This long but gentle rise, followed by Streatham Hill, attaining to a height of 184 feet, did, indeed, tax the climbing powers of the weaker machines, and, as was subsequently reported, many of them got no further; but given a good car, we soon left the laggards behind. It was at the Crown and Sceptre, where the pilot car took refuge for a while, that we started in good earnest, travelling through thick lanes of men and women and children, pursued by a flight of cyclists, and running side by side with trotting mares in tandem, on one of which was impudently perched a dog, maintaining his equilibrium wonderfully. To this point we had been an hour on the journey for the six miles covered; but in spite of the rising ground, which did not trouble us much, except to put into play the gearing for reduced speed, with increased climbing power, we got to Streatham Library at 11.40, ten minutes after leaving the Crown and Sceptre; and four minutes later we were passing the common, and left behind us the Excelsior coach, which had been obliged to stop to water its horses. But we needed nothing for many a mile yet. Onward we sped, a welcome warmth diffused about our feet, and a trail of steam behind us, which was reminiscent of the atmosphere of "washing-day," but otherwise there was no discomfort due to the vehicle itself. It is true we were bespattered with mud, but this was thrown up from the tyres of some too attentive cyclists who, realising that the car was a good pace-maker, rode closely in our rear, trusting to us for a signal to check a collision, as they were without brakes. Out-distancing an Irish jaunting-car tandem, down we went to Norbury, made light of the ascending road through Thornton Heath, and so on to West Croydon, and into its main street, as the hands of the clock of the Town Hall pointed to the hour of noon—just 10 miles in one hour and a half. The Croydon townspeople to a man had turned out of doors, business came to a standstill, and domestic servants and errand boys rejoiced in a brief respite. Away we went through the High Street of the suburban borough, past the coaching-houses, once the pride of the old town and the hope of the future, now that the glories of the road are to be revived, and so into the open country, with the rice thrown by a well-wisher still in our ears and working down our backs, just as though we were a runaway pair returning from Gretna Green, and were welcomed by friends who had aided in bringing about the elopement.

At Purley Corner, a point from which the bicycle records are made, we began at 12.10 p.m. a run of 10½ miles to Reigate, for the road led us through Redhill. But we had a long climb before us, having to ascend from 220 feet to 434 feet—the highest altitude of the chalk ridge just before reaching Merstham. The fog had now lifted, and the genial weather had tempted carriage folk from miles around to line the roadside, and holiday had been permitted to the boys and girls of the Reedham Orphan Asylum, who gave us a hearty cheer.

Down the hill into Merstham, having caught here and there a view of the special train from Victoria on its way to Reigate, we plunged. For the first time we felt the exhilaration of travelling at 25 miles an hour in a motor-car. Not a thought of danger, not a thought of what might happen if the smaller car in front of us suddenly broke down, and we were unable to avoid a collision; but full of confidence in our driver, down we went, descending over 200 feet in the couple of miles which separates the picturesque village of Merstham—one of the old coaching places of call—from Redhill. This is the modern part of the ancient borough of Reigate, and it owed its creation entirely to the reluctance of the Reigatonians of those days to allow the Brighton Railway to pass through their town—an error of judgment which has ever since been regretted. Into

Redhill, avoiding the shorter route *viâ* Gatton Corner, we go, leaving its Marble Hall and quaint Town Hall—a relic of the days when Gatton was a pocket borough—behind us as in a flash, for it is nine minutes only since we quitted Merstham. At Redhill two roads are open to us, either we may take the "classic" coach road through Horley, Balcombe, and Cuckfield, places whose inns figure so frequently in old prints—or we may diverge through the rapidly extending residential town much patronised by stockbrokers and City magnates, into Reigate. It was at Reigate that luncheon awaited us, and our appetities were sharpened by the fresh air. So thither we proceeded, a little more cautiously, perhaps, as the throngs of bystanders were great. We pulled up in the market-place, close to its quaint isolated Town Hall, at 1 o'clock, having completed the 10½ miles from Purley Corner in 50 minutes, and the whole distance from London, 22½ miles, in two hours and a half, in spite of all obstacles of crowded streets, and unfavourable conditions of the roads.

"Reigate welcomes Progress." Such was the inscription prominent amidst the flags and bunting. The market-place was jammed with vehicles and cyclists. Never in its history, not excepting the memorable occasion when, in 1880, 40 cyclists essayed and 20 only succeeded in ascending Reigate Hill by the help of the stone tram line, has the retired coaching town been so busy. Its hostelries were overflowing, and mine host of the White Hart, what with coach parties to provide for, cyclists and others, was obliged to have recourse to the Public Hall as a supplementary luncheon place, where many of the motor-car visitors, most of whom had arrived by train, could be served with a substantial meal. For us it was a meal taken in a hurry. We were anxious to make the most of the daylight, and we were free to start as soon as ready. During the 50 minutes we stayed in the town there were a few opportunities of comparing notes. We learned that certain Bollée tricycles had gone ahead, and that the first car to enter Reigate 20 minutes before us was the Duryea—an American invention, which explodes the charge in the motors by an electric spark. It had joined the procession on the road. The Duryea pressed onwards, and the first prize winner in the Paris race was the only car visible when we drew up alongside it; but in a few minutes we were joined by the pilot car, driven by Mr. H. J. Lawson, which had waited a little on the road, and at a quarter to two the Paris car, driven by Mr. Turrell, came to hand, with a grievous tale of disaster; for, after water leak had been put right, the gearing went amiss, and the brake broke. What became of this unfortunate car, in the end, I am unable to say. We saw, too, the roofed phaeton come in, and subsequently heard of the parcel vans, after some misadventures, and the Anglo-French conveyance putting in their respective appearances. But time was up, and off we started independently at ten minutes to 2 o'clock for a run of 30 miles to Brighton.

A fairly level road between Reigate and Crawley, passing through Hoothwood and Lowfield Heath, suggested to Lord Winchilsea some timing. Accordingly, he discovered that the first mile was covered in 4½ minutes, the second in 3 minutes 20 seconds, the third in 4½ minutes, the fourth in 4 minutes, the fifth in 4 minutes 40 seconds, and the sixth in 4 minutes. Of a dozen cyclists who had started from Reigate with us quite fresh, eight now remained, and we passed the phaeton which had gone ahead of us. Cottagers waved us welcome as we sped by, and peasants stared at us in amazement. Crawley we found in festive array—with a great banner in blue and white strung across the road, between its open-timbered or tiled-fronted houses, to bid "Success to the Motor-car." The George Hotel, with its curious dragon signboard swinging from a beam athwart the high road, was the centre of local activity. Away we went, over the level crossing, near which a train was kept in waiting, and through the town, the inhabitants giving us a pretty wide berth. They had grown cautious already; for, as we afterwards heard, an accident had, a short time before our arrival, happened. The first car to pass through the old-world town had knocked down a little girl named Dyer, the daughter of a publican at Three Bridges. She had been struck on the head whilst leaning forward, and a cyclist who was following fell on her with his machine. She was removed to the inn, and the latest reports were that she was not injured seriously. Our time to Crawley for the last three miles had been 13½ minutes; and, as one after the other the milestones were passed, we completed 9¾ miles in 45 minutes. It was a delightful piece of woodland road which took us in the direction of Handcross. Brown oak leaves, the ruddy foliage of copper beeches, and the green Scotch pines, made together a picture of late autumnal beauty, but the trees, charming as they were, and the carpet of dead leaves, caused the road to be very damp, and at this period of our journey it took us fully 11½ minutes to complete one mile, and in this the cyclists gained upon us, as they always did when we were laboriously, but steadily, ascending declines.

"This hill is dangerous for cyclists." Whether M. Merckel saw the placard or not, or whether he chose to disregard it, I cannot say; he certainly approached the notorious descent of Handcross Hill with apparent indifference. To rush through the air at the speed of a torpedo-boat destroyer, down a narrow, curving road, enclosed with hedges, and without being able to see what was to the front of us, was a novel and thrilling experience. The gradient is very steep. One minute we were 500 feet above the sea level, and the next 300 feet only. We had accomplished this rapid descent of 200 feet in a few seconds of breathless suspense, when the slightest error of steering would have landed us into one bank or the other, or plunged us into the midst of cyclists who were waiting at the bottom of the hill to see how we should take this admittedly awkward piece of country. We did it magnificently, without a swerve. And all the while our motor was actively impelling us onward, adding to the velocity which had been already imparted to the vehicle by the momentum. It was a grand sensation, and the danger of the feat was not lessened by a rearing horse attached to a cart which we narrowly shaved at the foot of the hill, and which we had calculated would involve us all in utter wreck and discomfiture.

After this incident things appeared somewhat tame, and it scarcely stimulated our pulses to hear that we had covered two miles in five minutes. But the cyclists deserved attention. One by one they had found the pace too killing or had met with mishaps. The gruesome, mud-bespattered group, one or two with blood running from their lips, into which they had pressed their teeth, their haggard faces covered with splashes of clay, held on manfully as long as they could. One man incautiously followed too closely in our rear, and when we suddenly slowed he could not avoid a collision. Frantically he grasped the back of the car, and away he was dragged from the saddle of his machine, whilst his friends cried out, "Let go, let go!" as he was borne off at 10 miles an hour, until, releasing his hold, he fell in the road, picked himself up, rejoined his cycle, and was seen no more. Another tumbled from his machine, and rolled neatly to one side just in time to avoid a second motor-car which was catching us up. A third man held on to our car for miles, but in spite of the lift, and the circumstance that the roads were getting less greasy, owing to the rain, he could not go the pace, and he, too, dropped off—the last of the disheartened men of the wheel who had failed to beat the motor-car. The driving rain tended to make the last stage of the journey one of discomfort. At Bolney (3.6 p.m.) we rejoiced the heart of an ostler by proving to him that our motor could drink up two large pails of water, and a liberal tip was forthcoming for it. At Albourne Green, four miles farther on, happily, we did not need to patronise the facetious blacksmith, who placarded his forge with a notification that motor-cars could be repaired "while you wait." Some other car did, however, break down hereabouts. Having left Bolney at 3.22, we arrived at Piecombe at 3.53, and thence, with a descending gradient, passing on the road foxhounds, coaches, carriages, cyclists, and spectators of all sorts and conditions, who had defied the weather. We ran past Patcham, where another breakdown subsequently happened, and so to Preston Park, where we were welcomed with the flattering inscription: "Centuries look down upon this, your immortal ride." We had allowed Colonel Sir Vivian Majendie's car to get ahead of us, so that on arrival we found ourselves second in the order of the procession which the Mayor of Brighton was waiting to conduct to the Hotel Métropole, so soon as the pilot car should arrive, which it presently did. We pulled up in line at 4.15 p.m., and thus we had been 5 hours 45 minutes on the road, or, less the time spent at Reigate and Bolney, 4 hours 40 minutes for the 50 miles.

It was blowing half a gale and was very wet when, having safely traversed the crowded thoroughfares of Brighton and the Front, we reached the hospitable quarters of the Hotel Métropole, and at this destination other cars arrived one after the other; but it was impossible to tell which had survived the extremely hard test to which the motors had been subjected. Telegrams posted up in the hotel announced to the visitors that 60 vehicles would start from Charing Cross, but "they will not all reach you." And this was true. But the actual number could only be conjectured. A thinning-out process went on all day. At Brixton the numbers declined; at Streatham, 28 had passed at 12.39 p.m.; at Thornton Heath, 26 at 1.45 p.m.; at South End, Croydon, 22 motors were counted by 1.48 p.m.; at Reigate, at 2.2 p.m., 9 cars had arrived; at Crawley the first car passed at 1.20 p.m., and 4 others at 1.30 p.m.; at Hurstpierpoint, on the Cuckfield Road, one car went by at 2.11 p.m. At Brighton, at 6.30 p.m., Mr. Harrington Moore stated that 15 had arrived, and amongst the minor accidents notified was a punctured tyre, which, however, did not prevent the Kane-Pennington bicycle from arriving all right.

The following is the official list of the cars which reached Brighton in the course of the afternoon and evening up to 6 o'clock, when the timekeepers (Messrs. J. Dring and R. Coleman, who officiate for the National Cyclist Union) retired:—

Description of car.	Time of arrival at Brighton. h.	m.	s.
Bollée car	2	30	25
Bollée car	2	45	20
Panhard omnibus	3	46	10
Mr. H. J. Lawson's car	4	52	30
Panhard and Levassor	4	53	15
Britannia bath-chair	4	57	10
Daimler phaeton	4	57	25
Pennington tricycle	5	2	0
Bersey landau	5	4	40
Panhard wagonette	5	7	13
Anglo-French phaeton	5	14	45
Daimler dog-cart	5	27	13
Bersey hansom	5	41	30

Some adverse comments having been made in the Press as to the comparatively small number of motor-cars which arrived at Brighton compared with those which paraded outside the Hotel Métropole, it may be as well to explain that more than half of the owners never intended to go all the way to Brighton, it being arranged that they should simply take part in the inaugural start. The reason for adopting this course was in order that the public safety might be ensured, because with comparatively inexperienced drivers the task of negotiating a new vehicle through the immense crowd which thronged the streets would have been fraught with great danger. The police authorities would not give any facilities for practice before the Act of Parliament actually came into force, as shown by their successful prosecution of one driver who ventured out at 10 o'clock on Friday night and also by their unsuccessful application for a summons against Mr. H. J. Lawson for driving a motor in the Lord Mayor's Show. Then, too, after a few miles had been traversed, the unfavourable state of the roads and weather doubtless deterred many of those who would otherwise have gone the whole of the journey.

With reference to this point the Motor-Car Club yesterday issued an official report on the run from London to Brighton on Saturday. The committee state that it was at first decided that only cars officially tested and passed should enter for the ride, but this was overruled, and an open event decided upon. Instead, therefore, of 20 efficient cars entering as pre-arranged, all kinds of experimental machines took part in the demonstration. The committee go on to explain the manner in which the cars arrived, and state that no accident of any kind happened to those belonging to the club. After the banquet the committee examined 20 cars, and beyond the lower half of each vehicle being smothered with mud, they were in perfect condition, and ready to take the road again immediately. Eighteen of these cars were lent by members of the British Motor Syndicate. The committee award gold medals to the first eight motor-cars which arrived in the town. Considering the head wind, the beating rain, heavy roads, and congested traffic, and considering the fact that 20 motors out of 22 which left Brixton arrived at Brighton during the evening without accident, they add that a feat has been accomplished far exceeding their most sanguine expectations.

DINNER AT THE MÉTROPOLE.

The dinner given in the evening at the Hotel Métropole, Brighton, by Mr. Harry J. Lawson, "in celebration of the passing of the Locomotives on Highways Act, 1896, the Magna Charta of Motor-Cars," took place in the Clarence Rooms, and was a brilliant success. The company numbered some 200. Lord Winchilsea (President of the Club and Chairman of the Great Horseless Carriage Company) presided, having, on his right, Mr. Harry J. Lawson, the genial host of the evening, and on his left the Mayor of Brighton (Alderman J. G. Blaker, J.P.). Those present also included:—

The Marquis of Queensbury, Sir Somers Vine, Sir Joseph Ewart, M.D., J.P., the Mayor of Reigate. Mr. J. T. Allbutt (Humber and Co.), Councillor Broadbridge, Mr. J. Bradford, Mr. J. B. Baxter, Mr. C. N. Baker, M. Bollée (inventor of the Bollée car), Mr. W. C. Bersey (Great Horseless Carriage Company), Mr. J. J. Clark, J.P., Mr. C. W. C. Crandon (Great Horseless Carriage Company), Mrs. Crandon, Mr. Childs, Alderman Davey, J.P., Mr. Devine, Mr. Dalziel, M. Daimler (inventor of the famous motor), Mr. Duncan, Mr. C. McR. Turrell (Deputy Secretary British Motor Syndicate), Mr. H. Fenney, Mr. Roger Fuller, Mr. S. Gorton (New Beeston Cycle Company), Rev. Prebendary Hannah (Vicar of Brighton), Mr. D. Sherwin Holt (Daimler Motor Company), Mr. Rowland Hill (New Beeston Cycle Company), Mr. Innes (Beeston Tyre Company), Dr. Iliffe (New Beeston Cycle Company), Mr. Henry Jelley and Mr. James Jelley (Beeston Tyre Company), Mrs. Harry J. Lawson and the Misses Lawson, Mr. J. H. Mace (Daimler Motor Company), Mr. W. Olliver, Mrs. Olliver, Mr. C. Osborn (Secretary Great Horseless Carriage Company), Mr. W. Phillips (Humber and Co.), Mr. E. F. Pierson (British Motor Syndicate), Alderman Sendall, J.P., Councillor Stafford, J.P., Mr. Frank Shorland (Raleigh Cycle Company), Mr. C. N. Stewart (Great Horseless Carriage Company), Mrs. Stewart, Mr. J. Tonks, and Mr. Van Praagh.

The loyal toast having been honoured, the Mayor of Brighton proposed "The Motor-Car Club," remarking that although, in accordance with the request he had received, his remarks would be few, they would be none the less sincere and cordial. He was sure they would agree with him that that would be a red-letter day in the history of the country, and certainly in the history of the town of Brighton (applause), because they took it as a compliment that on that, the first day on which the Act came in force, the Motor-Car Club should have chosen their town as the one to come down and visit. (Applause.) He had the pleasure of riding down from Preston Park on the foremost car, and he was bound to say it was one of the most pleasant rides he had had in his life. It was true that the elements were not altogether favourable to the ride, but he would venture to call their attention to the fact that it was a big christening, and that they very often found water at these christenings. (Laughter.) As they were aware, the reason that they were that day, for the first time allowed to pass along the Queen's highway, was the removal of a flaw in the law, and it was largely through the influence of the Motor-Car Club that the law had been so altered as to allow the public to make use of this—in his opinion—greatly improved means of locomotion. In honour of the eveut the Brighton and Sussex Goldsmiths' Association had presented him with some of their registered designs, with the arms of Brighton suitably engraved, and he would ask their Chairman whether he would accept, as a small memento of the occasion, one of those medals. (Applause.) It was characteristic of the town that people coming there to live never left the town. By some singular accident twenty years ago Mr. Lawson did leave Brighton, but he had returned to it in his triumphal car, and they might depend upon it that if he weut away it was because he had that car, and could so easily come down again from London to Brighton. (Laughter and applause.) He had great pleasure in submitting to them the toast of "The Motor-Car Club," coupled with the name of Mr. Lawson. (Applause.)

Mr. Harry J. Lawson, in responding, said that remarkable occasion was the first meet of the Motor-Car Club on the great day of the emancipation of his very much-beloved motor; it was the day of the great deliverance of our roads and highways from the reign of quadrupeds and the rule of, well—other animals. (Laughter.) For 16 long years the lovers of science had been waiting for this day with the full knowledge that machinery and science were equal, nay, vastly superior, to any animal power. (Hear, hear.) That day was a victory. (Hear, hear.) He did not know how many there were at the start—but he himself counted 32 cars. At the start the procession was broken in halves by a great rush of people, and he had heard that a part of them never started at all. (Laughter.) It was utterly impossible to get through the people; the enormous crowd was greater than that at the Lord Mayor's Show on the previous Monday. (Hear, hear, and applause.) The 11 cars which were particularly his detachment were his Syndicate's cars, and they were supposed to be the latest improved patterns. (Hear, hear.) He was very pleased to be able to announce to them that every one of those cars was in Brighton that night. (Applause.) With the exception that a bolt fell out of the cylinder of the car on which he rode, involving half an hour's delay, he had had the most pleasant ride the weather would allow. (Laughter.) It was lovely until they got just beyond Crawley, and then it did rain very hard. (Laughter.) He thought the rain was helping them, because had the weather been fine people would have said they would not have brought out their cars had it been heavy weather. In spite of the weather, however, in spite of many inexperienced drivers, and in spite of the very hilly nature of the roads, he had a telegram to say that no fewer than 22 cars had arrived in Brighton—or were still on the road. (Laughter and applause.) The most remarkable performance of the day was undoubtedly that of M. Bollée, the great French inventor, who was there that evening. He left Brixton at half-past 11 and arrived in Brighton at 25 minutes past 2. (Applause.) Mr. Lawson then gave the names of others who were among the earliest to arrive, and said the question was, What did all this mean? It meant that they were able to deliver goods by road from London to Brighton; and they had done so that day. (Applause.) Now they would be able to start a carriers' wagon at 5 in the morning, arrive in Brighton and return again to London by 1 o'clock, and once more return and make a second delivery in Brighton in the afternoon by 5 o'clock, returning to London again by 9 o'clock in the evening. Proceeding, he said he believed the coach which accompanied them that day arranged for five changes of horses to keep up with them. That was 20 horses for the one journey. Of course, there were some trotting mares on the road which simply went by his car, but he pointed out that there was very good reason for not keeping up with them, because the law forbade him to travel more than 12 miles an hour, though trotting horses, cyclists, and butchers' boys might travel at any rate they liked. (Laughter.) He went on to say that that was the inaugural day, the birth, of one of the greatest industries the world had ever seen (hear, hear), because it would branch off in all directions. Their forefathers made great fortunes by the introduction of machinery, and he hoped that men of the present day would do the same. (Hear, hear.) According to the Press of that week, the safety bicycle trade, of which he was, as they knew, the acknowledged founder, had already reached an annual sale of no less than £12,000,000. And if that had been done with regard to cycles, what, indeed, would motors do? He believed that almost every kind of domestic life was going to be affected by it (laughter), and that the value of property and land would also be affected. The Brighton builders gave season tickets to connect their houses with London. They would not do that in the future. They would put up a handsome little coach-house, and put a handsome little motor in it, and by that very motor they would connect it with the town. Land 10 miles outside the town would become almost as valuable, if there were good roads, as land in the interior. Now, that was an enormous item, but it was bound to come; there was nothing to prevent it. He did not believe it would stop even there. He believed the houses themselves would take to moving. (Laughter.) Why should they all stick together in one place? Why should they not be able to say in London, "We have had enough of London; we'll be off to Brighton"—then put a little oil into the motor and away you go! The houses moved in America, and houses were going to move here. They would naturally like to know what kind of system was employed in propelling the cars that day. In nearly every case oil was used, but he pointed out that the benzoline, which was meant by the word "oil," only escaped by half-drips, and that the atmosphere had an important part to play in supplying the motive power. When electricity was used the only trouble was in "charging up," but wherever the electric light was there they could get it charged. They simply had to take out one set of batteries and leave them to be charged while they used another lot already charged. Motor-cars were not fully developed yet. It seemed to him that if oil could give all this immense power at present, it was only for them to wait a few months and Great Britain would produce, he hoped, a car really perfect—that was to say, with much less noise than at present. Numbers of the cars that came that day were English as well as French, German, and American, and every one of them was a little better than the other. They kept on improving. He did not know a single accident that had happened that day—except two. (Laughter.) One of them he saw himself. A horse (it pained him to say) and trap knocked down a cyclist and ran over him. He was sorry to say, also, that he saw a motor-car knock down, he believed it was a child, at Crawley, but he was pleased to say it was not one of their cars. He believed, however, it was not at all the driver's fault, for it seemed the police had just cleared a pathway, and then the child dashed right across in front of the motor. Such an accident would happen to anyone, horse or motor. (Hear, hear.) People who saw his carriage in the Lord Mayor's procession on the previous Monday confidently informed him that it was driven by electricity. One man shouted out to him, "What about the 'osses, sir?" He said, What about them? He saw that the "whip makers of Walsall" had been holding meetings and writing to the papers carefully signing themselves anonymously as "friends of the horse" (laughter and applause)—the poor animal with a "leg at each corner" which stood so much flogging from them. Oh, the irony of it! Friends of the horse! After they had broken his heart, broken his spirit, "broken him in," as they called it, they put a great load behind him, and because he tried to run away from it and run away from them, because he could but drag the load with him in his vain attempts to get free, they said, "Behold the friend of man!" He was afraid if they gave the horse a chance he would not show such friendship. He had a painful recollection of giving a horse a chance in Richmond Park the other day. He suddenly put his steering wheels round where his head was, while he himself went straight on! And when he woke up among the dead leaves he found the "friend of man" had gone home. But not so the motor: like a fair angel of science it now stood holding out to them and to all Britain its dainty levers, saying, "Take me; I am your willing slave. I will work incessantly from early morning till late at night—all night, too, if it is only your will ; and, as your most humble and obedient servant and slave, I will earn the everlasting gratitude of mankind, the triumph of science, and bring wealth and prosperity to the whole nation at large."

Mr. Van Praagh, in proposing "The Industry of Motor-Cars," said the day was not far off when it would be as difficult to think of the world without motor-cars as it was now to think of the world without railways. Only a year ago, when Mr. Lawson told him he was going to buy the Daimler motor, he could scarcely imagine a man speaking in that way, and he ventured to say there were very few in that room who knew a year ago about motor-cars. Mr. Lawson, in forming the British Motor-Car Syndicate, had brought into it three important factors—himself, his money, and his influence. (Applause.) By his influence he brought in some of the most important men who directed the industries of the present day, and the Syndicate set about buying all the patents of any value, making the industry what it should be, to place England side by side with Germany, and France, and America, and other nations of the world. Mr. Lawson was the pioneer of this industry, and by his exertions, directly or indirectly, he had brought about the alteration in the law without which the event of that day could not have occurred. The British Motor-Car Syndicate had now given birth to a great and important Company, the Great Horseless Carriage Company, which would give English engineers and inventors an opportunity of competing with the world in designing and making motor-cars. The Daimler Company had also been formed, and now they were on the eve of a new departure—an electrical cab company for London, which, he understood, would be launched almost at once. In conclusion, he eulogised the services of Lord Winchilsea in connection with the movement, remarking that they might be proud and grateful to have such a leader. (Applause.)

Lord Winchilsea, in responding, said he had been asking himself whether they were that day taking part only in an interesting scientific experiment, or whether they had been founding a great national industry. He was bound to say that that afternoon he had felt they were making an industry very fast, when he found by his watch that they were working on at something like 24 miles an hour. (Laughter.) The impression that they had arrived at a very practical point in this industry was put in his mind as they flew over the intervening 50 miles between London and Brighton. He must say that, bar weather, he had never had a more delightful ride in his life. (Applause.) He was delighted to find there was a complete absence of smell and a complete absence of vibration, and that the carriage was under perfect control, while horses had such little regard for their impending doom that they took no notice whatever of the car as it passed. (Applause.) He was struck with the attitude of the crowds which lined the roads everywhere. It seemed to him that they too felt that something more than an experiment was being carried out, and that a practical step forward had been taken to increase the facilities and enjoyment of their lives. Of course the legal restrictions which only came to an end that day had been a very serious barrier indeed to the prosecution of the motor-car industry in this country—so much so, indeed, that practical engineers had scarcely turned their attention to the subject. At the same time, he believed that when their engineers did turn their attention to the matter England would not long remain behind other nations in this respect. Such companies as the Great Horseless Carriage Company had great responsibilities in placing before the public really serviceable articles, and he hoped the public would be patient with them for a few months while they were perfecting their types, and that when they were placed in the hands of the public a certain amount of responsibility would rest with their owners, and that they would be treated with the forbearance due to an instrument, of whose powers those who used it had an imperfect knowledge. He believed motor-cars would be of the utmost use in collecting and distributing agricultural produce. (Applause.) He had long felt they would be infinitely superior to light railways, and the Chairmen of more than one of the great railways, with whom he had had an opportunity of discussing the matter, shared that opinion ; and looked forward to the time when they could be supplied with motor parcels vans to send out to agricultural districts as feeders of their main lines. He was very glad to think the use of motors would be by no means confined to private individuals. He believed the Government would make large use of them to expedite and improve the parcels post. (Applause.) The industry would give employment to numbers of people, and afford an outlet for a great deal of capital at present locked up. He must point out, on behalf of those responsible for the industry, that the motors already introduced might, even in the opinion of their inventors, be immensely improved, and that probably the motors of a few years hence would be very much more perfect than the motors of to-day ; but with that reservation he was convinced that they had arrived at a period at which these motors were, if not perfect, yet applicable for practical purposes. (Applause.)

Sir Somers Vine, in proposing the next toast, said those who were interested in this motor-car industry should acknowledge the hearty co-operation they had received from the representatives of the local governing authorities. The authorities might well be expected to be among the first to practically apply this industry within their respective areas, and certain it was that in the exercise of their judicial and administrative functions they would have an influence on the industry which might be most conducive to its prosperity. These authorities were represented there that night by the Mayors of Brighton and Reigate, and he asked them to drink to their healths.

The Mayor of Reigate having briefly replied, saying he was extremely pleased with the proceedings and speeches,

Alderman J. G. Blaker (Mayor of Brighton) said he was a little more doubtful than the previous speaker about the proceedings and speeches. He was quite prepared to hear from Mr. Lawson great things, but he was not prepared to hear him say that houses were likely to go about like motors. (Laughter.) If that was the case he was quite sure they would be found to be missing when the collector of rates went round (renewed laughter), and if that were so they would not find such fine roads as they did when they entered Brighton that day, or that electric light which had so brilliantly lighted the thoroughfares. In the name of the Corporation and inhabitants of Brighton he must cordially welcome them to the town. (Applause.)

Alderman Davey then proposed "The Press," saying he was proud of the independence it displayed, and glad that England had a Press second to none in the whole world. The toast having been acknowledged,

Mr. Lawson presented M. Daimler with the handsome silver trophy which was won in the Paris-Marseilles race by Messrs. Panhard and Levassor, who desired that it should be handed to M. Daimler, because he was the inventor who, ten years ago, made the first successful oil motor.

M. Daimler briefly replied, and the company then dispersed.

Yesterday morning, at Brighton, there was a parade of motor-cars. Thirteen vehicles assembled at the Hotel Métropole, including heavy vans, cycles, and phaetons, and went along the front to the eastern boundary and back to the hotel, where the procession dispersed. Subsequently the cars were to be seen in various parts of the town, especially on the King's Road, where great crowds of people had assembled. Numerous photographers were at work, and several cars and groups of cars were taken. With few exceptions the horses at Brighton have shown no alarm at the motor-cars. One horse attached to a private carriage became alarmed when the procession returned to the hotel, and jumped the railings in front of the building. It alighted safely on the pathway, but the shafts were broken, and the vehicle was otherwise damaged. The cars returned to London this (Tuesday) morning, parading at the Hotel Métropole at half-past ten.

Some idea of the large number of persons who witnessed the run to Brighton may be gathered from an experience of our own. We published a cheap souvenir number of The Automotor and Horseless Vehicle Journal, containing a programme, some information, and a few pictures of the carriages. The issue was, perhaps, one of the largest ever made by a technical or trade journal; but it was exhausted in the London streets in less than one hour; while from the orders which rained in from the agents at least another 25,000 could have been absorbed in the metropolis alone—to say nothing of the principal towns on the line of route, Brighton alone asking for a further supply of 5,000.

With the object of inspecting the carriages which the British Motor-Car Company (Limited) and Mr. H. J. Lawson intended to send on the journey to Brighton, we recently visited the exhibit at Wembley Park. Armed with a permit signed by Mr. Chas. McRobie Turrell, Mr. Lawson's able private secretary, we examined the remarkably interesting collection of motor-vehicles which has been collected there. They show at a glance the progress which has been made on the Continent in the manufacture of these carriages; and one is enabled to trace almost instantly the evolution of the automotor of to-day—from the original Daimler motor, constructed some 12 or 15 years ago, to the actual winners of the Paris-Marseilles race—purchased by the English Company and then finding a resting place at Wembley pending the tour to Brighton. In Mr. J. Thompson Smith the Company has an able and obliging representative, who kindly placed the whole of his exhibit at our disposal, and enabled us to test the smooth working and excellence of the motors of the various manufacturers which are represented. Perhaps one of the most interesting items of a long series of trials was a run on the Panhard et Levassor carriage, which took the second prize in the Paris-Marseilles contest, with the driver "up" who successfully steered it throughout the 10 days of the French run.

What skill and an amplitude of brake-power can accomplish when accompanied with pluck was well shown by him. Driving his carriage at a rate of more than 23 miles an hour down a hill, he steered it round ponds and obstructions with an ease which rendered one oblivious of the danger which would otherwise have been too apparent. The certainty with which this master of the new art could manipulate his mechanism was shown by the fact that, running at full speed down hill, he could stop at a signal within five yards of operating the brakes. All who wish to see what can be done now, and who would desire to form an opinion of the future possibilities of motor-carriages should visit Wembley and see the most concrete exhibition of varied applications of motive power to road vehicles which at the moment of writing can be found in the country.

We photographed some of the most interesting exhibits; all, with the exception of the first, being among those which took part in the procession to Brighton. They are reproduced on pages 64, 65, and 66, and the following particulars briefly describes them; but we shall doubtless deal with some of them more fully in an early issue, when we have more space at our disposal:—

Fig. 1.—The original Daimler motor, constructed by M. Daimler, and in connection with which all his original experiments were made. It is of historical interest, and its owner would not allow it to be sent to this country until a bond of something like £1,000 had been entered into to secure it safe return. The material used throughout is of the crudest description, the seat being a piece of sheet iron bent over. It is well worthy of inspection by all interested in automotor work.

Fig. 2.—Daimler quadricycle, a much more recent machine, but still an intermediate vehicle in the stage of development.

Figs. 3, 4, and 5.—These represent the three winning Panhard et Levassor carriages in the Paris-Marseilles contest. In Fig. 4, the driver photographed is the same who was in charge of the vehicle throughout the French race.

Fig. 6.—The Dion tricycle, which has hitherto proved the most successful oil-motor for light work on the Continent. Its splendid racing performances were set out in our last issue.

Fig. 7.—Daimler *vis à-vis;* about three and a half horse-power, with four speeds of four, seven, 11, and 14 miles an hour.

Fig. 8.—Daimler omnibus, with six places; five I.H.P., reversible at all four speeds to which it is geared; the maximum rate of progress being 16 miles an hour.

Fig. 9.—Roger Victoria; about three and a half I.H.P., with two speeds and two independent brakes; maximum speed 10 miles per hour.

Fig. 10.—Serpollet steam carriage, with six seats; fitted with two independent brakes; speed about eight miles per hour.

Fig. 11.—Bath chair, electrically propelled on the Britannia Company's principle.

Fig. 12.—Daimler phaeton; reversible on all speeds—of which there are four up to 18 miles; I.H.P., about four.

Fig. 13.—Daimler omnibus; four places; for railway station work.

Fig. 14.—Daimler Victoria (French type); reversible; four speeds, maximum 16 miles per hour; about three I.H.P.*

FRENCH CONTESTS FOR 1897.

The directors of the Automobile Club have decided to institute a series of trials for heavy vehicles to be held early next year. These trials will last about ten days, and will be divided into three classes of vehicles with fifteen and thirty seats and goods delivery vans. The programme of these trials will be published in about a fortnight's time. The directors have also made arrangements for the apprenticeship of auto-car repairers, who will be trained in the factories of the principal makers, and thus be fully qualified and competent to carry out in different parts of the country any repairs required by the auto-car owner.

Journalism on the Rampage.—The *Evening Standard*, in its desire to be picturesque, is becoming inaccurate. In the course of a description of the Lord Mayor's Show it stated, with reference to the motor-carriage which took part, that "the stench of the petroleum it emitted was strong enough to excite a good deal of hostile comment along the whole line of route. If this is the case with an ordinary carriage of the brougham class, what is to be expected now that omnibuses, cabs, wagons, and carts are all to be driven by machinery? Cologne, one of the foulest-smelling towns in Europe, will be as Arabi the blest by the side of London. It is to be hoped that someone will invent a respirator for the nose and mouth, containing a drug to neutralise the odour of petroleum." We have never contended that perfection has been reached in our infant *protégé*, but a description such as this could only have been written by a student of romance, or by a correspondent who, not being present, took the "Show" for granted.

* The photographs for these illustrations and of the other carriages appearing in this paper, which took part in the Brighton trip, were specially taken for the Automotor and Horseless Vehicle Journal by Mr. H. W. H. Palmer, Springvale, St. Germain's Road, Forest Hill, S.E.

ANSWERS TO CORRESPONDENTS.

W. H. ANDREWS (Colchester).—An engraving, showing the details of the motor in question, has been prepared and will appear in an early issue, probably the next. We are utterly unable to advise you as to "exact results on a prolonged run"; you had better apply to the inventor for permission to make a trial.

K. C. CARMICHAEL (Leith).—Your better course is to consult a reliable patent agent; in our own opinion, the combination specifically as claimed would be good subject-matter, but any re-shuffling of the parts would put you out of court.

NEMO.—Write to Chapman and Hall's for a copy of their catalogue; if they have nothing to exactly suit you, Spon's may supply you with an American work.

G. MOORE (Newcastle-on-Tyne).—We have already arranged; but thank you, and shall always be pleased to obtain particulars of the forthcoming novelties which you mention.

G. S. (Liverpool).—A gradient of one in ten can easily be surmounted by a Levassor carriage. For particulars as to prices in England, write the Great Horseless Carriage Company (Limited), 40, Holborn Viaduct, London, E.C.

EDWARD C. (Southport).—Whether you hold your shares or sell them must depend to a large extent upon your financial position. If you can afford to lock them up and wait, keep them, but if you want money sell them, they are unquestionably speculative.

F. C. WHITTON (Essex).—We do not care to give you the information for which you ask. We can supply you with a list of the directors of the companies you mention, but it would not be fair to furnish the names of their confidential *employés*. If you wish to apply for a situation do so in the usual manner.

G. F. (Maidstone).—Emphatically no; we have not any axe of our own to grind.

ECCLES (Maida Vale).—Write to Mr. Andrew Bait, at 32, Moorgate Street. He will send you full particulars of the objects of the Self-Propelled Traffic Association.

A. VESEY.—Communicate directly with MM. Panhard et Levassor, 19, Avenue d'Ivry, Paris, or to the British Motor Company (Limited), and they will give you particulars of some vehicles which will meet your requirements.

G. EDWARDS (Brixton).—Your better plan would be to finish the experimental motor before advertising for a partner, as you state that you have the means to enable you to do that. You will then get far better terms—if your expectations as to the results are realised. We return your drawing; the weak point is that you have not adequately provided for compression.

NOVICE (Manchester).—You may take it as positively certain that the cylinder of an engine of that power would have to be water-jacketted for any lengthened run.

NOVELTY (Bristol).—An ether engine is very alluring, but you under-estimate the practical difficulties.

INFORMATION WANTED.—Read our description in this issue, and then pay a visit to Wembley Park.

WE have just received from Messrs. Whittaker and Co. two works on motor-carriages, viz., "Carriages Without Horses Shall Go," ably written by Mr. A. R. Sennett and splendidly illustrated. It is published at 2*s*., and is wonderfully cheap. The other book is "Autocars," a translation from the French of M. D. Farman. As these have come to hand on the eve of publication, we hold over detailed notices till next issue.

LAW REPORTS.

Alleged Infringement of a Patent.

THE patent action Magee *v.* Tangyes (Limited), was decided in the Scotch Court of Sessions on the 4th instant. The plaintiff appeared in person; the defendants were represented by Mr. Ure and Mr. Wilson, who were instructed by Messrs. Davidson and Syme.

After hearing evidence, Lord Pearson disposed of a note of suspension and interdict presented by John Magee, engineer, 36, Pembroke Street, Glasgow, against Tangyes (Limited), hydraulic and general engineers, Cornwall Works, Birmingham, and carrying on business there and at 96 and 98, Hope Street, Glasgow. The complainer averred that he was the true and first inventor of improvements in gas motor engines, patented by him in 1892, which were of great commercial value, and that the respondents in the course of their business had infringed his patent by manufacturing and selling gas motor engines embodying a material part of his invention. He applied for interdict against the infringement. The respondents pleaded that they had not infringed the letters patent founded on, or otherwise that the letters patent were invalid on several technical grounds, and also for the reason that the complainer was not the true and first inventor; or that the invention was not new at the date of the patent; that the alleged invention did not constitute proper subject-matter as a ground of letters patent, and that the invention was not useful.

Lord Pearson decided that the respondents had not infringed the complainer's patent, and that the patent was invalid. He therefore refused the note, with expenses.

A Motor-Car Purchase.

IN the Court of Queen's Bench, on Monday, the case of Koosen *v.* Rose was heard.

In this Mr. John Adolphus Koosen, a gentleman residing at Southsea, sued Mr. S. Rose, a bicycle manufacturer, carrying on business at Southsea, to recover £150, the price of a motor-car. Defendant denied liability.

Mr. Wheeler, Q.C., and Mr. W. H. Nash appeared for the plaintiff, while Mr. Willis, Q.C., represented the defendant.

It appeared that last summer plaintiff was the owner of a Lutzmann patent motor-car, constructed to carry two, which had been exhibited both at the Imperial Institute and the Hurlingham Show. In August plaintiff and defendant met, and plaintiff said that, after having had a trial of the car on Southsea Common, the defendant, on August 22nd, agreed to purchase it for £150—£100 down and £50 in three months. A receipt was drawn up and signed, but plaintiff said it was not handed over, as defendant had not a cheque for £100 with him. The defendant took the car to the carnival which was held later in the day on Southsea Common, and on the following Monday he refused to pay any portion of the purchase-money or to take the car, which had been placed in the plaintiff's stable after the carnival. Plaintiff further said that the car was capable of going up gradients.

The defendant contended that the contract to purchase was conditional on the car working satisfactorily during the carnival, and that as the car broke down he was under no obligation to complete the purchase.

Mr. Justice Wright, at the conclusion of the evidence, said that plaintiff's story as to the sale was borne out by the receipt which had been put in, and on which the defendant made an endorsement. He therefore gave judgment for the plaintiff for the amount claimed.

AN important patent action is in progress in the Chancery Division of the High Court, before Mr. Justice Romer, viz., the Pneumatic Tyre Company (Limited) *v.* the East London Rubber Company, Limited. A talented array of counsel is engaged on both sides, and the decision on the alleged infringement will be awaited with great interest. As only the pleadings have been opened, we withhold a report until our next issue. The next case in the list before the same Judge is the Pneumatic Tyre Company (Limited) *v.* Friswell.

MESSRS. NEW & MAYNE (LIMITED).

A COLLECTION of interesting objects was recently collected at the Royal Aquarium under the title of the Craftsmen's and Industrial Exhibition. There was little to specially interest our readers, with the exception of the stand of Messrs. New and Mayne, of Palace Chambers, Westminster. This enterprising firm, besides a varied collection of electric-light fittings and sundries, showed a Woolf-Muller bicycle operated by a petroleum motor, the oil used being a safe form of benzoline. Although there are many points in connection with this machine which need perfecting—indeed, we believe that a new type will be shortly placed on the market—it is an interesting object. At the meeting of the Manchester Wheelers it is credited with a run at the rate of 30 miles in an hour, and it has covered a mile at Catford in $2\frac{1}{5}$ minutes. It has been run comfortably from Woking to Devizes, and was frequently seen in various parts of Surrey until the police interfered. Another object which is well worth inspection is the well-known New-Mayne patent electric rudder-motor. To those who are in search of an ingenious and efficient power for the propulsion of small motor boats, we can cordially recommend this as worthy of investigation and trial. We herewith illustrate an automotor laundry van just completed by Messrs. New and Mayne. This vehicle took part in the tour to Brighton on Saturday last.

HA hirdetök irják kérunk a "THE AUTOMOTOR AND HORSELESS VEHICLE JOURNAL" gondolni.

ACETYLENE MOTOR-CARS.—The *Journal of Gas Lighting* states that a firm of Italian engineers has recently built some miniature motor-cars for which acetylene serves as the motive power. The charge consists of acetylene diluted with 15 times its volume of air; and with this mixture it has been found unnecessary to use water for cooling the cylinder. The method of igniting the charge has not been divulged. According to the "Gastechniker," the motors maintain a speed of 600 revolutions throughout a working period of 15 hours. The weight is only about 20 lbs.; and 0·8 brake horse-power is developed. The cost of working is said to be about 0·6*d.* per hour.

MOTOR-CAR CONTESTS IN AMERICA.

IN our last issue we gave brief particulars of the results of the horseless-carriage races held at the Rhode Island State Fair. Now that our American exchanges are to hand we are able to give fuller particulars, and the *Horseless Age* supplies us with the following particulars:—

Out of the twelve original entries only eight started. These were the Duryea Motor-Wagon Company, J. Frank Duryea, George Henry Hewitt, Fiske Warren, George H. Morrill, jun., William M. Ashley and Son, Riker Electric Motor Company, and the Electric Carriage and Wagon Company. The last two were electric vehicles, the first being an entirely new one and the second the "Electrobat," which received the gold medal at Chicago last autumn. All the remaining wagons were of the Duryea model, one being entered by the Duryea Company and the rest by private purchasers.

On Monday, September 7th, about 5.30 p.m., the carriages were called upon the track, and numbers were assigned to them, as is customary in horse racing.

Each carriage being required to carry a weight of at least 165 pounds in addition to the driver, all preferred to take this in the form of an extra passenger, who was either an *employé*, or friend of the owner, or some well-known student of the subject.

All the contestants were sent back some distance behind the post for the start, and came up in good order. At the word the electric-carriages shot ahead, followed by the entry of the Duryea Motor-Wagon Company. The other Duryea wagons were road-wagons not geared for high speed, and they fell back from the start. Throughout the five miles dash the electric-carriages gradually increased their lead, finishing close together, the Riker carriage first.

The first Duryea wagon was about three-quarters of a mile behind the winners.

A very strong wind was blowing, and the track, while fast for horses, was too rough and lumpy in parts for motor-carriages. The time of the four leading vehicles for the first heat was as follows:—

Riker Electric Motor Company	15 m. 1 s.
Electric Carriage and Wagon Company	15 m. 14 s.
Duryea Motor Wagon Company	18 m. 47 s.
William Ashley and Son	20 m. 59 s.

As this was the first heat ever run on a track between motor-vehicles, it is reasonable to suppose that the contestants felt new and strange, and could not do themselves full justice. On the second day, however, they gained courage, and determined to improve on the time of the previous day.

At the word the Riker vehicle took the lead, as on the first day, maintaining it to the finish, closely followed by the Duryea wagon and the wagon of the Electric Carriage and Wagon Company.

This heat was closely contested by the three leaders, and evoked great enthusiasm from the spectators. The time was a considerable improvement over that of the preceding day.

Riker Electric Motor Company	13 m. 6 s.
Duryea Motor Wagon Company	13 m. 13 s.
Electric Carriage and Wagon Company	14 m. 33 s.
William Ashley and Son	16 m. 31 s.

On Wednesday and Thursday a violent north-easterly storm prevailed throughout that section of New England. Rain fell in torrents, and the wind played havoc with the shows and with the plans of the management, and, therefore, all races were declared off on these two days.

On Friday the weather cleared, and by the afternoon the track was in good condition.

The electric carriages dashed off at a two-minute pace, closely followed by the Duryea wagon. A little beyond the half-mile the Duryea wagon was pulling up with the two electrics when a tyre punctured, and the wagon gradually lost headway. The Riker carriage maintained its lead until the home stretch was reached, when the other electric spurted ahead and crossed the line a second ahead of its rival. Much better time was made by all the entries in the third heat, scarcely one falling below the 15 miles an hour limit. The times of the four winners were as follows:—

Electric Carriage and Wagon Company	11 m. 27 s.
Riker Electric Motor Company	11 m. 28 s.
Duryea Motor Wagon Company	11 m. 59 s.
William Ashley and Son	15 m. 47 s.

The race was conducted by the Association under the general rules applied to trotting races, and the awards were made upon this basis. The conditions called for a 20-mile race of five heats of five miles each, one on each of the five successive days of the fair, but as unfavourable weather prevented the completion of more than three heats, three-fifths of the purse only was divided in the following proportions:—First money, to the Riker Electric Motor Company, of Brooklyn, N.Y., 900 dollars; second, to the Electric Carriage and Wagon Company, Philadelphia, Pa., 450 dollars; third, to the Duryea Motor-Wagon Company, 270 dollars; fourth, to William Ashley and Son, Springfield, Mass., 180 dollars.

Public interest in the motor races in Providence and vicinity was very keen, and quite a number of students of the new method of locomotion came from distant points to witness the trial of speed.

The electric carriages weighed from 2,200 to 2,500 lbs. in racing trim, including passengers, the heavier of the two being that of the Electric Carriage and Wagon Company. The leading Duryea wagon weighed about 1,200 lbs. all on.

The fastest mile was covered by the Riker electric carriage, the time being 2 minutes 13 seconds.

It was quite generally commented on by the audience that the electric vehicles made as much or more noise than the gasoline at high speed.

Professor W. H. Pickering, of Harvard University, acted as Chairman of the Board of Judges.

From the Chairman of the Judges.

Cambridge, Mass.,
September 20th, 1896.

Now that the Providence races are over, and we have had an opportunity to examine and weigh the results, I think we must conclude that some very valuable information has been obtained. Unlike the Chicago and New York competitions, this was a speed contest pure and simple. Only eight vehicles were entered for competition, and, therefore, according to the published rules governing the races, no other points were considered by the judges. The comparison between the electric and gasoline carriages was particularly interesting, and the results were quite different from those obtained at Chicago. No electric carriages were entered in the New York contest. While at Chicago the electric carriages were badly beaten, at Providence both of those entered came out with flying colours, distinctly in advance of the best gasoline engine.

The reasons for this difference are obvious. In Chicago the race lasted several hours, and the course lay over a rough and very difficult track. In Providence, on the other hand, the race lasted but a few minutes, and the course lay over a hard and perfectly level road. Both vehicles, doubtless, have been much improved since the Chicago race; but were it to be tried over again to-morrow, we cannot doubt that the result would be the same.

QUIPS AND CRANKS.

Not a Novelty.—"A fine idea these new horseless carriages are, and what a novelty!"

"Novelty? Not a bit of it. I travelled in one more than thirty years ago, when I was a little child."

"Nonsense! Where?"

"At Margate. It was in a railway train."

The *Westminster* cartoon for the month of October, by Mr. E. Blomfield, quaintly represents some woe-begotten quadrupeds looking over a fence at automotors and motor-driven bicycles careering gaily by. Above their heads is a board with the inscription:—"Horses for sale, very cheap; no reserve. Reduction made if bought by the dozen. Premises to be used for motor-car sheds." The prophetic newspaper quotation at the foot of the picture is as under:—"[The establishment of so many autocar and motor-car companies in Victoria Street is causing grave concern to the equine interest, who foresee with sorrow that their services may soon be at a discount.—*Vide* Daily Press.]."

The *Entr'acte* expects that the motor-carriage will bring about the destruction of a good number of old horses, in which case we may expect to find some of our beef-essences quoted at lower prices than those which now obtain.

Our contemporary *Answers* recently published an amusing article on the future of horseless carriages, the illustrations accompanying it showing a run with the hounds on a motor "bike"; a cricket match, England *v.* Australia, played on wheels; the Derby of 1906, ridden on wooden horses propelled by motors; a convenient suburban residence being removed on wheels by a tractor to the seaside; and an excited crowd at the Zoo inspecting a "very rare animal"—the horse—described as the "Equs Cabullus; born in the menagerie."

The motor is not to have it all its own way. Someone in Perthshire is advertising for a "steady, respectable man as Postboy."

Our contemporary the *Referee* recently celebrated its thousandth number by a special and exceedingly interesting issue. "Dagonet," in the course of an amusing attempt to forecast the contents of the two thousandth number, gives the following as an extract from it:—"The Zoological Society have been fortunate in securing a splendid specimen of that now almost extinct animal, the horse. It will no doubt be an object of great interest to the thousands of young people who have heard their parents speak of this once-popular beast of burden, but have never seen one themselves." *Verb. sap.*

The *Daily Mail* celebrated the 14th inst. with a humorous forecast of the automotor carriage in 1921. One picture, representing the petroleum-driven sportsmen of the future stalking wild horses, was very funny.

A Cycle, Tyre, and Motor-Car Exhibition is to be held in the Royal Dublin Society's premises at Ballsbridge, Dublin, from the 16th to the 23rd of January, 1897. Applications for space should be made to Mr. R. Wilson, 14, D'Olier-street, Dublin.

TRADE NOVELTIES.

A New Solid Rubber Tyre.

Messrs. J. W. and T. Connolly and Co., of Wharfdale Road, King's Cross, London, are the introducers of the "Ideal" tyre, which, although comparatively new in this country, is a tried and proved success in the United States. It comes from the land of its origin with unquestionable evidence in its favour, as most of the leading carriage-makers have sent testimonials in its favour—until they bulk up into a very considerable volume. Many of those who have fitted it to all descriptions of vehicles state that they prefer it to all other makes, and in proof of their faith in it have discarded other tyres which they had previously used, and rely entirely on this one. We have had an opportunity recently of testing this tyre, and we are of opinion that it is exceedingly well suited to automotor carriage work of all kinds, and will be extensively employed in this industry. The details of the construction of the tyre and the means of securing it will be readily seen from the following illustrations:—

Amongst the many advantages which are justly claimed for it we think the most important may be briefly summarised as follows:—From the method in which the tyre is fastened on to the rim by two heavy endless wires it is a mechanical impossibility for the tyre to roll out of its rim, while the rim cannot cut or injure the rubber. Here we may incidentally mention the fact that the material used in making the tyre is of the best quality, and is quite equal to that used by our own leading manufacturers. In consequence of the method of making, and the high-class character of the rubber, it is found possible to highly compress the rubber in placing it upon the wheel, so that, should the tyre be cut or damaged by contact with sharp stones, bottle glass, or any undesirable obstacles of that kind, it will rapidly close up, and no distinguishable injury is sustained. As a consequence the wheel rims look fresh and well, even after a considerable amount of hard wear. Those in search of a reliable tyre for all kinds of work, which will stand all sorts of usages and still ride smoothly, should communicate with Messrs. Connolly, who have already introduced it largely into the metropolis. It is claimed that the amount of rubber used in one of their 1½-inch sections is greater than that contained in an English section of 1¾-inch. The broad fact that in America there are more than 10,000 sets of wheels running with these tyres without any complaint will doubtless be the most effective testimonial in its favour.

The Britannia Company's Motor.

Experiments have been in progress for some months past at the Britannia Company's works in Colchester, with a view to the perfection of an engine and auto-car to meet the requirements of the Act. The engine is very small and light for its power.

The motor and carriage are not yet quite completed, but we trust in an early issue to publish a sectional detail and the result of an experimental ride on the vehicle. In the meantime we publish an external view of the motor, which is to be called the "Facile."

The advantages claimed by the manufacturers are the following:—

1. Great simplicity.
2. Automatic ignition after a few minutes of preliminary heating.
3. No heating tube is required, hence the burstings and renewals are avoided.
4. A battery is not used.
5. An impulse takes place every revolution.

We look forward with interest to a test of this motor and carriage.

Gearing for Motor-Cars.

A patent has been taken out by Mr. Nightingale, of Chester, for an improved gearing for bicycles and motor-carriages. The chain is so constructed that it runs on a drum between discs on studs, pins, or rollers, which are said to "give it tremendous gripping power, and at the same time reduces friction to a minimum." The gearing can be changed at will for one of greater or smaller diameter, to suit the rider's choice, thus adapting the machine for hill-climbing. The advantages claimed by the patentee are that it is impossible for the chain to kink or slip. The chain differs in design from any other, and although each section is made of solid steel of great strength, it is lighter than those in ordinary use, its weight being only ¾ lb. The sections are so formed that it can be worked over a much smaller driving-wheel than those at present in use for high gears. On account of the chain running between discs there will be no necessity for a gear-case, and there is no danger of the clothing getting entangled in the gearing, as only a smooth surface is presented, the conical portion of the groove facing downwards. This gearing will, it is stated, be exhibited at the Stanley Show.

IT has occurred to a lady resident in the outer London suburbs to patent a detachable motor, which shall be alike available for a family carriage, a farm wagon, a common cart, a plough, a thrashing machine, or a chaff-cutter. She has given her motor the figure of a horse, on which the driver may or may not sit, on the assumption that the real live horse already in possession may not take with kindly sympathy to its rival.

"THE coming of the motor-car," writes a correspondent in the *Illustrated and Dramatic News*, "seems to me to be a certainty as far as parcel traffic is concerned. The wear and tear of London van horses has immensely increased of late. In the large establishments the average working life of a horse is but three years, although each pair-horse van has two pairs, and each single one two. I am sure that for the quick-trotting vanner the demand will be much less in the future, and I strongly advise breeders and farmers to turn their attention from these to other sources of profit."

THE BERSEY CARRIAGE.

THE electrical carriage which is here illustrated is operated on the Bersey system, and the rights in it are held by the Universal Electric Carriage Syndicate (Limited), 39, Victoria Street, Westminster.

The accumulators are of special patented design and suited to the variations of discharge which are at times necessary. Instead of using an ordinary fluid electrolyte, a special "afnidic" or "dry" material is used, thus practically converting the cell into a dry battery. The many advantages of this are obvious, among others being the impossibility of spilling, splashing, and spraying of acid in the carriage. The strength is regulated by a single driving switch, giving any degree of speed required and also causing the vehicle to run either forward or backward. Re-charging can be readily effected, as the accumulators are carried in a tray, which slides into a well in the vehicle. A fresh set can be substituted for a discharged one in two minutes.

These carriages are lighted by electric lamps, supplied from the same accumulators working the vehicle.

An average run for a carriage is about 35 miles at about eight miles per hour without taking in a fresh supply of storage batteries.

Two motors are used in each vehicle, connected through a special two-speed gear to each of the carriage wheels. The speeds may be readily altered by the driver. The whole of the motors and gear and also the carriage wheels are run on special ball bearings. The steering is very easy, and can be readily acquired with a very small amount of practice.

MR. ANDREW W. BARR.

IN our last issue we published a photograph of Sir David Salomons, the President of the Self-Propelled Traffic Association, and in this, which is published a few days after the legalisation of such vehicles on our roads, it is, we think, appropriate to select Mr. Andrew Barr as the subject for our portrait gallery. As Secretary of the Association of which Sir David is the President, Mr. Barr has many qualifications in his favour. He is young, energetic, and clever, but besides all these attributes, invaluable as they are in themselves, as Secretary of the Institute of British Carriage Manufacturers and a member of the Coachmakers' Company it was a happy idea to ally him with the automotor vehicle. He has formed the connecting link between the old order of things and the new, and his unique position has enabled him to assist in bringing together the somewhat antagonistic elements which are comprised in the coachbuilders of to-day and the engineers who are hopeful of displacing the horse by steam, gas, or electrical power equivalents. The importance of combination in this matter can scarcely be overestimated—the coachmaker is as essential to the evolution of the horseless vehicle of the streets as the engineer, and without the hearty co-operation of the two the ideal vehicle which we all hope to see—and to own—will be almost an impossibility.

The constitution of the Self-Propelled Traffic Association has assisted materially in the getting together of an able and independent council. When a body of men of high standing are combined to obtain the repeal of an obnoxious law, without any ulterior objects in view, success can hardly fail to attend their efforts; and the ltimate result of the labours and advice of the President of this Association, and of its Council and Secretary, is to be found in the Locomotives on Highways Act, 1896, and the Local Government Board regulations, which we publish in another column. The aim of this public-spirited body has been not the aggrandisement of a few, but the welfare of the many, and as a natural consequence their representations have been treated with deserved respect by the great public departments and by the Minister in charge of the Government measure of last Session.

Like Sir David, Mr. Barr is by no means an enemy of the horse. In response to an interviewer he gave vent to the following views:—

"With regard to the equine world it will mean the survival of the fittest. We shall have good horses. The lame, the halt, the blind, and the 'roaring,' will go to the knacker's. There will be no use for the five-pound-ten 'work-him-till-he-drops-down-dead' animal which some omnibus and cab proprietors are in the habit of sending out to be 'used up' after dark. Our eyes will no longer be greeted with the spectacle of curious people crowding round the corpse of a horse which is awaiting the van that is to take it to the tan-yard. Horses will still be ridden and driven for pleasure, but for commercial purposes they will be almost universally discarded, so soon as the self-propelling cart is a recognised boon to every tradesman."

"Who will be the first to adopt the horseless carriage, do you think?"—"The omnibus companies, without a doubt. Why? Why, because they will save what they now spend on the up-keep of their horses—that is to say, they will save on each pair of horses from a pound to twenty-five shillings a week, and as each 'bus requires about five teams, the saving in horseflesh, stabling, and stablemen's wages will be very considerable. As far back as 1834 an omnibus used to run from Paddington to Regent's Park and the City, carrying 14 passengers at 6*d.* per head. It is certainly strange that 60 years have been allowed to pass by without an attempt being made in London to organise self-propelling vehicles of the same kind."

"I suppose there wouldn't be so many 'blocks' in the traffic if horses were dispensed with?"—"Well, there would be far more room, and, as the traffic would be less congested, self-propelling vehicles would widen the streets without making any charge for it. Another important advantage would be the diminution of the wear and tear which the streets suffer from the horses' hoofs. There would be a lot more room, you see, considerably less noise, a great saving in road-mending, and not half so much work for the hospitals in the shape of street accidents."

"But I suppose these self-propelled vehicles would occasionally cannon into one another?"—"Accidents of that sort would be very few and far between. A self-propelled carriage can be manœuvred as easily as a tricycle. Besides, there would be no loss of life occasioned by runaway horses."

"Can't the autocar run away?"—"No, nor blow up. The autocar, you must understand, is in very much the same stage now as the steam-engine was in 1820. But invention is encouraged in these days as much as it was stifled in those; so that directly the 'driving' of a self-propelled carriage in the streets is made legal, the manufacture of the New Vehicle will spring up all over the country."

With this slight statement of his opinions on automotors in general we must leave Mr. Andrew Barr for the present, with the addition of an opinion of our own, that he is distinctly the right man to hold a none too easy post, viz., that of smoothing the difficulties in the way of the transition of the carriages of to-day into the automotors of the future.

NEW INVENTIONS.

Compiled for "THE AUTOMOTOR AND HORSELESS VEHICLE JOURNAL" by HERBERT HADDAN and Co., Registered Patent Agents, of 18, Buckingham Street, Strand, W.C., London.

Patents Applied For.

20,951. September 22nd, 1896. W. S. ROSS and W. ALEXANDER. Improvements in driving gear for auto-cars and other vehicles and navigable vessels.

21,101. September 23rd, 1896. W. LOWE and G. R. WILFORD. Improvements in velocipedes, motor-cycles, motor-cars, and the like.

21,114. September 23rd, 1896. W. H. DEAVILLE. Improvements in motor wagons and vehicles for common roads.

21,122. September 23rd, 1896. E. A. ASHCROFT. Improvements in the propulsion of bicycles, tricycles, motor carriages, and like vehicles.

21,136. September 24th, 1896. F. LISTER. Improved oil or gas engine applicable for use in the propulsion of vehicles.

21,264. September 25th, 1896. F. C. BLAKE. Pneumatic spring or vibration insulator for motor-cars or other vehicles.

21,274. September 25th, 1896. W. J. MUNDEN. Improvements in motor vehicles.

21,307. September 25th, 1896. W. J. PERRETT. Improvements in motor-cars. (L. Lockert, France.)

21,330. September 26th, 1896. A. BAGSHAW and J. T. B. BENNETT. Improvements in driving chains for use in bicycles, tricycles, velocipedes, motor-cars, carriages, vehicles, and other such purposes.

21,429. September 28th, 1896. W. WOOLF. Improvements in driving chain for bicycles, tricycles, and other velocipedes and horseless carriages.

21,558. September 29th, 1896. E. THOMSON. Improvements in and connected with gearing for motor-cars and such like.

21,675. September 30th, 1896. C. M. JOHNSON. Improvements in and connected with motor carriages.

21,697. September 30th, 1896. F. W. LANCHESTER. Improvements in power-propelled vehicles.

21,731. October 1st, 1896. W. RICHARDSON, A. RICHARDSON, and S. GREEN. Improvements in velocipedes, bicycles, tricycles, motor-cars, and other road wheel machines.

21,743. October 1st, 1896. C. MARTEL. Improvements in the construction of hydro-carburetted air engines, and in their application to tram and other road carriages. (Date applied for May 5th, 1896.)

21,772. October 1st, 1896. F. W. LANCHESTER. Improvements in power-propelled vehicles.

21,802. October 2nd, 1896. S. GORTON, W. TAYLOR, and THE NEW BEESTON CYCLE CO., LTD. Improvements in or relating to velocipedes, auto-cars, and the like.

21,821. October 2nd, 1896. A. PFLUEGER. A new or improved alarm signal device for use on tramcars, motor-cars, and like vehicles.

21,968. October 3rd, 1896. C. A. BOUNEVIALLE. Improvements in driving gear for cycles, motor-cars, and similar vehicles.

22,085. October 6th, 1896. A. BLECHYNDEN. Improvements in self-propelled vehicles.

22,090. October 6th, 1896. D. CUTLER. Improvements in driving mechanism for cycles, common road vehicles, and machines generally.

22,144. October 6th, 1896. THE BRITISH THOMSON-HOUSTON CO., LTD. Improvements in electric or other motor-trucks. (N. C. Bassett.)

22,261. October 8th, 1896. L. B. TRISTRAM. Protector from motor-vehicles.

22,286. October 8th, 1896. W. H. WAUD. Improvements in gas or vaporised-oil driven locomotives or cars.

22,412. October 9th, 1896. F. F. WELLINGTON, E. P. ALLAM, and H. W. W. DRUMMONDS. Improvements in or connected with reversing gear for motor-driven vehicles.

22,453. October 10th, 1896. W. A. MARTIN. Improved driving gear for motor road cars.

22,609. October 12th, 1896. A. J. BOULT. Improvements in or relating to driving and guiding mechanism for self-propelled and similar vehicles. (G. Lacoste and H. O. Duncan.)

22,637. October 13th, 1896. G. PRIESTLY. Improvements in cycles, motor-carriages, and vehicles of a similar character.

22,668. October 13th, 1896. C. BURGESS. New or improved chain speed gear for motor-vehicles.

22,738. October 13th, 1896. THE STEAM CARRIAGE AND WAGON CO., LTD., and J. E. THORNYCROFT. Improvements in motor-propelled vehicles.

22,979. October 14th, 1896. L. GUNN. An automatic signalling appliance for motors, auto-cars, and ordinary carriages.

22,871. October 15th, 1896. W. SIMPSON, W. L. BODMAN, and D. H. SIMPSON. Improvements in the construction of steam generators for motor-vehicles.

22,915. October 15th, 1896. T. COULTHARD, jun. Improvements connected with the driving gear of auto-cars or mechanically-propelled vehicles.

22,922. October 15th, 1896. W. T. BURBEY and H. A. HUTTON. Improvements in and connected with motor-cars.

23,066. October 16th, 1896. R. J. WILKINSON. Improvements in brakes for cycles, carriages, motor-cars, and other road vehicles.

23,174. October 19th, 1896. E. T. WAINWRIGHT. Improvements in or relating to the construction of carriages (road vehicles), horse or horseless.

23,265. October 20th, 1896. J. M. COLLINS. Improvements in the driving mechanism of velocipedes and motor-cars.

23,337. October 21st, 1896. R. H. SMITH. Oscillant driving wheels for motor-carriages.

23,386. October 21st, 1896. G. MABBUTT and B. G. PRICE. Improvements in bicycles, tricycles, and other velocipedes, and in motor-cycles.

23,424. October 22nd, 1896. J. GRAHAM, Balbride, Carlogie Road, Carnoustie. An improvement in the apparatus for steering of vehicles, motor-cars, and the like.

23,604. October 23rd, 1896. J. ROOTS and C. E. VENABLES. Improvements in or connected with oil motors for vehicles, cycles, boats, and the like.

23,615. October 23rd, 1896. M. ARCHER. Improvements in auto-cars and like vehicles.

23,802. October 26th, 1896. J. O. O'BRIEN. Improvements in auto-cars. (L. M. D. Triouleyre.)

23,825. October 26th, 1896. H. BELCHER and A. H. NIBLETT. Improvements in or relating to motor-vehicles.

23,992. October 28th, 1896. R. A. MARPLES. A new system of electrical propulsion for cycles, and common road and other vehicles.

24,058. October 28th, 1896. R. A. MARSH. Improvements in gas and oil motors, especially applicable to motors intended for the propulsion of vehicles.

24,085 October 29th, 1896. W. ANGUS, and D. LEWARS. Improvements in the method of attaching motors to road carriages, vans, and other vehicles.

24,154. October 29th, 1896. A. ROUBLEFF. Improved means for preventing or reducing vibrations and shocks in motor-cars, cycles, and other vehicles.

24,280. October 31st, 1896. F. R. SIMMS. Roller springs for motor-cars and other vehicles.

24,306. October 31st, 1896. T. MCCARTER and T. COOPER. Improvements in fluid pressure motors.

24,338. October 31st, 1896. H. H. MULLINER. Improvements in motor-carriages.

Specifications Published.

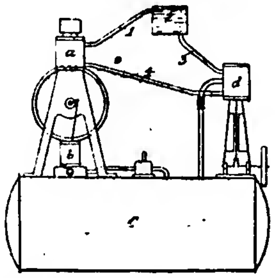
16,068. August 27th, 1895. Propulsion of road or other vehicles. MICHAEL HOLROYD SMITH, 161, Trinity Road, Upper Tooting, Surrey, Engineer.

According to this invention it is proposed to employ a small explosive engine such as indicated at *a*, which drives directly or otherwise an air-pump or compressor such as *b*, which serves to charge a receiver *c*, which supplies the compressed air to a small air-engine *d* running at a high velocity, and communicating its power to the shaft it is required to drive or to the axle or wheels of the vehicle either directly or by means of worm or other gearing.

In order to secure lightness, which is especially desirable in the case where the above arrangement is employed to operate a motor-car, the air receiver *c* may be made to serve as the foundation or bed plate for the explosive and air engines, and the oil-tank may be placed either below the receiver or in any convenient part of the vehicle, the stopping, starting, and speed of the air-engine *d* being controlled by valves and operating handles placed so as to be easily operated.

When compressed air escapes from the exhaust-pipe of an air-engine intense cold is usually produced, which may cause the outlets to become choked, and it is therefore proposed to employ an arrangement such as that shown, in which the the water in the jacket round the explosive engine cylinder *a* circulates by means of a pipe 1, tank 2, and pipe 3, round the exhaust port and cylinder, if desired, of the air-engine *d*, and thus imparts the heat the water has derived from contact with the explosive cylinder, to the ports, &c., of the air-engine, the water, which has then fallen considerably in temperature, being returned by pipe 4 to the cylinder *a*, which it thus tends to keep cool.

A valve arrangement for supplying the compressed air to the explosive cylinder for producing the compression charge (and thus saving the engine the work of compressing on its return stroke) is used, in which a piston-valve reciprocated by some moving part, and having a regulated stroke, works in a casing, preferably cylindrical, situated beneath or near to the cylinder *a*.



When an explosive engine operating in the ordinary manner is running and charging the receiver *c*, the pressure of air in the receiver may be made to operate a valve controlling the engine, and the arrangement may be used alone or in conjunction with a centrifugal governor.

As the duty of the explosive engine is to keep the receiver charged, thus maintaining a pressure and volume of air to work the air-engine, it follows that if the air-engine is doing light work the pressure in the receiver will rise and the load upon the gas-engine increase, and, unless some provision were made, the receiver would burst or the gas-engine be pulled up, and therefore it is proposed to employ a relief arrangement which may be a separate valve, or made in conjunction with the valves of the air compressor *b*, in which the inlet valve of the air-pump chamber is controlled by a diaphragm in a passage leading from the exit valve to the receiver.

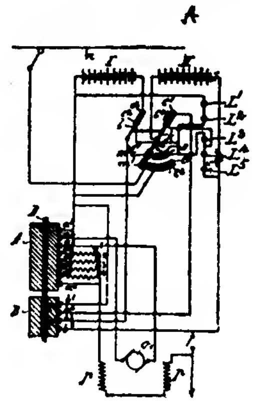
The axle is driven by means of worm gearing contained in a casing, the receiver *c* being then arranged in the form of tubular chambers placed above and below the main axle, so that a low centre of gravity is obtained, or said receiver may be in the form of a coil or in other suitable forms.

11,552. May 27th, 1896. Means for switching current, applicable for electric motor-cars operated by a mixed supply. CLEMENS ADAM, 7, Tulpenstrasse, Hanover, Germany.

This invention relates to a switch device for those electric motor-cars wherein the current is supplied in sections from the outside and from an accumulator battery carried on the cars.

The present invention affords an extremely simple method or means of switching current, by means of which both useless consumption of energy and interruptions in the working caused by seizing wrong handles, short circuiting, and the like are avoided.

The improved method of switching is based on the use of two switch drums coupled in a peculiar manner, one of which operates the switching on or off of the current during the starting or stopping of the car, the other the switching on of the batteries in parallel and in series, whilst a main switch assumes various fixed positions in order to allow of current being sent simultaneously either into the motor and the batteries, or into the batteries alone, or from the outside conductor to the motor, or finally from the batteries to the motor.



In the drawing, the three switching devices are indicated by the letters A, B, and C. The two switch drums A and B are arranged on a common spindle D with which the drum A may revolve whilst the drum B is revoluble independently on said spindle.

Both drums are also connected in a peculiar manner, as will be more particularly described hereinafter.

The main switch C, which is independent of the spindle D, comprises two switch arms *k* and *l* connected by a link and contacts c^1, c^2, c^7, c^8, also an arm *m* attached to the arm *k* with contacts m^1 and m^2 and concentrically arranged contacts c^3, c^4, c^5, c^6. The arrangement is so coutrived that the main switch can assume three different positions. In the position shown in the figure, the switch arm *k* rests on the contact c^1 and the switch arm *l* on c^2. The contacts c^1, c^7, and c^2, c^8 are simultaneously interconnected, whilst contacts c^3, c^4, c^5, c^6 are out of contact with the contacts m^1, m^2.

The connections of the separate contacts and brushes with the halves of the battery I and II with the outside conductor *n*, with the two drums A and B, the armature *o*, the field coils *p*, and resistances R^1, R^2, R^3, R^4, and with the lamps L^1, L^2, L^3 L^4, and L^5 are shown in the drawing and can easily be understood.

Printed Copies of the above Specifications Published may be obtained by forwarding 1s. for cost of each copy and postage to Messrs. Herbert Haddan and Co. Applications not yet Published.

MOTOR-CAR PASSENGER INSURANCE.—A new departure in accident insurance has been made by the *Whitehall Review* in conjunction with the Ocean Insurance Company. Our contemporary has signalised the inception of the motor-car era by insuring its readers for £1,000 in case of fatal accidents.

The SUBSCRIPTION LIST OPENED MONDAY, November 16, 1896, and will CLOSE on or before WEDNESDAY, November 18, at twelve noon, for Town and Country.

This Company will work under a sole license from the British Motor Syndicate, Limited, and will at once contract with the Great Horseless Carriage Company, Limited, for the manufacture of electric cabs, which will be let out to ply for hire in the public streets.

THE

LONDON ELECTRICAL CAB COMPANY, LIMITED.

SHARE CAPITAL - - £150,000.

DIVIDED INTO 150,000 SHARES OF £1 EACH.

Payable—5*s.* on application, 5*s.* on allotment, and the balance of 10*s.* two months after allotment. Of this issue £100,000 in cash or shares is for working capital.

DIRECTORS.

H. R. PATERSON, Director of Carter, Paterson, and Co., Limited, Carriers.
The Hon. REGINALD BROUGHAM, Director of the London Electric Supply Corporation, Limited.
H. H. MULLINER, Director of the Coupé and Dunlop Brougham Company, Limited, and Chairman of Mulliners, Limited.
The Hon. EVELYN ELLIS, Director of the Great Horseless Carriage Company, Limited.
J. H. MACE, Director of the Daimler Motor Company, Limited, and of the Northampton Street Tramways Company.

CONSULTING ENGINEERS.

KINCAID, WALLER, and MANVILLE, 29, Great George-street, Westminster, S.W.

SOLICITORS.

ASHURST, MORRIS, CRISP, and CO., 17, Throgmorton-avenue, E.C.

BANKERS.

LONDON AND MIDLAND BANK, LIMITED, 52, Cornhill, E.C., and all Branches.

BROKERS.

G. H. and A. M. JAY, 17, Old Broad-street, and Stock Exchange, London, E.C.

AUDITORS.

MONKHOUSE, STONEHAM, and CO., 28 and 29, St. Swithin's-lane, E.C.

SECRETARY AND REGISTERED OFFICES.

MAURICE JENKS, A.C.A., 6, Old Jewry, E.C.

PROSPECTUS.

This Company has been formed to place on the streets of London electrically-propelled cabs (British Motor Syndicate Patents), to supersede the present hansoms and four-wheeled cabs.

There can be little doubt that electricity is about to become the motive power for cab traffic in London, and the Act of Parliament passed last session (coming into operation on the 14th instant) opens up great financial opportunities in this direction.

The British Motor Syndicate, Limited, by far the most important corporation dealing with this industry, claiming to possess all the patents of value in connection with motor-carriages, will grant to this Company a sole license to work within the metropolitan area under such of their patents as this Company will require, at a royalty of £4 per cab per annum.

The Great Horseless Carriage Company, Limited, concur in the license, and will enter into a contract to manufacture the cabs for this Company as and when required.

Whilst petroleum may become the motive power in country districts, and steam will probably be used for very heavy vehicles, there is no doubt that electricity will be the most advantageous where the traffic can be located within a radius. There is no smell, no noise, no heat, no vibration, no possible danger, and it has been found that vehicles built on this Company's system do not frighten passing horses.

Electrical cabs have great advantages over those at present in use. They are far more under control than horse-driven vehicles; they can be driven at any speed; and no accidents can arise from horses falling, shying, bolting, or moving when the vehicle is entered, &c.

The drivers require no knowledge of electricity—in fact, the present cabmen will doubtless become the drivers.

FORM OF CAB.

The cabs (the construction of which has been provisionally protected) will fulfil all the requirements of the new Act, and of the police regulations.

They have been most carefully studied, and they will possess many more luxuries than those now in use, such as arrangements for opening windows and doors; electric light inside and in the outside lamps; rubber tyres, improved upholstering, spring cushions, and other advantages.

The necessity for keeping them up to a high standard of excellence has also been realised, and a larger amount than is usual has been provided in the estimates for this purpose.

METHOD OF WORKING.

The cabs will ply for hire in London in the same manner as the present hansoms, and at the same rates.

Two sets of accumulators will be suplied to every cab, each set capable of propelling the vehicle forty miles with one charging. These accumulators can be changed in a few minutes. The same cab can thus be used continuously day and night.

It is intended to open depôts in different parts of London, so that the driver will be able to change accumulators without always having to return to his own station.

The electric supply companies have shown great willingness to co-operate with this scheme, as their current can be taken when not required for lighting purposes. The London Electric Supply Corporation, Limited, are prepared to make special arrangements for supplying the electricity at a very low price.

THE ELECTRICAL SYSTEM TO BE USED.

The system under which this Company will work is that of Mr. W. C. Bersey, A.I.E.E., who has agreed to act as electrical manager, and who has devoted the last eight years to the subject of electrical motor-carriages, one of his carriages having already run several hundred miles.

Mr. W. C. Bersey has been able, owing to his large experience in building electrical motor-carriages, to obtain several valuable patents in connection with their construction. The sole right to manufacture under these patents for the Company's purposes is included in the license from the British Motor Syndicate, Limited.

The electricity is carried in cells placed underneath the vehicle. These are of special patented design and suited to the variations of discharge, which are at times necessary, and are regulated by a single driving switch, giving the degrees of speed, and enabling the vehicle to run either backward or forward as required.

In order to thoroughly satisfy themselves respecting the electrical system under which the Company propose to work, the whole scheme has been submitted to Messrs. Kincaid, Waller, and Manville, the leading experts in this country in connection with electrical traction, whose opinion is as follows:—

EXPERT'S OPINION.

"29, Great George-street, Westminster, S.W.;
"November 12, 1896.

"The Directors of The London Electrical Cab Co. (Limited).

"Gentlemen,—We have examined the electric motor-vehicles built on your system, and carefully considered their suitability for use as hackney carriages in London, and we are of opinion that they are thoroughly adapted to meet these requirements, being practically noiseless and vibrationless, and easy of control, also extremely economical in maintenance, as the following estimates we have prepared will show:—

COST OF EACH VEHICLE.

Each cab, including painting, upholstering, electric lights, door-opening apparatus, wheels with rubber tyres, brake, steering apparatus, together with motor and gearing, switches, and resistance, fixed complete..	£150 0 0
Two complete sets of accumulators, each capable of propelling the vehicle 40 miles without recharging, at £50 each	100 0 0
Total capital cost ..	£250 0 0

COST OF MAINTENANCE PER ANNUM.

"We have estimated the cost of working, maintenance, or depreciation on the following liberal basis:—

Repairing, painting, depreciation, &c., per cab per annum	£42 0 0
Maintenance of two accumulators, including all risks (other than street accidents), at 10 per cent. per annum of costs, as quoted by manufacturers	10 0 0
	£52 0 0

TOTAL COST PER DAY.

Maintenance as above, at £52 per annum, equals per day	£0 2 10½
Electrical energy amply sufficient to run a cab 50 miles—22 B.O.T. units, at 1½*d*., equals per day	2 9
	£0 5 7½

"The contract which the accumulator makers are prepared to make is an excellent safeguard of your interests on the only point that might be open to question, *i.e.*, the maintenance of accumulators.

"From our experience as engineers to many of the electrical tramway campanies, we see no reason why electric traction for hackney carriages should not supersede horse traction.

"Yours faithfully,
(Signed) "KINCAID, WALLER, and MANVILLE."

FINANCIAL ESTIMATE.

The present reduced price paid by the cabmen for hire of a hansom, with use of two horses (under the Asquith award), averages 12*s*. 2¼*d*. per day, and assuming that this Company charges the same (though it is fair to suppose that they will be in a position to charge more) there will be 6*s*. 7*d*. per cab per day available as profit.

This is equivalent, on a basis of only 320 cabs (which, at £250 each, as above, would cost £80,000) to an annual profit of £38,446 13*s*. 4*d*.

From this would have to be deducted the sum of £1,280 to cover the royalty of £4 per cab, and the usual administration expenses, including rent, rates, taxes, and management charges.

As there are over ten thousand licensed hansom and four-wheeled cabs in London, the scope for profit to be made by this Company is very great.

Should further capital be required at a future date for the construction of more cabs, it is intended to make an issue of Preference shares at a fixed rate of interest only, or Debentures secured upon the Company's stock of vehicles, thereby increasing the profit divisible on the present issue of shares.

PURCHASE OF LICENSE, CONTRACTS, &c.

This Company will acquire for the price of 50,000 shares, or cash in lieu thereof, on the terms of the contract hereinafter mentioned, the license herein referred to from the British Motor Syndicate, Limited, subject also to the payment of a royalty of £4 per cab per annum. The said price has been fixed by The Traffic Syndicate, Limited (in which the last three-named directors of this Company are interested), who are the vendors to this Company, and will pay all expenses of and incidental to the promotion of this Company and issuing of this prospectus, excepting the cost of stamp duty on registration and the legal expenses of this Company's solicitors. The following contracts have been entered into (1) dated the 12th day of November, 1896, and made between The Traffic Syndicate, Limited, of the one part, and this Company, of the other part, whereby for the consideration above mentioned, and subject to the provisions of such contract, The Traffic Syndicate, Limited, agree to procure for this Company the license and agreements above referred to: and (2) dated the 12th day of November, 1896, and made between the Great Horseless Carriage Company, Limited, of the one part, and this Company of the other part.

Applications for shares should be made on the form accompanying the prospectus, and forwarded, with the amount due on application, to the Company's bankers. If the number of shares allotted is less than that applied for, the surplus application money will be credited to the amount due on allotment, and any balance will be returned to the applicant.

Copies of the above-mentioned contracts, and of the memorandum and articles of association of the Company, with the original report, can be seen at the offices of the solicitors for the Company.

Prospectuses and forms of application may be obtained from the registered offices of the Company.

London, November 12th, 1896.

LONDON ELECTRICAL CAB COMPANY, LIMITED.

APPLICATION FORM FOR SHARES.

To the Directors of the London Electrical Cab Company, Limited.

Gentlemen,—Having paid to your bankers the sum of £.........., being a deposit of 5*s*. per share on an application for .... shares of £1 each in the above-named Company, I request you to allot me that number of shares, and I agree to accept the same or any smaller number that may be allotted to me, subject to the memorandum and articles of association, and upon the terms of the prospectus dated the 12th day of November, 1896, which I have read; and I authorise you to place my name on the register of members in respect of the shares so allotted me, and I agree to pay the further instalments upon such allotted shares when the same becomes due.

Name (in full) ....

Address ....

Description ....

Date .... 1896.

All cheques to be made payable to the bankers.

THIS FORM MAY BE CUT OUT AND USED.

THIS

is the "FACILE" Petroleum Oil Motor, which requires

No spirit or dangerous essence.
No heating tube.
No constant-burning lamp.
No battery.

All of these are causes of trouble.

SOLE MAKERS:

BRITANNIA CO.,
Colchester.

"FACILE"
CARRIAGE MOTOR.

No connection with other firms advertising under similar name.

CHADWICK AND SONS,

AUCTIONEERS, LAND AND ESTATE AGENTS, AND SURVEYORS.

84 & 85, ST. MARTIN'S LANE, CHARING CROSS, W.C.

ESTABLISHED OVER 100 YEARS.

Auction Sales of Freehold and Leasehold Properties periodically, including Plant and Machinery, Steam and Marine Engines and Boilers, Automotors, Marine and River Launches and Yachts, Bicycles, Agricultural Implements, Pictures, Works of Art, Furniture, Jewellery, &c.
Surveys and Valuations for Partnerships, Company Promoters, Probate and Administration, Land and Agricultural and Trade Valuers.
Civil and Ecclesiastical Dilapidations Surveyed and Assessed.
Advances also made to any amount on Property intended for Sale.
Estate Development and Sanitation a Speciality.

SITUATIONS WANTED.

GENTLEMAN (33), having considerable practical experience of oil motors, desires engagement as representative, manager, or any position of responsibility; highest references. Address, "Motor," care of Messrs. King and Co., Limited, 62, St. Martin's-lane, W.C.

AS DRIVER.—Capable of taking charge of dynamos, motors, and electric fitting, &c.; age 20. H. Millman, 9, Leslie-street, Barnsbury.

AS DRIVER.—Can take charge of cars, &c.; fitter and erector; age 36. W. Robinson, 11, H Block, Peabody-buildings, Bedfordbury, W.C.

AS DRIVER or CONDUCTOR.—Capable of taking charge of cars, &c.; age 21. G. Snell, 11, Rodney-place, Islington.

COMPETENT DRIVER.—Knows London well; age 45. A. Fox, 2, Lyall-place, Eaton-place, S.W.

AS DRIVER.—Electrician and mechanic; thoroughly experienced. Walter Woods, 23, Grove-place, Ealing, W.

AS DRIVER or CONDUCTOR.—Capable of taking charge of motor. F. Lancaster, 12, Hall-street, City-road.

AS DRIVER.—Engineer and fitter; thoroughly capable; age 32. G. Rowell, 54, Lydford-road, Paddington.

AS DRIVER or CONDUCTOR.—Licensed bus driver; good references. F. F. J. Piper, 9, Upper-mall, Hammersmith.

ASSISTANT DRIVER.—Cycle engineer; good references; age 19. William Hedrick, 8, Westmoreland-row, City-road.

AS DRIVER or CONDUCTOR.—Experienced; good references; age 46. Chas. Little, 362, Lillie-road, Fulham.

RECENT DEVELOPMENTS IN MECHANICAL ROAD CARRIAGES.

THE following paper was read before the Society of Arts,* on Wednesday, the 25th ultimo, by Mr. Worby Beaumont, M.I.C.E. Sir Frederick Bramwell occupied the chair, and there was a full attendance.

Mr. WORBY BEAUMONT said:—Since I last had the honour of addressing you on this subject in December last year, the most important development has been that of public opinion, which has forced upon the Legislature the necessity for the removal of the restrictions which until now have effectually prevented the development of road traction, and of carriage by mechanical means on the common roads of the United Kingdom. British engineers were fined for running a motor tricycle for experimental purposes on our roads at a speed of more than two miles per hour unless preceded by a man on foot to clear its way, until the 14th of November, 1896, the day on which the Locomotives or Highways Act of 1896 came into force. The long existing and extremely absurd restrictions against travelling over the country by mechanical means must ever be regretted, not simply because of the deprivation of those who would have reaped the benefit of mechanical transport for trading purposes, but because of the prohibition of all experimental running, which prevented British engineers from developing the steam or other road carriages, the construction of which might by this time have formed a greater industry than it has already done in the hands of our unrestricted competitors abroad. The result is that everything towards the construction of light motor vehicles has now to be commenced, while for a foreign trade other countries are now two years ahead of us.

All this is to be regretted, but it is past, and there now only remains a few restrictions which the lapse of a very few years will probably see removed from the Local Government Board list of regulations. These regulations have, in general, the assent of the motor carriage building and using public, but there are some which are of the nature of dictates to mechanical engineers, who, on such structural detail as reversing gear, brakes, and wheels, should be left to provide that which they, by past or coming experience, know or will find is best.

A year ago the modern mechanical road carriage, as distinguished from the steam boiler and engine vehicles, with a few seats attached, made in England between 1858 and 1876, was almost entirely the French and German ordinary carriage driven by a Daimler or a Benz petroleum spirit motor. Several of these were, in their more developed forms, the product of the incentive in the form of prizes offered by the French *Petit Journal*. For those prizes, it will be remembered, these vehicles ran from Paris to Bordeaux and back, several of the carriages doing some remarkably creditable running. The most striking feature of the results of those trials was the defeat of the steam vehicles by those driven by petroleum spirit motors, although in previous shorter races the steam vehicles had given much promise. The speaker then proceeded to give a detailed description of the French and American contests, which has already appeared in our columns.

Turning now to the lessons of the Paris-Marseilles race, Mr. Beaumont said: It will first be noticed that no steam vehicles were present; all these long distance runs were made by benzoline-motors. The well-known Serpollet carriages were not even entered, although they had done so well in the *Petit Journal* competition in 1894 and 1895, and attracted much attention, when shown in the Hurlingham grounds and in the recent Crystal Palace exhibition.

* This paper—together with the illustrations—is reproduced by permission of the Society of Arts and of the author, Mr. W. Worby Beaumont, M.I.C.E.

In these competitions there were other steam carriages by Scotte, and by De Dion and Bouton. In 1894 the second prize was awarded to the latter firm for their steam tractor or steam bogie, and the third prize was awarded to M. le Blant for a steam carriage for nine persons, fitted with a Serpollet boiler. It is thus evident that that the Continental motor-carriage builders with their now very extensive experience in this matter, have found the construction of a steam motor-carriage a much more difficult problem than the construction of one operated by benzoline or petroleum spirit. One of the first difficulties is the much greater weight of the steam carriage, almost all of which is due to the weight of the boiler and its connections, and also to the weight of the supply of fuel and water required for a journey of any distance. The steam motor itself may be very light indeed and yet sufficient for the purpose. The Serpollet instantaneous generation boiler seemed at one time to be likely to meet the requirements of this essential part of the equipment of a steam motor-carriage, and but for the weight of it and its case, and the coke fuel, there is no doubt it would, and it seems probable even yet that with certain modifications it may provide all that is required. The boiler, as is well known, is built of tubes having exceedingly small water capacity as compared with their thickness and weight, as is shown by the view on the screen.

Now, in connection with the use of steam under the circumstances of very variable demand, as in the case of the motor-carriage, there is no doubt very distinct advantage accruing from the use of heavy thick tubes carried within a refractory case and heated by a powerful coke fire, because the mass of heated material constitutes a very effective heat accumulator capable of instantaneous conversion on demand. The frequent stoppages, the easy work on level roads, the complete absence of work in going down hill, all are conditions which make a heat accumulator steam generator with small water capacity desirable, and especially as such a generator will respond to the sudden call for a quantity of steam for starting or for climbing short hills largely in excess of its mean capacity. But there is nothing mysterious about the capacity or performance of such a boiler, and it has to be remembered that the steam required for mounting a long hill gives the measure of the boiler capacity required. When the accumulated heat in the mass of material forming the tubes has been used up during the mounting of a hill, then the Serpollet boiler, like any other, depends upon the quantity of its heating surface and upon the amount of fuel which can be effectively burned in heating it or, in other words, upon the grate surface and draught or fuel burning capacity. It is from this cause that the Serpollet as made in 1894 and 1895 was heavy for ordinary easy road travelling though very efficient for the purpose when it was made with sufficient surface for long hill climbs. More than a year ago M. Serpollet ceased for a time to give his attention to his steam-carriage so as to enable him to develope the application of his system to mechanically propelled tramcars, with which he has attained considerable success.

Whilst he has been so engaged very little progress has been made in France with steam for road traction. His old vehicle was not suited to everyday use. It could only carry a supply of coke for a run of from 40 to 50 kiloms., or from about 25 to 30 miles. It attained high speeds on level roads or easy gradients, was handy to drive, and economical, but it was cumbrous and heavy, and coke was not a pleasant fuel to use. The steam tricycle constructed in 1889 also used coke. The generator weighed 350 kilos. with the fuel.

The vehicle more lately constructed runs on three wheels, the rear wheels serving for propulsion, and the front bicycle wheel for steering. The generator is placed at the back of the carriage, and the two-cylinder motor, inclined at 90°, is under the seat, bolted to the steel tube underframe which curves up in front for the steering head. The crank-shaft carries a pinion which gears into a large wheel on the driving axle, so that the usual intermediate gearing is dispensed with. For fuel, petroleum is now used, a Longuemare burner being employed. The ordinary lamp petroleum is admitted at the bottom of the burner, and is forced up through a spiral tube, where it volatilises under the heat of the flame, and descending to the bottom of the burner, passes through a form of metallic filter to relieve it of impurities. It then enters a chamber, from which it passes through small holes into a second chamber containing eight jets, through which it issues as petroleum vapour and burns with an intense flame, spreading out to cover the whole area of the funnel formed by the spiral tubes and space above it containing the Serpollet steam generator. The burner is started in the ordinary way with a little methylated spirit, and in from eight to twelve minutes the machinery is said to be ready for starting.

The new three-wheeled carriage is merely an experimental one. It was not intended to do any serious work, and yet it has already, it is stated, run more than 1,000 kiloms. They say that they can run at higher speeds than have yet been attained. They can run easily at 35 kiloms. an hour, and even in going up the Surenes Hill, which is particularly long and steep, they can go at 25 kiloms. Everything is tested in France by speed of travelling. The speed can, with steam, of course be regulated with precision, and with the power this carriage appears to have there is no necessity for mechanism for changing speed. The speed mentioned is, however, unnecessary, and its possibility shows that the boiler and engine are larger than necessary. In the experimental vehicle a reserve of 22 litres of petroleum and 50 litres of water can be carried. With this supply of petroleum the carriage has run from Paris to Rouen —about 140 kiloms., or 88 miles—without replenishing the oil. The time occupied in covering the distance was, the author is informed, six hours. The weight of the carriage without load is 700 to 800 kilos., or from 7 to 8½ cwt.

M. Serpollet is building a new carriage with four wheels, in which he will make certain modifications. The steam generator, instead of having circular spiral vapourising tubes, will have them arranged in a square placed one above the other, so as to obtain a larger heating surface. It will also be fitted with a condenser underneath the carriage. With this he intends to condense the steam in the winter, and return it to the boiler, so as to suppress the exhaust, and make renewal of the water supply less frequently necessary. In the summer, he says this is of no importance, as the steam, being sent away with the heated gases, will not then be visible. The gearing is light and compact, and will be enclosed in a gear case to protect it from dust and mud.

The same system of boiler construction for oil fuel is to be applied to tramcars, the weight of the boiler being very much reduced by it.

The De Dion and Bouton boiler is a much more delicately constructed boiler, consisting as it does of an exterior annular water case, connected to a central, similarly-constructed, annular water and steam space by a large number of upwardly inclined radial and steam tubes.

One of these boilers, weighing about 530 lbs. empty, contains 22·75 square feet of heating surface, and has a grate area of 1·86 square feet. It will, it is said, evaporate about 6 lbs. of water from average temperatures per lb. of coke, and yet it is said to be sufficient for an 18 horse-power motor. It thus has only about 1·26 square feet of heating surface per horse-power, and only 0·103 square feet of grate surface per horse-power. Assuming the little engine employed, which was a small compound engine, to be capable of giving a brake horse-power for 30 lbs. of steam, then it will be seen that each square foot of surface would have to evaporate no less than 23·8 lbs. of water per square foot per hour, and, further, that no less than 52½ lbs. of coke would have to be burned per square foot of grate surface per hour.

Now, inasmuch as the Serpollet boiler is not credited with evaporating 6 lbs. of water per lb. of coke, it will be readily understood that both these boilers have been very much overrated, and hence the difficulty of providing steam for full power for more than a very short time. The Serpollet mass of heated material will, of course, enable the user for a few seconds, or a minute or two, to obtain many fold the average power of the boiler on continuous load, but the store of heat is soon gone, and the boiler soon flooded if water is sent in at maximum rate.

This will be easily seen when it is remembered that the latent heat of evaporation of water from, say, 62° is 1,116 units, and, therefore, no less than eight times the total heat of the iron tubes, even assuming them to be at a 1,000° in temperature when called upon to give up their store. If then, as appears to be the case, these two boilers are the best, or, at all events, the most favoured by those who have been working at this problem for years, it would appear obvious that the great advantages offered by the steam-engine have hitherto been unattainable because of the difficulty which besets the problem of constructing a sufficiently powerful boiler of sufficient lightness.

It is owing then to the hitherto unattainable in steam-generators that the light oil-motor has, as in the recent Paris and Marseilles race, displaced the steam-engine, and it is not easy to see how with the low weights possible with the oil-motor anything yet known in the form of steam-generators, the steam-engine with everything else in its favour can compete. It is true that success is said to have attended the trials of the Blackburn dog-cart in which a comparatively small coiled tubular boiler, heated by a Bunson methylated spirit burner, was employed, but inasmuch as the trials of this dog-cart were made over very short distances, and the engine employed not of high efficiency, it does not appear to have been demonstrated that this boiler was capable of generating sufficient steam for meeting the demands of ordinary road travelling. Considerable advances have been made in the last few years in the construction of water-tube boilers, and some of these boilers will no doubt generate more steam per unit of their weight than was possible with most of the boilers used in steam-carriages between 1858 and 1878, or any of the boilers used in the modern light road locomotive, highly efficient as some of these are. They do not appear, however, to offer any advantage not equally secured by the boilers of Dance, Gurney, Church, Hancock, and Macerone 60 years ago, and it is possible that some of these and the high pressure tubular boiler of Loftus Perkins may even yet, aided by the possible very high temperatures obtainable by the combustion of petroleum as fuel, yet enable us to employ the steam-engine.

It may be asked what, after all, are the advantages which steam offers, and we may answer this question by saying, firstly, the steam-engine affords greater range and ease of manipulation within the limits of no power, and full power than any other motor; secondly it may be stopped and started with more freedom, certainty, and smoothness than any other motor, with the exception of the electrical; thirdly, it may be employed for travelling any distances with fuel everywhere available, is easily fitted with reversing gear, and is easily understood.

Now, as against these high qualifications there is the great disadvantage, as compared with the oil motor, of the necessity for manufacturing on the road the working fluid by means of a boiler. With the equivalent of this the oil motor is able to dispense, for even where a vapouriser is employed, or a carburettor, the weight of these parts is comparatively insignificant, and they require but little, if any, attention. Recent advances seem to show that even this may not in future be necessary, for, with a mixture of oils, or with a light oil or petroleum spirit, the carburettor may be dispensed with, and the vaporiser may be either rudimentary or non-existent. To this point return will be made hereafter. The chief disadvantages at present attending the use of the oil motor are, firstly, the necessity for keeping the motor running while the car is standing; secondly, the vibration set up by the explosive impulse, which is very irregular, especially when the motor is running light, or nearly so; and, thirdly, the necessary use of clutches and rather complicated gearing for putting the light running motor into gear, of changing the speed by means of gear. In spite of these difficulties, however, the oil motor vehicle has made such advances in details of its construction that the race from Paris to Marseilles and back was not only a possibility under adverse circumstances with vehicles of various types, but may be looked upon as a certainty for everyday purposes in the hands of people who are willing to bestow upon them their careful attention.

All the carriages of the Paris-Marseilles-Paris race were fitted with gearing very much the same as that which was in, more or less, general use by the several leading makers more than a year ago, and it does not appear that anything more than slight additional strength and improved form of clutches—by means of which the motor can be put in and out of gear with smoothness—are necessary to enable vehicles to run any length of time, as far as this detail is concerned, with satisfaction.

The carriage which won the first prize in this contest was of the Panhard and Levassor construction, driven by a light oil or benzoline motor of the Daimler type. It drove gearing by the arrangement described by the author last December, and as shown by the view now thrown upon the screen.

It cannot be said that any development can be particularly referred to in this carriage, its motor, or gearing, but great care has been bestowed on the design, construction, and workmanship in particular of all the details. The second and third prizes were also awarded to these makers for vehicles similarly operated, and the fourth and sixth prizes to M. Delahaye for vehicles similar to that, a view of which is now thrown upon the screen. This vehicle was exhibited in England last summer at the Crystal Palace Exhibition, and is one of those in which the motion is transmitted from the engine shaft by belting, the motor being, as most makers now prefer, of the horizontal type. It is one of those which received a diploma for gold medal at the Crystal Palace Exhibition. The carriage with which the fifth prize was won by MM. Peugeot et Cie., was similar to that described last year, and was driven by a modified Daimler type motor. The seventh and eighth prizes were won by the Maison Parisienne, or the Benz Company, of France, with vehicles fitted with the Benz horizontal petroleum spirit motor, the ignition of the charge in which is effected electrically. The ninth prize was won by a vehicle by MM. Landry and Beyroux with a cabriolet, driven by a petroleum spirit horizontal motor. Both the tricycles which took prizes in the third-class were of the Dion and Bouton type, as shown by the view now thrown upon the screen. The motor used in these tricycles is not fed directly with the petroleum spirit, as in the case of the latest forms of Daimler motor, but receives a charge of carburetted air from a carburettor. Its arrangement is shown by the diagram on the wall.

Another carriage of which notice should be taken is that of M. Triouleyre, made by the Compagnie Générale des Automobiles, of Paris, which did some excellent running, and is operated by means of a horizontal benzoline motor, which drives a second motion shaft by means of leather belting, the driving wheels being actuated from this shaft by pitch chains. Two of these vehicles entered for the Paris-Marseilles race. A feature of M. Triouleyre's carriage is an arrangement of tubes and air blast for cooling the jacket water, the details of which are not, however, yet made public.

It is worth notice that M. Roger, the French concessionaire of the Benz motor-carriages, refused to enter the Paris-Marseilles trials, because they were races rather than tests of useful qualities.

The steam-van illustrated by a plan, section, and elevation in Fig. 1 has been made this year by the Thornycroft Steam Carriage and Van Company, Chiswick. It was one of those exhibited at the Crystal Palace Exhibition. It is a light van designed to carry 1 ton, with floor space available for goods of 25 square feet.

Its length over all is 11 feet, of which 4 feet 6 inches are devoted to the boiler and machinery. It is fitted with a Thornycroft water-tube launch boiler, having 50 square feet of heating surface and 2½ square feet of grate, and water-tube fire-bars, as shown in the engraving. The engine is a little double compound, having cylinders 2-inch and 4-inch by 3-inch stroke, and arranged so that the steam can be admitted to the low-pressure cylinders direct for steep hill climbing. The engine is geared to the driving wheels at the ratio of 9 to 1. The fuel used is mixed coal and coke, about 4 lbs. per average mile being consumed. A skew-toothed pinion of large size gears into the corresponding teeth of the rim of the wheel carrying the compensating gear, this wheel being carried by the two inner ends of the second motion shafts, which at their outer

F 3

ends carry the chain pinions by which motion is communicated to the driving wheels. An air condenser is fitted on the roof of the van, which is capable of condensing all the steam at ordinary rates of working, and weighs less than 2 cwt. Its construction will be gathered from the end and side elevation, and it contains about 130 feet of surface, the tubes being of thin copper, half inch diameter, connected in groups to short lengths of 1¾-inch tubes held together by long bolts. The van complete weighs unladen about 30 cwt., of which 22 cwt. is on the driving wheel.

The general arrangement of the van and its machinery is well shown by the engravings. The bearings which carry the intermediate shaft are connected by radius bars to the main axle, to preserve the proper distance between the two sets of chain-wheels, and have free play of the springs by which the van is carried. The chain-wheels are fixed to the back of the driving-

slight improvements in the steering arrangements might be made, and, if possible, the number of handles to be used should be lessened, and the exhaust should be capable of diversion into the chimney for hill climbing. All these are more or less easy of achievement, and the van meets the requirements of the Local Government Board under the new Act. The van recently ran from Chiswick to Windsor Castle, a distance of 20 miles by road, carrying over ½ ton of load, in 2¾ hours, with 90 lbs. of coal and coke mixed in equal bulk, the run to Chiswick and back being made without any stoppage for adjustment or other purposes, and the Castle Hill was climbed without difficulty. This steam van may be taken as representing a class for which it may be expected considerable demand will arise, namely, a van to carry a ton and upwards of goods. The example shown is of the smaller size of a type which, running at a maximum speed of about eight miles an hour, would perform

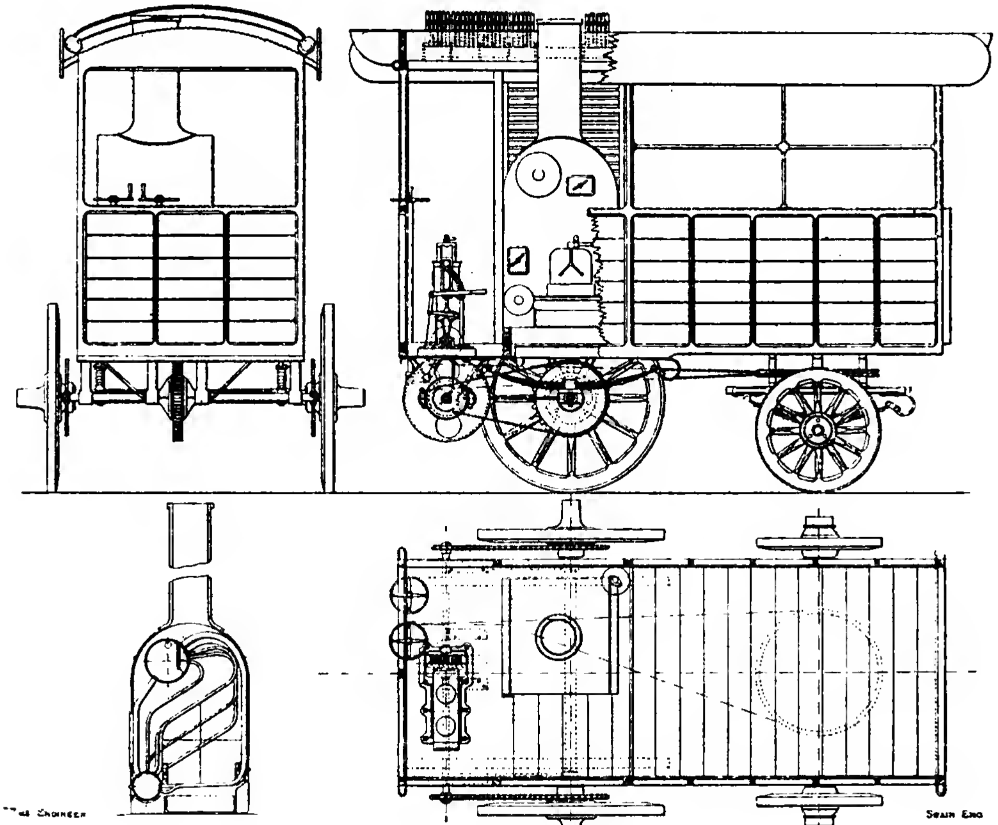

FIG. 1.—THORNYCROFT STEAM VAN—PLAN AND SECTION.

wheel naves. The steering is effected by a hand-wheel on a verticle spindle, at the lower end of which is a worm gearing into a wheel of about 8 inches diameter, cast with which is a wheel which carries an ordinary link chain. This chain is led to a horizontal steering wheel on the locking-shaft steering wheels at the rear end of the van. The chain on this wheel is capable of adjustment for taking up slack. The brake is also put on by means of a hand-wheel and vertical spindle next the steering wheel. The steam connections between the engine and boiler are not shown in the illustrations, but they are of simple kind, a stop-valve being within easy reach of the driver, who can also reach the link motion lever. The van was shown running in the Crystal Palace grounds, over roads which are in some places small loose gravel, which is trying, especially for iron-tyred driving wheels. The van runs very satisfactorily and smoothly, and will meet the requirements of a great many who, as carriers, are now waiting for such a vehicle. Some

the work of country carriers and numerous classes of traders. In these the small extra weight of parts not admissible in the light passenger vehicles hitherto referred to, is a matter of smaller importance, and the maximum speed being low, they may be worked and steered with safety and certainty. The heavier class of vehicle, to carry and haul from three to seven, or more, tons, have yet to be made; and while for the light, quick passenger vehicles the experience and practice of the carriage and the cycle makers will be invaluable, it is the experience of the light road locomotive and traction-engine builders which will be drawn upon to make a success of the heavy motor-vehicles. The author was recently called upon to express his views on motor-vehicles for the heavy traffic of the Liverpool traders, and surprise was shown when he stated that although for those who really required them, light vehicles of a useful character could be had at the present time, those suitable for heavy traffic had yet to be made. For this reason he advised those whose expectations had been unduly raised with regard to such vehicles, not to be in a hurry to part with their horses. This view he still holds; but the realisation of the requirements of merchants, of places like Liverpool, or of some of them, is perhaps within a measurable distance. The problem to be solved is, however, anything but an easy one, and if it is to be solved by means of the steam-engine, it would appear that very high pressures, high-speed engines, and high-class light boilers will have to be employed, rather than the very heavy boilers, and comparatively low-speed engines at present used for light road locomotives. The development of the oil-engine is, however, sufficiently rapid to lead to the belief that this form of motor will ultimately take the place of the steam-engine for this class of work. Some indications of this are already afforded by the efforts of Messrs. Hornsby and Sons. Much attention has yet, however, to be paid to the transmission and stopping and starting gear to be employed.

The Duryea carriage, to which reference has already been made as being one of those present at the opening run from London to Brighton, contains several features of interest, one of which is that the motor has an oscillating cylinder; that it is supplied with gases the product of explosion of carburetted air under pressure from a separate explosion chamber. A lamp is used to effect evaporation, an electric arrangement being used for ignition of the charge. The motor transmits motion to a second shaft by means of belts for three speeds, and a cross-belt is used to obtain reverse motion at another speed. Jockey pulleys are used for giving either the one or the other of the

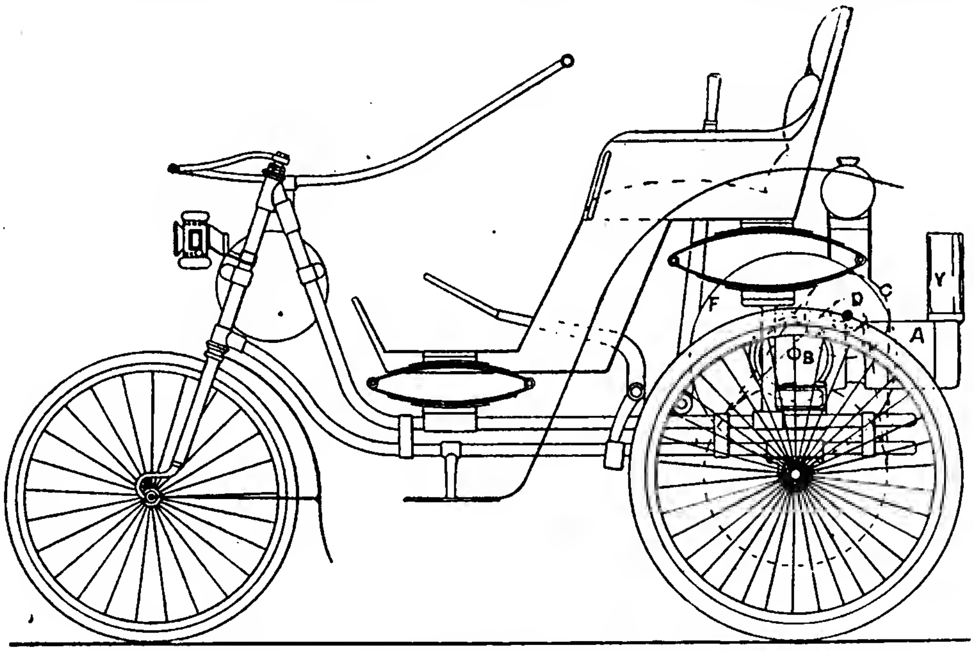

Fig. 2.—Roots and Venables' Petroleum Oil Carriage.

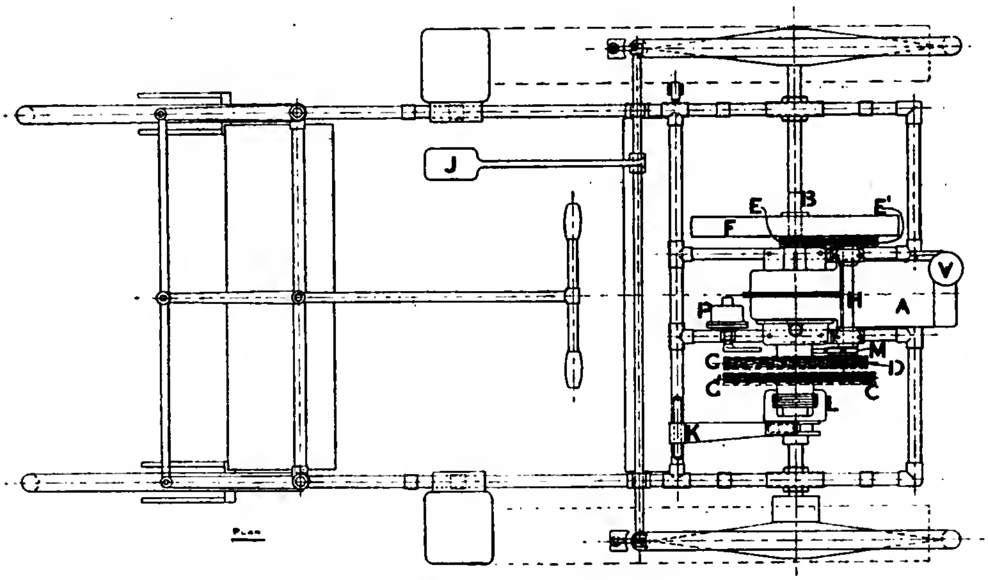

Fig. 3.—Roots and Venables' Petroleum Oil Carriage—Plan.

belts sufficient tightness to enable it to drive. Spur pinions on the end of the second motion shaft convey motion direct to a hollow axle surrounding the driving axle, and carrying a compensating gear in the centre. It carries benzoline sufficient in quantity for about 100 miles' run.

The carriage, of which two views are shown in Figs. 2 and 3, is one which has been built by Messrs. Roots and Venables, and is fitted with a motor which works with the ordinary lamp petroleum. The arrangements are in several ways novel and interesting, and it is one of the first finished carriages yet constructed to use the heavy oils of high flashing point. The motor works on the Otto cycle, and the rotating valve shaft, which must run at half the speed of the crank shaft, is utilised as a means of obtaining the first speed reduction. This is a very considerable gain, and allows of convenient arrangement.

In the engravings, A is the motor cylinder, B, the crank shaft geared to the wheel, C, by means of a Reinhold chain, this wheel being on the rotating valve shaft, which is made large enough to transmit the power either by the chain on the small pinion, D, or the larger one, C, either of which are thrown into gear by means of a clutch at L. The oil supply is seen at O, and the vaporiser, on Root's system, is at V. J, is the foot lever for a brake, and a vertical lever enables the driver to throw the motor in or out of gear, or to give the carriage one or other speed. The frame is formed of a double set of tubes which act as water coolers for the jacket water which circulates through them.

The carriage shown in Figs. 4, 5, 6, and 7 is a petroleum motor-carriage made by Messrs. Petter, Hill, and Boll, of

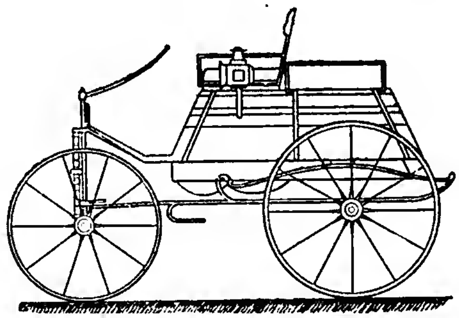

Fig. 4.—Petroleum Motor Carriage by Messrs. Petter, Hill, and Boll.

Yeovil, the motor being the design of Mr. Percival Petter, and the vaporisor used in connection with it is shown by Fig. 5 to be rudimentary only. Several carriages fitted with the arrangements of machinery shown in the figures have been made by this firm, and the author is informed that they are running with success. The motor is of the horizontal type, having two parallel cylinders, M M′, coupled to one crank shaft, N N′, upon which is a flywheel, W, and the pulleys A, B, and C, upon which are belts for driving either the high speed pulley, A′, or the low speed pulley, B′, or the reversing pulley, C″, through the medium of the rider pulley, C′, the three pulleys, A′, B′, and C′ are fixed upon the second motion shaft, H, in the centre of which is the usual compensating gear, G, and on the ends of which are the two chain pinions, J J′, communicating motion to the driving wheels by means of pitch chains running on the wheels, K′ K′. From the sectional elevation it will be seen that by means of the handle, E, at the right hand of the driver, the belts connecting the pulleys, A A′, or B and B′, are thrown alternately into gear by pressing either the jockey pulley, D or D′, upon those belts. As shown in the engraving with the handle, E, in the position 3, the jockey pulley, D, is tightening the belt on the pulleys, B B′, for driving the carriage at the slow speed. When the handle, E, is placed in the position 2, both sets of pulleys are out of gear and the belts free to slip; but when the handle is in the position 1, the jockey pulley, D′, comes into play, and the belt connecting the pulleys, A and A′, is tightened upon them for driving at high speed. The handle, E, is on a shaft, F (Fig. 7), which carries levers from which depend links having on their ends the stud spindles of the jockey pulleys, D D′, which are controlled in their movements by the radius rods, G′ G″. An ingeniously simple reversing motion is obtained by means of the belt connecting a pulley, C, and pulley, C′, the latter being carried upon a stud spindle held by the arm, F′, and under control of the foot by means of the pedal, I. When not in action, a spring at S keeps the pulley, C′, and the belt upon it from contact with the driving pulley, C″, but when it is desired to bring the reversing motion into gear, pressure upon the pedal, I, brings the pulley, C′, with the lower part of the belt running over it intervening, upon the pulley, C″, and thus a slow movement in the reverse direction to that given by the other pulleys is obtained. The pulley, C″, acts also as the brake pulley by means of a band brake embracing about half its circumference, and brought into play by means of the pedal, L. In Fig. 5, A is the compression space and combustion chamber; B, oil inlet cock; D, inlet

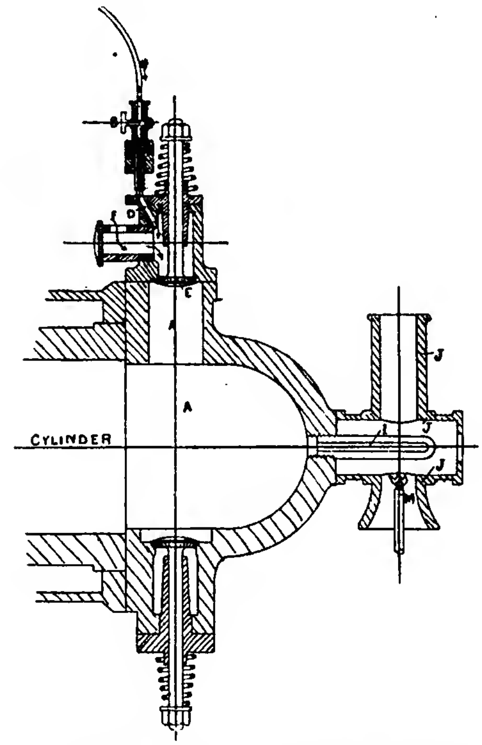

Fig. 5.—Petter's Oil Motor Cylinder and Valves.

passage to valve space; F, air inlet to valve; E and J, ignition tube, heated by burner, M.

The views which are shown in Figs. 8 and 9 illustrate a motor quadricycle made by Mr. P. Crastin, of Holloway, and operated by an oil-motor using ordinary lamp petroleum. In the motor employed there are some details of interest, and, though not at liberty to describe some of these, some views and details are now given. From the general views it will be seen that the quadricycle with two seats is driven by a motor through the hind axle, and the first speed reduction is obtained from the rotating valve-driving spindle; which, as in other Otto cycle-motors, runs at half the speed of the crank shaft. By means of the remaining gear, which is clearly seen, the speed of the motor, which runs at about 580 revolutions per minute, is reduced to the 130 revolutions per minute for a speed of 12 miles per hour, of the driving wheels, which are 2 feet 6 inches in diameter.

The motor itself is double acting, that is to say, it has a double-ended cylinder in which the explosive impulse takes place alternately, so that one impulse is given for each revolution. A sketch diagram of one end of this cylinder is shown in Fig. 8. A shows the casting carrying the water jacket and the internal steel tube, T, which is fixed within it and protrudes into the cover, B. Wiihin the steel tube, T, which has a slot, S, in the middle of its length for the accommodation of the cross-head pin, P, is a second tube, T′, carrying at the centre of its through a valve at D, and an ignition tube is placed at E; exhaust valves are fitted at F. The vaporiser employed is shown in a case at the back of the vehicle, and it consists of a small annular vertical vessel formed by an inner and an outer steel tube closed at both ends, the inner tube forming the chimney for a small vaporiser lamp. At the lower part

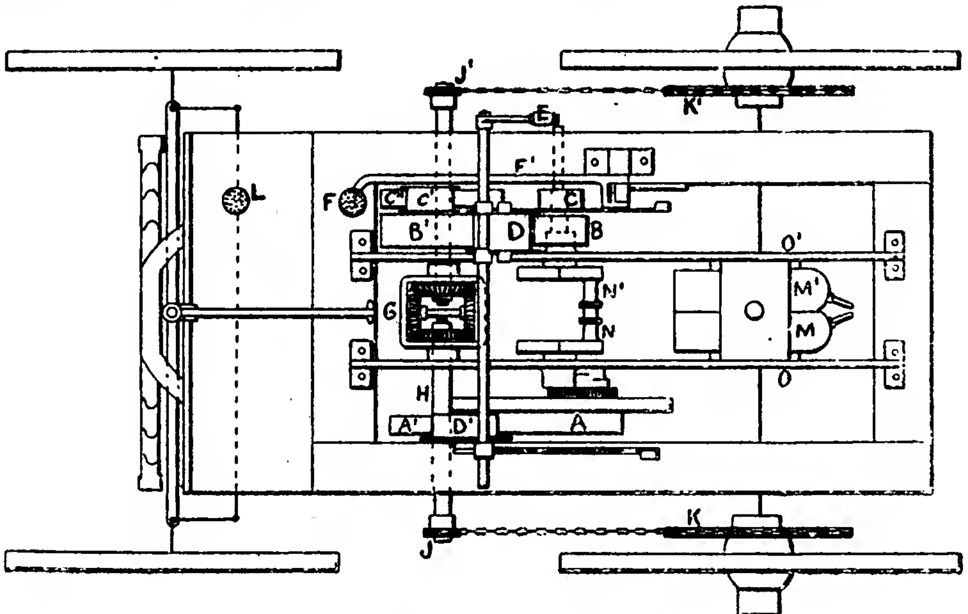

FIG. 6.—PETTER, HILL, AND BOLL—PLAN.

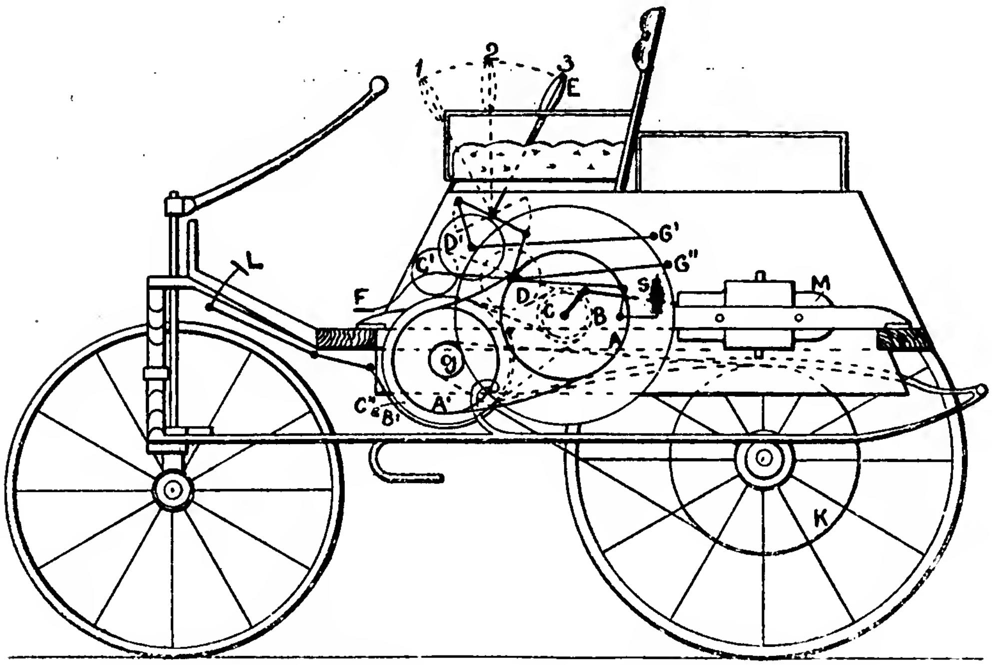

FIG. 7.—PETTER, HILL, AND BOLL—SECTIONAL ELEVATION.

length the crosshead, C, and at each end the piston block, C′. In the lower part of the cylinder casting is fixed the tube, H, which provides for the circulation of the water through the jacket, G, from which it passes by a pipe at the cylinder top.

The cylinder is fixed to the frame of the quadricycle by the clamp piece shown. Air and vapour enter the cylinder cover of the annular space a tube is inserted, into which oil, from a form of sight-feed lubricator, drops, and is drawn into the vaporiser when a suction charge is made, but passes away into an overflow tank when a charge is not required. The double-ended piston of this motor is 1·75 inches in diameter, and has a stroke of 4 inches.

Figs. 10, 11, and 12 illustrate a steam-carriage under construction, largely from the designs of Mr. Percy Holt, and although not yet completed, a description of it will be of some interest as being, as far as the author knows, one of the very few attempts to produce a steam carriage of considerable power and of light weight to carry four persons. From the three views it will be seen that there are two small steam-engines carried in two cases completely enclosing them, and driving, by gearing also enclosed, a pair of grooved driving pulleys acting directly on the peripheries of the pneumatic tyres to the driving wheels. The cases containing the engines are so mounted that when steam is turned on to set the carriage in motion the grooved pulleys are automatically brought into contact with the driving wheels. The boiler is of a novel type, and will be described hereafter. From the engines, either or both of which may be used, the exhaust steam passes into a condenser which is an air condenser acting partly on steam is only admitted to one engine, but when gradients require it, it is automatically admitted to both engines by a movement corresponding to the loosening of the reins. When steam is shut off from the engines for stopping or for running downhill, a simple form of regulator cuts off the oil supply to the greater part of the oil burners by which the boiler is heated, the other burners being so situated that they are automatically relighted when steam is turned on by those which are not extinguished when steam is turned off. The boiler, which is shown in Fig. 10, consists of two main parts, namely, a water-heating part in which the water fills the entire capacity, and is maintained under a pressure of from about 500 lbs. per square inch and upwards. This part is connected by a reducing-valve automatically controlled by the consumption of steam by the second part in which steam at a low pressure of say 250 lbs. per square inch is generated. The first part or receptacle consists of the larger tubes, A, B, and B′, and the second part or recep-

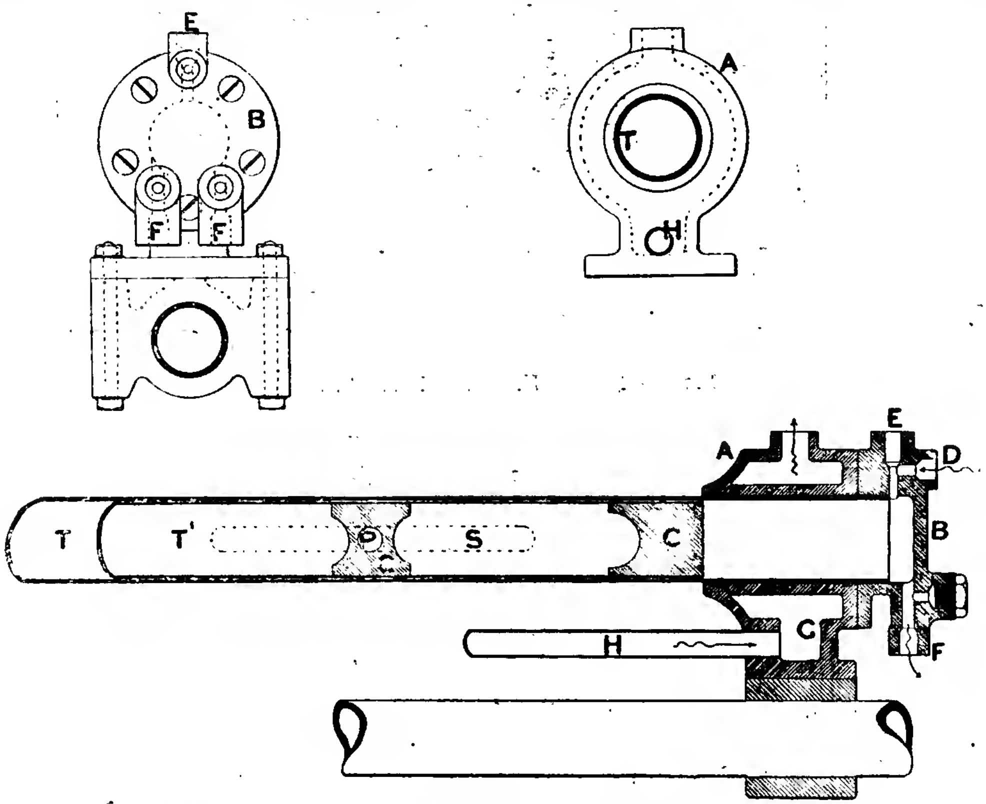

Fig. 8.—Crastin's Motor Quadricycle—One End of Motor Cylinder and Piston.

the principle of an evaporate condenser, the exhaust steam itself actuating a fan which assists in the action of the air-cooling current. As far as is possible, the control of all the parts has been made automatic, dependent only on the action of the steering handle influenced as far as more or less steam, *i.e.*, more or less speed, and as to the quantity of steam generated, and as to the amount of fuel used, and the application of the brake, all as far as possible controlled by a movement simulating the action of the driver of a horse who gives more or less rein to his horse for more or less speed, or pulls very hard on them if he wishes the horse to understand that he is direly in need of all his help for a sudden stop. When the carriage shown is standing the brake actuated by the steering levers is in action. When the driver is in his place the steering levers, with a sleeve on the rod connecting them, are raised more or less, and this admits by the lever connections, shown in rather exaggerated dimensions, steam to one, or by further movement, steam to both of the engines. When running on a level and good road tacle consists of the interior smaller tube, C, within the water-tubes, A, B, B′. The feed-water is admitted at the top at A, and passes downward through the coil, A, to the junction piece at A′. Here it passes from A into the annular spaces within the coils, B, B′, and outside the coils, C, in which it passes up to the reducing-valve and connection at R. When steam is required, some water is automatically admitted into the inner tubes, C, in which from its high temperature and pressure it partly flashes into steam, and is partly vapourised by the heat transmitted through the high temperature water to these inner tubes, the steam passing off to the engine at D.

There are many makers in this country busy on the construction or the design of motor-carriages, but few of them are at present prepared to show what they have done. Some, including the makers of the Pennington motor-cycles and bicycles, are so well known as to need no reference here.

There are several questions which arise in connection with the subject of this paper to which reference must be made.

One of these is the speed question, because with it is involved that of power. For the present, at least, it must be conceded that the maximum speed for which motors and gearing for any motor-carriages should be designed ought not to exceed the reasonable 12 miles an hour permitted by the Local Government Board regulations. This should not only be admitted on the grounds of public safety, but because of the lesser power which such a speed, as a maximum requires, as compared with the speeds which are being attempted, but because of the smaller weight of the necessary motor. It may be further urged that all the purposes of the greater number of users of these vehicles will be best served by the power which is sufficient for this speed as a maximum on good roads, and a correspondingly lower speed on any ordinarily steep gradients which can be surmounted by the same power. There is nothing fine or particularly laudable in rushing up steep hills at high speed, any more than there is in doing so with horses, while there is, on the other hand, very considerable possible gain by adopting the slow speed for hills, which also secures greater power for starting and working over bits of bad road. This consideration shows that for most vehicles, and particularly for trading vehicles, even when driven by steam, an effective arrangement of speed gearing, which can with smoothness be put into or out of gear, so as to provide high-power by slow speed for starting and hill climbing, is necessary. In this way the small boiler power sufficient for maximum speed on good roads will be sufficient for bad roads and hills.

A diagram was then shown giving the power required for different speeds on different gradients for a vehicle and load of 2½ tons, and shows how very much the power increases with the higher speeds.

The limit to speed for lighter vehicles is possibly a very high one, but for vehicles for the average user it must be determined by some reference to economic running, to cost of the vehicle, and to the average conditions imposed by the observance of legal restrictions, and ordinary traffic convenience. In towns the limit and the maximum power required are in most places soon reached.

Fig. 9.—Crastin's Quadricycle—End View, Vaporiser and Casing Removed.

With regard to the use of petroleum or petroleum spirit motors, the recent alteration of the conditions under which the latter may be used in this country has removed the necessity, from a legal point of view, for adhering to the use of oils having a flashing point of above 73°. There is no doubt that there are good reasons for wishing that the oils of high specific gravity should be used, but it must be admitted, on the other hand, that the employment of benzoline has been singularly free, both on the Continent and in America, from mishap in connection with motor carriages. Some English firms, as already mentioned, have succeeded in making motor-carriages propelled by motors which will use ordinary petroleum lamp oil, and having done so much, there are reasons for expecting that development in this direction may take place.

It cannot, however, be denied that the advantages from the point of view of simplicity of the motor attending the ready vaporisation of the lighter oil in the motor admission valves and passages, and ignition in the cylinder, are very great indeed, and that the objectionable smell of the exhaust gases is very much less than from the heavier oil. The great variation in the power required from the motor of a mechanical carriage, namely, as between the maximum power for climbing a stiff hill and the no power required when descending hills, introduces variations as to vaporisation, quantity of oil to be dealt with, temperature of cylinder, and ignition, which, as far as at present can be seen, must occasionally cause the ejection of much partially-burnt oil with the exhaust, a difficulty which is much lessened by the use of petroleum spirit. The advances which have been made in the last year in the construction of oil or spirit-motors are not of a striking order, and the best known and most used of all is the Daimler of the improved form, described by the author in the Cantor Lectures last December. The float-feed regulator of this is used by M. Bollee in his tandem tricycle, which has done such remarkable running, and the new horizontal motor by M. Peugeot is made on lines similar to the Daimler. The feed apparatus cannot very well be conceived to be much simpler, and the automatic spray making preparatory to vapouring is so introduced that it adds nothing to the parts to be attended to. One at least of the makers seem to have courted disaster by using horizontal Otto cycle motors. the end of the cylinders of which were open for the reception of any dust and dirt that could find its way there, and several of the makers use horizontal motors of moderate speed, and consequently large diameter of cylinder, as the stroke is not long. There seems to be no doubt that in the future exceedingly good design, workmanship, and material must be combined, and very high speeds for motors be observed. This makes possible, not only small area of piston, but smaller impulse and less variation in the strength of the impulse. Some of the very small motors made by Mr. Pennington are said to be very good indications of the lines on which the motors for light vehicles will have to be made.

In the use of the heavier oils some advances have been made, but as the author has not actually tested any of the motors said to work satisfactorily without vaporisers, even of the simpler forms, he is unable to say more than that he is informed these motors do work with the heavier oils of specific gravity 0·8, and flashing point of over 73°.

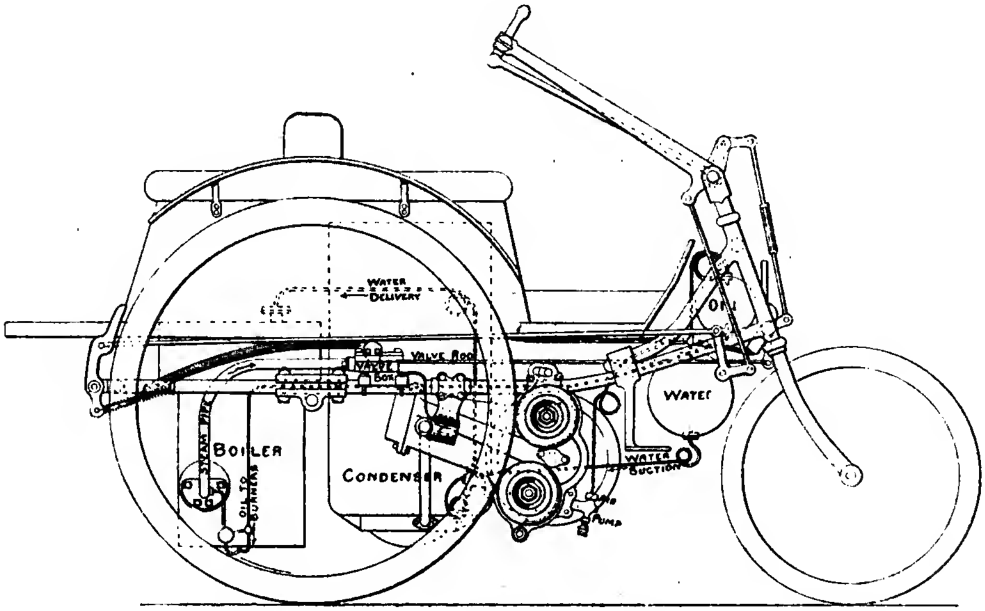
In the construction of frames for motor-carriages, the experience and inventions of the cycle manufacturer will be of very great help. Not only may the systems of building-up be employed, but the tubular form may be usefully employed as storage or cooling surface for jacket water.

In some of the machines which took part in the Paris-Marseilles trials, it was found that under the excessively severe ordeal of a 1,000 miles race, often over excessively bad roads, the frames were severely tested, and brazed joints in several instances were found defective. On the other hand, mechanically connected frame members behaved well. When motor-carriage construction has been sufficiently standardised, it will, no doubt, become common to connect members of the frames by castings and stampings, which are employed also as parts of the machinery.

The only novelty in the method of building up frames which has been announced is that of Mr. C. T. Crowden, according to which the tubes are slipped into their connecting collars or other parts, such as the cycle head and crank bracket, and then subjected to an internal water pressure of about $2\frac{1}{2}$ tons to the square inch. The inside of the sockets, of whatever form, are first grooved, so that under the water pressure the thin tube is swelled into the grooves. The sockets and tubes being, for the purpose of the process, placed within strong, well-fitting, cast-iron clamped dies, or moulds, so that the water pressure does not burst either the thin pipe or the sockets. Some samples of frame joints made this way are here upon the table.

There seems to be great probability that the light aluminium alloys having a specific gravity of from 2·9 to 2·95 appear to be well suited for making the castings for the frame and machinery connections, because excellent castings of any form can now be made with these alloys, and the strength for a given weight is not only ample for every purpose when the thickness is enough to secure stiffness, but it is considerably stronger than steel, weight for weight. Steel castings cannot be made very light,

FIG. 10.



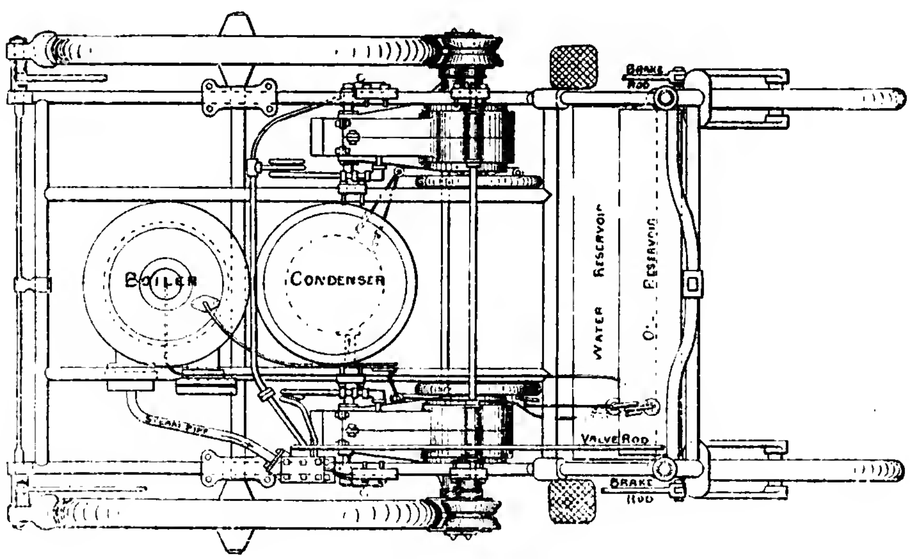


FIG. 11.—HOLT'S STEAM CARRIAGE.

and when necessary stiffness is taken into consideration, an alumininm alloy of specific gravity 2·95, and tensile strength of from 12·5 to 15 tons per square inch offer very considerable advantages, especially as such alloys work well in the machine shop and with the fitter.

With regard to the tyres of wheels for light carriages and the lighter omnibuses and vans, experience to the present time seems to confirm the opinion of those who strongly favour the use of indiarubber, and particularly of pneumatic tyres. Experience and invention are no doubt developing the air tyre, so that its advantages will ere long far outweigh the disadvantage of their high cost. Very high speeds are, however, especially with any considerable weight, very destructive both of solid and of pneumatic tyres. For the heavier vehicles now permitted under the recent Act and regulations there seems little doubt that wheels fitted with renewable wood treads may be very favonrably mentioned, and it may be hoped that the Local Government Board Rules will in this respect, and in one or two other matters on structural points, be modified in accordance with the experience which will soon, it may be expected, make modification necessary.

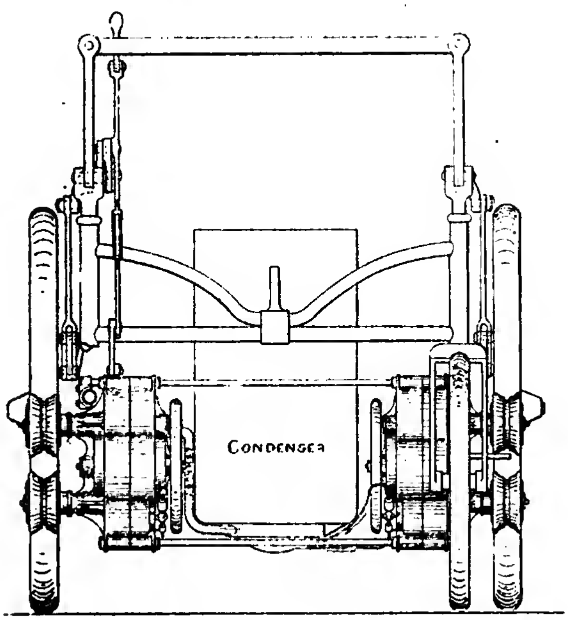

Fig. 12.—Holt's Steam Carriage—Front View.

With a consideration of the kind of tyres most suitable for motor vehicles, arises the subject of road improvement, and the opinion may be confidently expressed that if mechanical transport on the high roads is to acquire the importance and the universality that its promised advantages make desirable, more attention than ever will have to be paid to the construction and maintenance of roads, and more money than ever will be profitably employed on this work.

Thus far no reference has been made to the development of electrically operated motor vehicles. This is because the development resolves itself almost entirely into a question of secondary battery construction. There can be no doubt that the electrical motor is, at present, the only one which offers a complete equivalent of the steam-engine with regard to range of power within the maximum, facility of starting and stopping, easy working, and freedom from vibration. It must, however, be left to those who have had recent personal experience in the use of secondary batteries for this purpose to state what the recent developments actually are, for the author's own experience in their construction cannot be quoted in connection with recent developments.

During the coming year great activity may be expected in connection with mechanical road carriages. British engineers are busy, and the prizes offered by the proprietors of *The Engineer*, to the value of 1,100 guineas, will, it may be expected, bring forward a great many vehicles, which will take part in the competitive trials to be held at the end of May, or beginning of June next. The conditions of this competition were published in *The Engineer* of the 20th of that month (November).

DISCUSSION.

The Chairman said this subject was now occupying public attention a great deal. It interested engineers at very nearly the beginning of the century, but now the public had got hold of it, and probably there would be the usual story—a good many failures, a good many accidents, a great deal of dissatisfaction, and then it would fall into disrepute. After the pendulum had swung in that direction, it would probably come back, and after a time the matter would be taken up in a proper and true spirit—that of engineering, not of company promoting. When that point was reached, it would be found that this mode of locomotion was really very valuable. He had so often spoken of his own experience, which went back, he was sorry to say, for 60 years, that he hardly liked to repeat it, beyond saying that, according to his judgment, nothing had been done recently which surpassed what was done then. There had certainly been a change from steam to oil motors, but he was glad to see that the reader of the paper appeared to be of opinion that the last word had not yet been said with regard to steam. Mr. Thornycroft's steam-van, and Mr. Holt's steam-carriage were illustrations. He did not consider that the flashing of water into steam was a very nice way of doing the work. It did not follow because you used water that you need carry several hundredweight of it; and, he might remark, that whether it were in a boiler or in a tank it weighed exactly the same. It was only the initial low-water level in the boiler which was extra, and the boiler need not be very heavy. With regard to reversing gear, Mr. Hancock, who was most successful in the use of road locomotion 60 years ago, told him that he never would allow his carriage to be reversed in London by the driver. The driver would only get into a fluster and back into something, and they would have the pole of an omnibus going through the casing of the boiler or something of the sort. All he allowed the driver to do was to steer, or put on the brake with his foot, or stop, and that was found quite sufficient. If the Serpollet system used coke, he did not understand how the fire was damped down, or how they avoided getting too high a temperature when standing. He could understand that with petroleum it would be easy to prevent that taking place. Many present were probably aware of the arrangement of Mr. Howard, of the King and Queen Iron Works, many years ago, in which the boilers had no water in them, but just enough was injected to make one stroke of the engine, and that was repeated. There the reservoir to take up the heat of the fire was an amalgam of lead and mercury, and the water was injected on to a plate covered by this amalgam, the plate being indented so as to give more surface. There was another boiler, called the Parks boiler, very much like it. This system was used on a steamboat which ran from London to Ramsgate during the whole of one season; it was applied to a ship of war, and for years it drove the engines for the rolling mill at the King and Queen Iron Works at Rotherhithe. He did not know what objection there was to coke as a fuel when properly burned. All fuel must give off carbonic acid if burned properly, or carbonic oxide if burned imperfectly, and he did not know that coke gave off anything else. They all knew the difficulties with coal, but he could not speak from experience as to the lighter oils. When he was putting up an engine for an electric plant in a house he had in the country, he was deterred from using an oil-engine by an epigram. A friend said to him, "Do not use that thing; it will stink like a cat, and bark like a dog." Not liking that prospect, he put up an ordinary steam-engine. He did not gather how the draught was obtained in cases where a fire was used; as a rule it appeared to be produced merely by the ignition of the vapour in the cylinder; nor did he gather how the noise of the exhaust was got rid of. Some years ago he was much interested in an endeavour to introduce in London tramcars worked by compressed air, as they had been worked now for 15 years in France. They had to get rid of the noise of the exhaust air, and after trying many costly things, he at last thought of something very simple. He took an old hamper, doubled it up, and broke it, and put it in a case, and then turned the exhaust air into that, and the twigs of the hamper so bothered the compressed air, that they never heard any more of the noise. A similar kind of device was used with gas-engines. He did not quite understand one of the boilers which had been described as having a high-water pressure, and low-steam pressure. Perhaps Mr. Beaumont would explain it.

Mr. Beaumont said there was a reducing valve between two parts of the boiler. The part containing the water was constructed of tubes, and the water in those tubes was carried very much in the same way as it was in the Perkins hot-water heating apparatus, from that the water was taken through a reducing valve, and converted into steam.

The Chairman said he was surprised to hear that pneumatic tyres would stand the wear incident to traction wheels. He remembered Mr. Hancock telling him that he had much less trouble with the wear of his engines and boilers than with the wear of his tyres. If pneumatic tyres by reason of their pneumaticity (so to say) were capable of getting over that trouble, it would be a very important matter. He often thought that if he were a man of wealth and leisure, he should like to make a servile copy of one of Hancock's steam-omnibuses, and put it to work, as the original did, between Paddington and the Bank, and then ask the present generation of engineers to try and improve upon it.

Mr. Walter Hancock said no one was more surprised and delighted that so much had been done with petroleum motors, but at the same time the advantages of steam were so thoroughly worked into his whole thoughts, that he could not but think that there was a good deal to be done yet by the steam-engine, when the attention of the engineers of the present day was directed to the problem of road locomotion. Going back to the time when his uncle first worked at steam-carriages, and comparing the steam-engine of those days with those of the present—considering the form of the slide-valve, which then had none of the advantages of lap and lead—which had produced such an economy in working, and thinking also of the change introduced by the link gear by which the expansion was now controlled, and, therefore, the consumption of steam according to the varying load, it might be safely said that the little van described by the author was one which pointed very strongly to the advantage to be gained by the use of steam. The engines in that van were little more than toys: the cylinders were only 2 inches and 4 inches, in fact, he thought it carried economy of engine-power to exception. If the cylinders had been 2½ inches by 5 inches he thought it would have been a most economical machine for traction on roads. As it was it, it would carry something like a ton. He hoped the engineers of to-day would devote their skill and energy to this question, and adopt all the improvements of the modern steam-engine to road motors, and then he believed steam would hold its own for both economy and comfort.

Mr. A. R. Sennett, referring to the Chairman's remark that he regretted that his experience went back 60 years, said he was inclined to think that he would rather have lived 60 years ago, for that was evidently an engineering epoch. Then a man who wanted a machine went to an engineer, whereas now he went to a company promoter. He had had some experience of the Serpollet boiler, and that afternoon had run some 30 miles with a carriage constructed by that inventor. With regard to the damping down of the fires where coke was used, there was no precaution taken, except that the ashpit door was opened towards the front of the carriage only. The blast up through the bars due to the motion of the carriage was all that was required. He had slightly altered M. Serpollet's arrangement by putting a hopper in front at an angle of 30° from the horizontal downwards; if anything, that acted rather too well, and all that afternoon they had rather too much steam. It now only required to be fitted with a butterfly-valve damper to be under perfect control. He understood the author to intimate that the reserve of therma energy in the Serpollet tubes was a matter of seconds—that it was soon exhausted. He would wish to emphasise the fact that the draught upon this reserve was made concurrently with the normal steaming of the boiler. It was far more than a matter of seconds, and its utility was of the greatest importance. That afternoon he drove from Worthing to Horsham—not the most level of roads—but though the carriage was provided with a hill-climbing speed and a high speed, they never put on the hill-climbing speed the whole time, and never saw any visible steam, even on the longest hill. His experience was that by putting on the slow speed you made such a vast number more revolutions in climbing a hill, and before you got to the top of it, if it took more than (say) 10 minutes, the superheating became ineffective, and you got visible steam, which was forbidden by the Act. It was curious in what a slipshod way the French carriages were put together; the syphon tubes outside the boiler were not protected in any way, and while the boiler tubes were at such a high temperature, immediately outside there was a rush of cold air. The same with the cylinders; they were not lagged in any way, and were placed in such a position as to catch all the grit and dirt. It was really wonderful how well the carriages behaved, built in the way they were. Of course, Serpollet was not the first to invent a flashing boiler, nor even to apply it to a carriage, and he was inclined to think that the Serpollet system was really an English invention. It was Jacob Perkins who taught them to use a flashing boiler, and Mr. Loftus Perkins, who did so much in high-pressure steam, built a little tractor, much smaller than any that Dion and Bouton's built in Paris to-day. It ran about London for some time, but being exiled by Act of Parliament, went to Brussels, where it ran a considerable time; then the boiler was taken out and copied and put into tramcars, and now the same system was carried out by M. Serpollet in a manner which did him great credit.

The Chairman said according to his recollection the Perkins' carriage, on which he had ridden, had a boiler containing water at high pressure—not a flashing boiler.

Mr. Sennett said he believed it was a flashing boiler. It was a tractor with only one wheel, which was attached to a four-wheel van. The single driving wheel was covered with india-rubber. As the Chairman had said, a flashing boiler did not reduce the weight; it was heavier if anything, but the extra weight was more than compensated for by its safety and flexibility. The Dion and Bouton boiler required a very large area or a very high rate of combustion, as a means of raising steam rapidly for hill climbing, and it was a most dangerous boiler to place in the hands of unskilled drivers. With a tubular flashing boiler all danger was eliminated. If you had to stop suddenly an ordinary boiler went on making steam, and up went the safety valve and frightened the horses. With boilers of the Thornycroft or Yarrow type you had great power, but there ought to be some means of arresting the combustion or radiant heat when the carriage stopped. He should like to know how the oil-feed in the Serpollet carriage was regulated. In the historic Parkinson and Bateman tricycle there was a regulating arrangement similar to one recently introduced by Mr. Cross, consisting of a steam piston, held down by a strong spring, so that directly the steam rose above a certain pressure the spring compressed, and the different jets were automatically shut down. He found nothing at all objectionable in coke, which was a much cleaner fuel than petroleum. They never put any coke on the fire; it was put in a hopper, and the shaking of the carriage shook it down. That afternoon they had rather less than one sack of coke put into the hopper at Worthing, and as a precaution about one quarter of a sack more was put on the front of the carriage. They ran the 25 miles into Horsham with the use of about three parts of a sack. It was, of course, very unscientific to use petroleum or liquid fuel for a steam-engine, because a steam-engine was a heat engine of low efficiency; whereas an internal combustion engine was one of high efficiency; but, nevertheless, the ease of manipulation, the simplicity, and the much-to-be-desired flexibility of power was so great in the case of steam, that now English engineers had a chance of working at it he thought they would put a different complexion on the matter. In reply to a question from Mr. Beaumont, he said he believed the carriage he had been describing weighed about 24 cwt., but he had not weighed it.

Mr. S. H. Terry said he was very glad to hear from so high an authority as the Chairman that steam was not dead yet, and he gathered that Mr. Beaumont also thought it had yet a future before it. He had brought with him some photographs, which perhaps might be thrown on the screen, of a once well-known steam carriage, called the "Fly-by-Night," built some years ago by Messrs. Carrett and Marshall for Sir Titus Salt, which afterwards became the property of Mr. Des Vigne, who was present, and, he hoped, would say something about it. It ran a great many thousand miles, but, unfortunately, owing to difficulties raised by the local authorities, its career came to an end.

The photographs having been shown,

Mr. Des Vigne said the "Fly-by-Night" had many points of interest, even at the present day. When first constructed from the design of Mr. George Salt it was not by any means perfect. The steering gear was not first rate, and it did not go round corners well. It had, perhaps, the first example of the "Jack-in-the-Box" compensating gear of bevelled wheels and hollow shaft. Then they could not keep steam; and after trying several sorts of feed water-heaters, they at last put some hanging tubes in the smoke box of a peculiar construction, by which they got the water into the boiler rather above boiling point, and that acted very well. There was also an expansion gear, which saved a lot of water, and seemed to do almost as well as a compound-engine. They could not use it except on a fairly level road, for when going up-hill, or over rough stones, the consumption of water went up rapidly. It weighed about 6 tons, and of course that wanted a lot of propelling; still they went up Chatham Hill with it all right. Mr. Aveling, who was present, said it carried too much steam, and that the pressure (150 pounds) was too high. However, when they had the expansion gear on, they put on another 30 lbs., and it stood it all right. When the Act was passed, the engine could no longer run; the engines were put into a steamboat, and the wheels were sold, but he still had some of the parts.

Mr. Terry then showed a photograph of another steam-carriage now being constructed at Teddington, by Messrs. Des Vignes and Co., with vertical tube boilers, the engines being entirely self-lubricating. He did not think any passenger would know there was an engine on board, which was not a common feature in motors. He did not want to disparage oil motors, for he thought the builders of them had taught them all some useful lessons, one of the principal being that they must keep down the weight. The "Fly-by-Night" was very heavy, but the one of which he had shown the photograph was not so heavy as it looked. The points required were strength and rigidity, with great elasticity between the road and the passengers, and even the engines, for you did not want the engine to receive violent shocks from the road, so that he thought they must employ some form of india-rubber tyre.

The Chairman, having proposed a vote of thanks to Mr. Beaumont, which was carried unanimously,

Mr. Beaumont, in reply, said the recent development in these carriages were necessarily matters of detail, and those who were engaged in perfecting them were not disposed to say much about them. In many cases, although he knew what was going on, he was not at liberty to publish the information. The value of the Serpollet flashing boiler lay in the fact that it was constructed of tubes, which were perfectly happy whether they had water in them or not. They were of considerable thickness, and being surrounded by cast-iron, might remain safely exposed to the heat of the furnace, much of the heat being accumulated in the mass of metal. The advantage was that when steam was not required, it was not being made, and no risk was being run of a sudden pop of the safety-valve. No doubt the tubes would gradually burn away, but that process would be very slow, and of little importance compared to the advantages secured, of generating steam only when required, and of having a boiler which anybody could use, and hardly know it was there. In reply to a question by the Chairman, he said he did not know what temperature the tubes reached, or whether the water in those very small tubes got at all into the spheroidal condition. The noise of the exhaust was prevented in some cases by passing it into the furnace, and out with the products of combustion. Pneumatic tyres had been used for a long time for traction purposes, but not for the heavier work, and for that further experience was required. The Perkins tractor he had described in his lectures last December. It had a Perkins boiler—not a flashing boiler—and was a single-wheeled engine attached to a four-wheel van. The Dion boiler was open to the objection that there was a certain quantity of water on which the fire still acted when the carriage stopped, and, therefore, steam was still generated. No one had a higher appreciation of the work done by Hancock, not only as regards actual achievement, but as indicating what might be done at the present time, and he wished that work was more studied. In the *Times* of that day there was a paragraph calling attention to the successful working of a coach built by Ogle and Summers, which ran from Oxford to Birmingham about 64 years ago. If they could do that with a steam-engine, and if Hancock did it continuously, as we know he did 60 years ago, surely those going into the question now would do well to study their work, and not throw away the advantage of the experience then gained. In those days the coaches or vehicles were much heavier than now, and the weight of the boiler and engine was, therefore, less in proportion to the total weight than in the small light vehicles now aimed at, and of course this introduced new conditions which had to be met. Still there was too much inclination to go to work without taking account of former experience. The carriage described by Mr. De Vigne was really only an engine and boiler on wheels, with a seat or two put upon it. It would not do now to build a vehicle weighing 2½ tons to carry four people.

PUBLIC ADDRESSES ON AUTO-MOTORS.

Mr. Shrapnell Smith at Liverpool.

In connection with the series of Corporation Free Lectures at the Picton Hall, an interesting paper was delivered on the 17th ult. by Mr. E. Shrapnell Smith, hon. local secretary of the Self-Propelled Traffic Association, upon the subject of "Horseless Carriages: their Past, Present, and Future." Mr. Isaac Turner presided over a crowded audience. After reviewing the early history and development of horseless carriages, the lecturer proceeded to describe the latest machines, and introduced his audience, by means of the limelight, to the various French motor-cars, to the Serpollet car (weight, 3½ cwts.; cost, £120), the Beeston-Humber motor-tricycle (weight, 120 lbs.; price, £50), the Pennington motor-bicycle (50 lbs.; price, £50), and other machines. Discussing the suitability of steam, oil, and electricity as motive power, he said that steam had the advantage of having no smell or vibration and great flexibility—that is, high maximum horse-power in order to admit of the negotiation of hills; that oil-motors were noisy, gave considerable smell, always vibrated when going slowly, and were troublesome to manage; and that electricity was the cleanest and easiest to manage but most expensive. Comparing the cost of working, a steam motor-car of the Serpollet type would run 80 miles in 10 hours at a cost of 2*s.* 6*d.*, an oil-motor for 3*s.* 4*d.*, and an electric-car for 4*s.* 8*d.*, taking the cost of electricity at 1½*d.* per Board of Trade unit. The initial cost was heavy, but he looked for a great reduction in the near future, and was confident that English engineers would do for motor-cars what they had done for bicycles and railway-engines. He anticipated great popularity for the motor-cars for touring purposes, and mentioned that four

G 4

friends might tour to Llandudno at a cost for travelling of 3s. The use of mechanical power would lessen the cost of repairing roads, as 60 per cent. of the wear and tear is caused by the horses' hoofs. A demonstration would be held in Liverpool in about two months' time, when it was hoped that specimens of the most practical machines at present made would be seen.

Professor W. H. Watkinson at Glasgow.

A paper on "The Mechanical Propulsion of Tramway Cars" was read on the 18th ult. to the members of the Glasgow Philosophical Society by Professor W. H. Watkinson, of the Glasgow and West of Scotland Technical College. Dr. Eben. Duncan, President of the Society, occupied the chair, and there was a large attendance, which included several members of the Corporation and a number of civic officials.

Professor Watkinson said he had made a special study of the subject during the past 12 years. There had been until recently no pronounced demand in this country for rapid street transit, and on this account comparatively few of their engineers had devoted much attention to this department of engineering, which, owing to recent legislation, promised to become in the near future one of our greatest industries. The great benefits to be derived from rapid street transit were now recognised, and the loss to a city like Glasgow through the lack of it, being seen to be enormous, the public would not long tolerate our present slow and cruel system of horse traction. After reviewing from an engineering standpoint the merits and prospects of the more common systems of rapid street transit—steam engines, compressed air motors, gas engines, oil engines, underground cable, and electric motors—the lecturer showed that recent developments in the knowledge of the principles underlying the design and construction of light engines and boilers had rendered it possible for any of these motors to be successfully and efficiently applied to the propulsion of tramway cars. He gave the preference to gas and oil engines as being the most likely to satisfy all the requirements of a large city. The cable system was the most economical of all when the traffic was very heavy, and he suggested a method of surmounting the principal difficulty in connection with this system—the extension of it to other districts after the plant had been laid down. For comparatively light traffic distributed over a large area, the electrical overhead trolley system was at present by far the most successful. In Glasgow it was absolutely necessary either to spend a large sum on increased stable accommodation and other matters, or to adopt at once mechanical propulsion, and it would probably be best to adopt the electrical method, although it was almost certain that the present overhead system and the present type of motors would be obsolete and so have to be replaced within a very few years. It would also be well to equip, say, the Whiteinch and Dalmarnock sections with cars propelled by gas engines. The outlay involved in the adoption of this would be comparatively small, and cars of this type were working very successfully at Blackpool and other places. The lecture was illustrated with lantern views.

Mr. G. F. Thompson at Liverpool.

"Self-propelling Vehicles" was the title of a lecture delivered on the 23rd ult. by Mr. G. F. Thompson, at the Royal Institution, before the Liverpool Polytechnic Society. After tracing the development of the self-propelling vehicle, the lecturer referred to the absence from the market of motor-cars of English design and make—a deficiency which, he thought, would soon be filled. Comparing the advantages and deficiencies of the horse and the motor, he said the horse adapted itself to greatly varying conditions without much guidance or assistance from its driver, while the mechanical carriage depended upon its manœuvring facilities and the skill and presence of mind of the driver. The motor had the advantage of having no vitality to tire or ailments to contract, while its initial cost was no more than that of a horse, and its keep less. The most objectionable features of large cities were noise and dirt, and the modification, if not the entire removal, of these nuisances, largely due to the horse, was a strong argument for the introduction of motor-carriages. After discussing the arguments for and against steam, oil, and electricity—the latter the perfect motive power for self-propelling vehicles, except with regard to cost—he urged the claims of the hot-air engine, which possessed all the conditions of success, and all the advantages of both steam and oil and some of those of electricity. He was strongly of opinion that the hot-air system offered a good field for inventors in the perfecting of effective and economical motors. The lecture was illustrated by a number of limelight views.

MOTOR FINANCE.

Under this heading our contemporary, *The Statist*, of the 21st ult., in the course of an analytical article on the subject, states that the registrations as public companies of concerns for dealing with this new industry have not so far this year been very numerous, and those where the capital runs into six figures are ten in number, some of them having not yet appealed to the public for capital. The list is as below :—

1896.			£
Jan.	17.	Daimler Motor Company .. .. .. (Prospectus, February)	100,000
March	24.	Britannia Motor Carriage Company .. (Prospectus, June)	100,000
April	21.	Motor Carriage and Cycle Patents	5,000
May	6.	British Horseless Carriage and Motor Cycle Company	10
May	18.	London Electric Omnibus Company .. (Prospectus, May)	250,000
May	14.	Great Horseless Carriage Company .. .. (Prospectus, May)	750,000
May	14.	Pennington Motor (Foreign Patents) Syndicate	100,000
June	5.	British Motor Carriage and Cycle Company (Prospectus, June)	200,000
July	25.	Tavenner Safety Motor Syndicate	3,000
July	25.	Anglo-French Motor Carriage Company .. (Prospectus, August)	300,000
July	31.	Motor Carriage Syndicate of Australia ..	5,000
July	31.	Motors	5,000
Aug.	7.	Davies Motor Company	160,000
Aug.	13.	Central London Omnibus Company	1,000
Aug.	28.	Millet's Patent Motor Wheel and Cycle Company	100,000
Sept.	29.	Esson Motor Company	20,000
Oct.	5.	Coventry Motor Company	10,000
Oct.	22.	Selections	2,000
Nov.	2.	Armstrong-Dove Motor Syndicate	6,000
Nov.	4.	Traffic Syndicate	10,000
Nov.	5.	Yeovil Motor Car and Cycle Company ..	1,000
Nov.	6.	London Motor Car Works	10,000
Nov.	11.	Pioneer Motor Car Syndicate .. .. (Prospectus, November)	10,000
Nov.	12.	London Electrical Cab Company .. .. (Prospectus, November)	150,000

We now deal with some of the above companies in their chronological order :—

Daimler Motor Syndicate.—This Company was formed in May, 1893, with a capital of £6,000. It acquired the goodwill of the engineering business of F. R. Simms, and contracts, including the agency for selling patent rights in England of the Daimler Motoven Gesellschaft. The purchase consideration was £3,000 in shares, and £562 10s. 2d. in cash. On January 14th, 1895, all the capital was issued, and held by 20 shareholders. In April following the capital was increased by £2,000 to £8,000, and at a meeting held December 5th, 1895, confirmed January 2nd, 1896, voluntary winding-up was determined upon. By an agreement of October 24th, 1895, H. J. Lawson acquired for £35,000 the business of the Daimler Motor Syndicate, the Syndicate having previously entered into a contract to purchase the patent rights of Daimler Motoven Gesellschaft's right for United Kingdom and Colonies (except Canada) for £18,750.

This motor, for the patent rights of which £18,750 was paid, seems to be the main basis of the group of companies now dealt with.

British Motor Syndicate, Limited.—This concern was registered November, 1895, with a capital of £150,000, which was increased in May, 1896, to £1,000,000 in £1 shares. In the return filed at Somerset House showing the position at April 30th, 1896, there were, of the then £150,000 capital in £1 shares, seven shares issued to seven subscribers £7 paid, and 135,000 shares issued to H. J. Lawson and others "considered as paid." Many transfers had been effected prior to the filing of this return. There were at April 30th, 1896, in all 33 shareholders, and amongst the principal holdings were :—

	At April 30th, 1896.	Previously disposed of.
H. J. Lawson	99,801	15,200
M. D. Rucker	5,000	25,000
Company Registration Syndicate ..	15,000	—
Somers Vine	1,000	—
E. T. Hooley	Nil	31,500
B. B. van Praagh	Nil	2,500
T. Robinson	1,000	—

The last three persons named appear as having acted as directors of the Syndicate. Two, it will be seen, did not hold shares in April last. Various contracts at different dates had been filed as between H. J. Lawson, as vendor, and the Syndicate. Reference to the Daimler Motor Syndicate particulars above mentioned shows what had been acquired by such Syndicate, including £18,750 paid for the Daimler patents for the United Kingdom and Colonies (Canada excepted), and that Mr. Lawson bought up the business that had been conducted by the Daimler Syndicate.

It would seem that what was represented by 135,000 shares fully paid was as follows :—

	£
Lawson's payment to Daimler Motor Syndicate ..	35,000
Lawson's payment to Baines for rights—Kanes Pennington Motor—for patents for mixing and volatilising gases for United Kingdom and West Australia	35,000
Lawson's purchase of electric motor car patent ..	500
Lawson's payment for letters patent	2,000
	72,500

Having got to this stage of what represents £135,000 "considered as paid," we have the feature that in July a contract was entered into by which the British Motor Syndicate acquired from Lawson, for 12,993 shares, rights of application for two patents. To carry this out, in the following month the capital of the Syndicate was raised to £1,000,000; but a resolution to change the name Syndicate to Company was ignored by the Somerset House authorities. Other contracts for the acquisition of rights in consideration of fully-paid shares seem to have since been made, as an advertisement this week refers to £250,000 having altogether been paid for patents. The advertisement referred to gives some fine illustrations of works erected or to be erected, the owners of which have secured licenses from the British Motor Syndicate.

Daimler Motor Company, Limited.—This undertaking was formed to manufacture and sell the Daimler Motor in this country. It was offered for public subscription in February, 1896, with a capital of £100,000 in £10 shares, paying the British Motor Syndicate for license to use patents in the United Kingdom £40,000 in shares considered as fully paid, or cash in lieu thereof. The return of shareholders on June 2nd, 1896, shows that apparently this Company was rushed for, there being some 700 shareholders, and no shares being mentioned as having been allotted as fully paid.

Great Horseless Carriage Company.—This Company was formed in May last, with £750,000 capital, to manufacture horseless carriages, vans, &c., but not to make motors. A contract was entered into for license to use patent rights belonging to the British Motor Syndicate. The consideration, according to the prospectus, was £500,000 in cash or shares, at the option of the vendors. Eventually, as to £250,000 the consideration was in fully-paid shares. So huge a sum to start a carriage-building business and right to pay for motors did not deter a large section of the public from applying for shares, when the prospectus was issued in May last. A contract with the Daimler Motor Company, the motor manufacturing concern, gave the Great Horseless Carriage Company the concession of purchasing Daimler motors at 10 per cent. less cost than any ordinary customer. The lease of a block of 12 acres, with mill, weaving shed, &c., at Coventry was acquired from the British Motor Syndicate. The return filed at Somerset House in respect of the Great Horseless Carriage Company's capital of £750,000 shows 61,502 £10 shares issued, with 25,000 shares "considered as paid." The Company has, approximately, 3,000 shareholders. In the return as at September 25th there is a curious feature, that only 3,116 £10 shares (say £31,160) stood in the name of the British Motor Syndicate. Among other large shareholders were :—

	£
J. H. Sturmey (director)	13,980
H. J. Lawson (director)	109,920
Company Registration Syndicate	15,670
T. Robinson	4,870
M. D. Rucker	5,500
B. B. van Praagh	2,500
F. Simms	3,870

Company Registration Syndicate, Limited.—This Company, registered in April, 1894, with a capital of £6,000 and powers to promote companies, figures as a large shareholder in both the British Motor Syndicate and the Great Horseless Carriage Company. The Company Registration Syndicate at the end of 1895 had a paid-up capital of £210 15*s.* in respect of 1,637 shares of £1 issued, 2*s.* 6*d.* called up on 1,630, and seven shares fully paid. Among the shareholders figured the following :—

	Shares.
T. Robinson (director of British Motor Syndicate, Limited)	280
C. Osborn	100
H. J. Lawson	100
London Mortgage Banking Company	1,000

Traffic Syndicate, Limited, registered November 4th, 1896, with a capital of £10,000 in £1 shares, has a contract with London Electrical Cab Company. Some of the same seven subscribers as of the Traffic Syndicate have figured in like capacity, or otherwise, in what we may term the Lawson group.

London Electrical Cab Company, Limited.—This concern issued its prospectus last week. It is formed, with a capital of £150,000, to acquire the sole license to work, within the metropolitan area, patents secured from the British Motor Syndicate, the Traffic Syndicate, Limited, receiving for such rights 50,000 shares, or cash in lieu thereof.

In the judgment of the House of Lords delivered on Monday, the action of the Aberdeen District Tramway Company in clearing away the snow from their lines so as to cause an obstruction is a public nuisance and must be interdicted.

Perhaps the best evidence, after all, of the reality and importance of the new movement in favour of horseless vehicles is the substantial air of The Automotor, the new monthly organ of automatic locomotion. The second number, published by Messrs. F. King and Co. (Limited), St. Martin's Lane, is a solid publication of 84 pages, full of articles on topics directly and indirectly connected with the subject at home and abroad, together with a large number of pictures of typical vehicles described in detail in the number. We need hardly say that the number also includes an authoritative account of the proceedings on Emancipation Day, together with a report of the dinner and speeches at the Hotel Métropole.—*Daily News.*

CONTINENTAL NOTES.

Motor Omnibuses for Paris.

The General Omnibus Company of Paris has published the following programme of a competition for designs for an automobile omnibus to replace those drawn by horses now in use. An illustration will be forwarded by the Company to intending competitors as a guide to the general requirements, the omnibus shown being that now in use, the form of which is by preference to be adhered to as much as possible.

Part I.—Motor and Mechanism.

1. *Data.*—(1) The weight of the vehicle fully loaded may be about 6,000 kilogs. (6 tons). (2) It must be able to travel up a slope of 65 per cent. (1 in 15) at a minimum speed of 6 kiloms. (3¾ miles) per hour. (3) The dynamometric trials made by the Company have shown that the starting effort may be 120 kilogs. per ton, and the average tractive force 20 kilogs. per ton. The power of the motor and the adhesion of the driving wheels to be adapted to these values.

2. *Character of the Motor.*—The motor, with its generator or accumulator of energy, may be of any kind, provided that it does not give off smoke, steam, or objectionable odours when at work. It must work as silently as possible. The transmission mechanism must as completely as possible be submerged in a permanent oil bath.

3. *Arrangement of the Motor.*—The motor, while placed so as to be easily accessible, must be enclosed in a sheet metal case to protect it from mud and dust.

4. *Length of Run and Duration of Stoppages.*—The run may be assumed at 6 kiloms. (3¾ miles) and the period of stopping at the ends of the line at six minutes each. If accumulators are proposed, two intermediate stoppages may be allowed for changing them, but not exceeding three minutes each.

5. The present programme may be modified by competitors in any way that they think necessary, if the reasons for the changes are explained.

6. The items to be submitted in competition are:—(*a*) Drawing of the generator or motor; (*b*) descriptive account; (*c*) prices and conditions of construction and delivery. The above programme is independent of the frame of the carriage, which forms the subject of the second, although it is desirable that they should be considered conjointly.

Part II.—Frame with Accessories.

1. *Frame.*—The framing should be of such a character as to enable the present thirty-seat omnibus to be utilised. The total weight should not exceed 4,000 kilogs. in running order without passengers, distributed as follows:—(1) Body of the omnibus, for carrying thirty passengers, 1,000 kilogs.; (2) allowed for motor or generator, 1,800 kilogs.; (3) leaving for the frame, properly so called, 1,500 kilogs.; total, 4,000 kilogs.

2. *Wheels.*—In principle, driving shall be done by the hind wheels, and steering by the front ones, although making both axles motors would be preferable. Constructors are therefore at liberty to adopt any system of driving, providing that the mobility of the forward axle and facility of steering is not prejudiced.

3. *Steering.*—Special steering gear must be provided, allowing the driver to guide the vehicle easily, which must be able to turn in curves of 6 metres—19½ feet—radius.

4. *Brakes.*—Sufficient brake power must be provided to enable the omnibus to be stopped, when running 7½ miles an hour, in 7 metres—23 feet—on a slope of 1 in 15. Each truck must have a brake, utilising, if possible, the motive power in addition to one applied by hand. Sand boxes to be attached to driving wheels front and back, and clearing guards to the front wheels.

5. *Driver's Platform.*—A platform rounded in front with a screen overhead for sheltering the driver, to be placed in front, with the steering wheel, brake, starting, and reversing handles, conveniently arranged for use.

6. *Buffers.*—The vehicle shall be supplied with elastic buffers.

7. *Suspension.*—Particular care must be taken in the suspension arrangements.

8. *Modifications.*—Builders are at liberty to make any alterations in the present programme that they may think useful, subject to the same being explained in their specification. As a preliminary, it is desirable that their attention should be confined to the omnibus carrying thirty passengers—inside and out.

9. *Items to be Submitted.*—Competitors are desired to submit (*a*) a drawing of the carriage; (*b*) a descriptive explanatory memoir; (*c*) propositions for construction, including price, conditions, and time of delivery, &c.

The following dimensions are given in *Le Genie Civil*:—Diameter of axle arms, front, 55 mm.; back, 64 mm.; length of axle arms, 24 cm.; inclination, 1 in 10; number of plates in the springs over front axle, 8; cross spring in the front, 10; over hind axle, 10; cross spring at back, 10 leaves; total length of body, 5·52 m.; surface occupied by omnibus, 12·58 square metres; total length over all, 7·54 m.; width of body, 1·48 m. to 1·56 m.; length of seat per passenger, inside, 0·48 m.; outside, 0·46 m.; weight, empty, 1,970 kilos.; full, 4,050 kilos.

The French Automobile Club Contest for 1897.

As briefly stated in our last issue, quite an original competition has been decided on by the Committee of the Automobile Club de France, and it will be invested with particular interest to manufacturers in this country, as it is international. It is to be decided on July 1st, 1897, and the five following days, within a certain radius of a town situated in the neighbourhood of Paris. Only large and heavy motor-cars will be eligible. The vehicles entered must be able to carry at least ten persons besides the drivers, or to convey goods weighing one ton as minimum. They will compete as if they were on the special services for which they have been constructed, each being provided with a timekeeper approved by the committee. The number of the motor-cars taking part in the contest will not be limited, but each manufacturer can only enter one vehicle of the same type and size, though he may send a dozen of different models and dimensions, and try his luck with all. The entrance fee for each car will be 200 francs up to June 1st, and double that sum afterwards up to the 25th, inclusive, when the list will be closed. Photographs of the vehicles entered, together with the sale price of each, must also be forwarded before the latter date. The total amount of ground to be got over in the six days will be 300 kilomètres, divided into three series, the first consisting of 40 kilomètres, with a stoppage at the end of every kilomètre, the second of 50 kilomètres, with a halt at the termination of every five, and the third of 60, with a stoppage at the close of every 10. Each series will be gone over twice by every vehicle. In the town selected as the centre of the operations a place will be set apart for the reception of the motor-cars, and any repairs that may be necessary will be effected in the presence of members of the committee, who will also carefully watch and take note of the qualities of the various vehicles. Medals and diplomas will be given to those which are found to be best adapted to the purposes for which they have been constructed, and an exhaustive report will be drawn up for publication. In fact, this is to be a thoroughly practical competition of the utilitarian order, under the auspices of the Automobile Club, which is anxious to demonstrate the advantages of motor-cars, not only for promenades, amusement, and journeys, but also for solid and substantial work in the carriage of a number of passengers and goods.

NOTES OF THE MONTH.

JUST as we are going to press we hear that Mr. McKim, of the Duryea Wagon Company, has purchased the rights in Messrs. Roots and Venables' patents.

AT a meeting of the East Ashford Rural District Council, Mr. Amos called attention to the fact that no stipulation was made in the regulations laid down for the traffic of motor-cars, compelling the drivers of such cars to assist a restive horse past. It was resolved to write to the Local Government Board stating that the Council thought it necessary that such a stipulation should be made.

MR. J. M. ANDREW, C.C., who was one of the occupants of the motor-carriage which led on the return journey from Brighton to London, writes:—"It was a most thrilling and novel ride; and when the course was clear in the country roads the first and second cars travelled at a very high speed. They ascended and descended hills with facility, and the skill with which they were steered through the towns and villages, instantly slowing or stopping, or quickening directly the road was clear, showed that they were under perfect control, and conclusively proved that these mechanical marvels can be driven with safety. They caused no inconvenience to anyone on the road, and no accident occurred. It was a record ride not to be forgotten, and made memorable in the infancy of this new industry. It may be mentioned that the cars travelled at the rate of 30 to 32 miles an hour, when the road was good and the course clear. It was most exhilarating travelling against the wind at 30 miles an hour, though it made breathing rather difficult, the sensation being similar to that experienced when riding on a switchback railway car."

WE learn from Ireland that Mr. Walsh, proprietor of the mail cars running between Sligo and Ballina, is making inquiries with the view of placing a motor-car on the road. We have also reason to believe that the new mode of locomotion, thanks to the enterprise of Mr. Maughan, may not unlikely be availed of for the busy traffic between Ballina and Ennismore next season.

MR. A. H. GIBBINGS, the electrical engineer to the Bradford Corporation, has presented an elaborate report recommending the adoption of electricity for the tram system in that city. The total cost of working a 15 minutes' service on the Horton route is estimated at 9·43*d.* per mile per car, and for a 10 minutes' service at 8·25*d.* The total capital cost for the Horton section is placed at £18,660, of which £2,000 is for sheds and offices, £1,600 for four cars at £400 each, and £15,060 for rails, cables, paving, &c. The length of the Bolton section being considerably less, the cost per mile per car is calculated to come out at 25 per cent. more than on the Horton section. If the two sections were worked conjointly, the cost would probably be reduced to 8*d.* per mile per car. The additional capital required for a 10 minutes' service, as against a 15 minutes' service, would be small compared with the material reduction in the mileage cost. As for the effect on the electricity works a charge of $1\frac{1}{2}$*d.* per unit would yield a profit of $\frac{1}{2}$*d.* per unit, or an income of £277 1*s.* 8*d.* on a sale of 133,000 units in the year, which would be gained without further expenditure on the works.

THE directors of Messrs. Campbells (Limited), Aberdeen, have under consideration the abolition of the large number of horses employed by them, and propose to substitute automotors in their stead.

THE Joint Committee of the county and burghs of Dumfries contemplate the purchase of an automotor for the use of their sanitary and weight inspector.

NOW that everybody is talking about motor-cars, and a wonderful vista of development is presenting itself to the eye of the sanguine, it will interest many to learn that half a century back a motor-car used to run for evening pleasure trips on the turnpike road from Neath Abbey. The car was built at the then celebrated Neath Abbey Ironworks. It was driven by steam, which was generated in a small vertical boiler, and carried from four to six passengers.

A GASOLINE inspection car for railways has been introduced in America. It runs along the rails at a speed of 15 miles an hour, and is very convenient. The car was built by the Daimler Motor Company, of the United States.

THE motor-car as an advertising medium does not find favour with the Leeds Corporation Carriages Committee. At a meeting of this body a letter was read from a large firm of cocoa manufacturers, asking to be allowed to continue to run a motor-car along the streets of the city as an advertising vehicle. Temporary permission to do this had been previously granted, but the committee, however, fearing that if such a method of advertising were permanently allowed they would be deluged with applications from other traders, deemed it advisable to pass a resolution prohibiting advertising of this kind. They have no objection, however, to the firm using the motor-car for carrying on ordinary trade purposes.

THE necessary steps preparatory to bringing the scheme for providing the township of Bray with a system of electric tramways connecting the main street with Bray Head before the Privy Council have been taken.

AT a recent meeting of the Sedgley District Council the general manager of the Dudley, Sedgley, and Wolverhampton Tramways Company, Mr. Hatch, attended the meeting, and gave an explanation respecting the proposed scheme for the adoption of electric tramways in South Staffordshire district, and also asked the Council to support it. He explained that an electrical engineer would visit the district. The Council expressed their willingness to confer with him with respect to the proposal to adopt the electric mode of traction.

The Liverpool Tramways Company are taking the necessary steps to obtain powers which will enable them to provide the public of Liverpool with expeditious mechanical traction on all their tramway routes. The Parliamentary notice seems to point more especially to electrical traction by means of overhead wires in the less densely-populated parts of the town, and by means of underground wires in the central districts.

At a special meeting of the Coseley District Council on the 18th ultimo, an engineer of the British Electrical Tractions Company attended, and stated that the Company were entering into negotiations for revolutionising the tramways in South Staffordshire by obtaining power to adopt overhead electric traction in lieu of steam. It was proposed to spend a million of money in reconstructing and extending the tramway, and it is believed the undertaking will prove remunerative, as by means of electricity a 10 minutes' service can be guaranteed.

General Frost will be one of the best allies of the motor-car. When during his skirmishing advance the London streets are strewn with fallen horses, when nervous people dare not drive, and the hearts of the sympathetic are wrung by the painful sights they witness, many will gladly surrender to the motor-car, which cannot stumble and cut its knees, or fall and have to be shot.

The directors of the Dublin and Kingstown Railway have determined to apply for powers to use electricity instead of stoking coal on their line in future. Their traffic is large and heavy, but they consider electricity would be cheaper for their purpose, and it seems that trains can be more easily stopped on the electric principle than by the system at present in use. If this Company succeeds in the venture, no doubt others will rapidly follow in their steps, but, of course, in the first instance it must be more or less experimental.

According to statistics just issued concerning the development of electric tramways in Europe during the past year, Germany possesses the greatest mileage of lines; France comes second, and England a bad third. Of the 111 lines now in operation, it is noteworthy that no less than 91 are worked on the trolley system—that is, with overhead wires.

The Links and Parks Committee of the Aberdeen Town Council have, without a dissentient, declared in favour of electrical cars, and an effort is to be made to introduce them at an early date.

The Blackpool Town Council have at length approved their big scheme for improving the Promenade. The proposal is the result of a tour of the watering places in England recently made by several members of the Council. It provides for a 15-feet footpath on the easterly side, a roadway 55 feet wide, a 10-feet island footway, a double line of electric tramways, and a Promenade 42 feet wide on the outer or westerly side, the whole width being not less than 140 feet. The estimated cost is £300,000.

At a ratepayers' meeting it was, on the 24th ult., unanimously resolved to adopt electric power for the Bristol tramways. A keen fight, however, took place over a proposal to compel the Company which works the lines to obtain its current from the municipality. After a prolonged discussion this was defeated, the supporters of free trade in the matter gaining a decisive victory.

The Stockton Rural District Council has had before it an application from the Middlesbrough Imperial Tramways Company for permission to reconstruct the tram lines in the Council's district (extending from Stockton borough boundary to Norton village), and to work the cars on the electric trolley system. The whole scheme is to amalgamate the Middlesbrough and Stockton companies, to carry the line from the terminus at Newport, Middlesbrough, to the terminus at Thornaby, thus making a continuous line from the Royal Exchange at Middlesbrough to Norton Green, viâ Thornaby and Stockton, and extending over a distance of about seven miles. The Council referred the matter to a committee for consideration.

Mr. Herkomer's great vivacity and determination to be of artistic assistance to everybody has made him turn his attention to the motor-car. Of course, Mr. Herkomer, in common with many other people, thinks that the form of the car is all wrong, and that the designers have failed to grasp the fact that a horse would not finish off the extremity of the vehicle. The master of Bushy's suggestions point to a form of vehicle which would approximate more nearly to the outline of a boat than anything else. He would allow craftsmen to exercise their skill on the motor-car, and secure for it a decorative appearance that will tend to make the streets picturesque.

The *Financial News* is responsible for the statement that the profits of the Dunlop Company for this year will not only reach the £600,000 which the prospectus stated to be probable, but that, from the orders in hand, profits amounting to £1,250,000 are certain. Our contemporary adds: "It is simply stupendous." In this we agree—but is the forecast an accurate one?

Mr. Charles Allan, the proprietor of the omnibuses plying between Aberdeen and Cluny, is inquiring for motor-cars to replace his present omnibuses. The kind of vehicle Mr. Allan requires is one that would carry about thirty-five passengers and a reasonable weight of luggage, and the difficulty, if it could be called a difficulty, would be to get a motor of sufficient power. At present the Aberdeen and Cluny 'buses, which are of the capacity indicated, are drawn by four horses, and Mr. Allan calculates that the motor would require to be of 8-horse power. Petroleum would be used for fuel. There are some rather stiff inclines on the route, particularly in the first five miles from Aberdeen, but it is not considered that these would be any impediment to the traffic.

The Ealing District Council have resolved to oppose the application of the London United Tramways Company for power to run their lines through Ealing.

MR. JOHN RICHARDSON, M.I.C.E., one of the managing directors of the firm of Robey and Co., the famous engineers of Lincoln, has been interviewed on the question of automotors. After passing in review the past history of the subject, and detailing some of the early experiences of his firm in the matter, he appeared to be somewhat dubious of rapid developments being made. His views may be best judged by the following expression of opinion:—"I think they would serve admirably for distributing light goods. They could be used by commercial travellers with samples, and possibly would be useful for the conveyance of passengers in some districts where there are no railways. But Lord Winchilsea's idea is absurd that automotors would answer the purposes of light railways for the conveyance of farm produce. It is very unlikely that, as an article of luxury, they will ever be used in the place of a carriage and pair. Either petroleum or steam engines require more attention and care than ordinary users would ever bestow."

SIR WM. ERROL, M.P., the well-known engineer, in addressing his constituents at South Ayrshire, said "He looked to the development of road locomotives or motors to do a great deal in the way of assisting the farmer. By their use he would be brought into closer contact with consuming centres, and in more remote districts with railway stations." (A voice: "What about the horse dealers?") "Well, the horse dealers could do as the rest did. When the railways were constructed there was a great outcry about horses being done away with altogether. The result had been, however, that more horses had been used in connection with railways than had been used before them. He thought that a similar experience would follow the introduction of the motor-carriage."

THE Edinburgh Town Council are considering the advisability of adopting some of the more recent mechanical motors, in view of the tramway extension to Portobello.

THE Rathmines Tramway Scheme—described in a recent issue—has been rejected by the ratepayers, and consequently falls through for this year.

AT a meeting of the Aston Urban Council, held on the 1st inst., the Clerk announced that he had received a communication from the City of Birmingham Tramway Company, notifying their intention of applying to Parliament for powers to construct a tramway along Summer Lane, up Alma Street, across High Street, Aston Newtown, down the Witton Road to Bevington Road. Mr. Sidney Fisher asked what the motor power was to be. The Clerk said he was not in a position to say. Mr. Fisher: I only wanted to know, as I shall certainly oppose the adoption of steam. The matter was referred to the Highway Committee.

As the local authorities object to tramways being laid in Llandudno, the neighbouring lines intend to fill up the gap by supplying a service of motor-carriages. The promoters estimate that six or seven vehicles will be sufficient at present; but in the summer these will have to be increased to about 40 or 50.

AT a recent meeting of the Valley Bridge Sub-Committee of the Scarborough Town Council, the Committee having considered the question of motor-cars or light locomotives, and other light vehicles passing over the bridge, and the tolls that should be taken for the same respectively, it was resolved to recommend that application be made to the Local Government Board by provisional order to alter or amend Sections 41, 44, and 45, and Schedule A of the Scarborough Valley Bridge Company's Act, 1864.

THERE does not at first sight seem to be any very clear connection between horseless carriages and sparrows. Our contemporary, *Lightning*, however, discussing automotors, asks, "What will become of the London sparrow? When the nosebag has departed from the cab-rank and the ordure of the streets exists no more, his precarious livelihood will be lost. He will peak and pine and slowly starve, till, faint and emaciated, he will fall, a disappointing morsel, into the claws of the London cat." 'Tis a sorry picture, but, we hope, a too dismal one. The sparrow may be able to adapt himself to circumstances, and cultivate some new tastes.

K. S. RANJITSINHJI is tempting Nemesis. To top the cricket record, to have at least three pet names with the public, to have a clause all to himself in a New South Wales Act of Parliament, and now to possess a motor-car, which he has ridden with a firm and graceful seat all the way to Cambridge—these things are too much for one young man in one year.

THE Dublin Cycle and Motor-Car Exhibition is filling up with rapid strides. The latest exhibit has been secured through the energy of Lord Mayo, that is the Great Horseless Carriage Company. They have signified their intention of showing their latest motor-cycles, carriages, and the famous car that won the great motor-car race between Paris and Brussels. Mr. R. Wilson, of Dublin, the secretary, has been working the exhibition in London for the past ten days, and in every case he has met with great courtesy and support among the English manufacturers.

PLANS, &c., of an electric tramway for Dundalk and Blackrock have been lodged with the local authority in compliance with the Act of Parliament. The Tourist Development Syndicate are seeking for a Provisional Order to enable them to carry out the projected work in conjunction with which they hope to establish a system of public and private electric lighting for Dundalk.

IN the course of an interview which a *Daily Telegraph* correspondent recently had with Mr. Edison, the following paragraph occurs:—"We began with the subject of the propulsion of motor-cars. For these, at present, he considers that the best form of motor lies between steam and the gas engine. The advantage might at any moment change to electricity, but such an occurrence depended wholly upon the discovery of some more efficient and stable system of storage batteries. Excessive weight, cumbrousness, and other drawbacks stand in the way of stored electricity as a motive power."

IN our last issue we fully described the motor vehicle run to Brighton, and have now only to briefly record the fact that most of them returned on the day we published, viz., the 17th ultimo. Taking advantage of some rather wild statements which were made, the London evening papers described in vigorous descriptive matter a wild race which ensued on the way to the metropolis—the carriages careering along at a mad speed of from 30 to 32 miles an hour. We understand, from one who took part in the journey, that although a few high speeds were undoubtedly reached for short stretches of level and down hill roads in unfrequented places, the mean speed was not excessive. The risk is too great, however, for anyone to again tempt the authorities—or rather, we should hope it is.

MR. J. A. WHEELER, of Natal, is sending out to Mafeking some motors on trial in order to test whether they can be utilised for service in dealing with the transport of food among the natives of Rhodesia.

WHIP-MAKERS have been deploring the advent of the motor-carriage, on the assumption that with its arrival their trade would come to an untimely end. It appears, however, that the street-boys of London have found out that as there is no danger of "whip behind" in the new vehicles, they can enjoy unlimited free rides without danger. A judicious application of a few electrical shocks when they can be conveniently applied will soon dissipate confidence on the part of the cockney gamins.

IT is stated that at present there are in use in America from 150 to 200 miles of street tramway lines, the joints of which have been all welded, either by the electrical or the "cast-welding" system, so that the rails are actually continuous. As to the success of this system, the testimony is rather conflicting; but it is obvious that the difficulties to be encountered are serious.

AT the close of the Aberdeen Town Council business on the 7th inst., the members of the Links and Parks Committee met, and appointed Councillor Wilkie (convener) and Councillor Gray as a deputation to visit London and report on the motor-cars in operation there.

A PRIVATE company has been formed in Falkirk with the object of acquiring two motor cars, to be used in conveying passengers from the Cross of Falkirk round by Camelon, Larbert, Stenhousemuir, Grahamston, and *vice versâ*. The shares, which are of £10 each, have all been taken up privately. The secretary of the company has been in communication with London to ascertain what kind of carriages would be best adapted for the local roads. Each is to hold from 25 to 30 people. Should the company prove a success a third car will be purchased.

THE management of the Grand Colosseum Warehouse Company of Glasgow have put on the streets of that city a motor-car for business purposes. It is the first of its kind to run in Glasgow, and, so far as is known, the only one in Scotland. The car is of French manufacture, and is driven by a Daimler oil-motor.

LAW REPORTS.

Mr. Humber and the British Motor Syndicate.

IN the Chancery Division, on the 2nd inst., before Mr. Justice Stirling, Mr. Graham Hastings, Q.C., moved, in an action Humber and Co., Limited, *v.* Thomas Humber and the British Motor Syndicate, Limited, that Thomas Humber be restrained by injunction, until trial or further order, from acting as a director or other officer or servant of the defendant Syndicate, and from being connected with or advising or assisting in the manufacture or sale of cycles or cycle accessories or any business cognate thereto, except on behalf of the plaintiff Company, in breach of an agreement of January 28th, 1892, between plaintiffs and the defendant Thomas Humber; and that the Syndicate be restrained from employing the defendant Humber as a director or other officer, and from representing by advertisement or otherwise, that he was a director. There being no appearance for the defendants, his lordship granted the injunction over Friday; but, soon after, Mr. Butcher appeared for the Syndicate, and asked and obtained leave to re-open the matter later in the day.

Just before four o'clock, Mr. Butcher again mentioned the case. He said his clients had not been able to communicate with Mr. Humber, who was, he believed, at Nottingham. He was, therefore, not in a position to argue why the injunction should not be made; but he understood there were negotiations between the plaintiffs and defendants as to bringing the matter to a conclusion. Unless some such settlement could be arrived at, he took it that his lordship would continue the injunction; but he would ask that it should only be until Thursday, by which time he hoped to have instructions from Mr. Humber.

Mr. Hastings said that the only injunction he had obtained was to restrain the defendant from acting as a director of the defendant Company till over Friday; and if Mr. Humber was at Nottingham the injunction over Friday would not inconvenience him much.

Mr. Butcher said that there might be a board meeting on Thursday, which he might desire to attend.

His lordship said that the motion had been brought on upon short notice.

Mr. Hastings' clients at this stage entered the court, and it was ascertained that an arrangement had been come to between the parties, that nothing should be done till over Friday, the defendant Company undertaking to pay the solicitors and clients' costs of yesterday's proceedings.

On this undertaking, the matter stood over until the following Friday, without any injunction. On that day, when the matter came on, Mr. Graham Hastings, Q.C., for the plaintiffs, stated that the parties had come to terms; and Mr. Butcher, for the defendants, said that the passing difficulties had been arranged to the entire satisfaction of all parties. In these circumstances, his lordship, by consent, made an order staying all further proceedings in the action.

Alleged Infringement of a Patent.

THE Pneumatic Tyre Company (Limited) *v.* the East London Rubber Company was an action for an injunction and an inquiry for damages in respect of an alleged infringement by the defendants of the plaintiffs' patent (No. 14,563 of the year 1890), the invention of Mr. Charles Kingston Welch, for improvements in rubber tyres and metal rims or felloes of wheels for cycles and other light vehicles. The hearing of the case occupied the Court for several days, and at the conclusion his Lordship reserved judgment.

Mr. Moulton, Q.C., Mr. Roger Wallace, Q.C., Mr. J. C. Graham, and Mr. A. J. Walter appeared for the plaintiffs; Mr. Bousfield, Q.C., Mr. Terrell, Q.C., Mr. C. E. Jenkins, and Mr. Munns for the defendants; and Mr. Micklem and Mr. W. E. Hume Williams held watching briefs for the defendants in other actions.

Mr. Justice Romer, in giving judgment on the 8th inst., said that he had come to the conclusion that the patent was valid; but as the case was one of considerable importance, he would give his reasons for arriving at this conclusion at length. He went in detail through the points of disconformity between the provisional and the complete specification, and decided that there was no such differeuce between them as to invalidate the patent. This matter of disconformity between the two specifications had been the principal thing contended for by the defendants. The patentees, in drawing up the complete specification, had not gone beyond the limits allowed to the patentees under the circumstances. His Lordship having disposed of other points which had beeu raised on the part of the defendants, said that his holding was that infringements having been proved the plaintiffs were entitled to the usual relief, and he granted an injunction against the defendants, an inquiry as to damages, aud an order to pay costs; but on the application of the defendants he stayed execution conditionally upon an appeal being forthwith entered.

Judgment for the appellants.

Damages against Motor-Carriage Owners.

BEFORE Judge Shand and a jury, at Liverpool County Court, on the 7th inst., John M. Sutherland, hay and straw dealer, claimed damages from the North of England Horseless Carriage Company, for injury caused to his pony and trap in consequence of the former having beeu frightened by a motor-car belonging to defendants. The plaintiff stated that the motor-car made a loud noise resembling the sound produced by a threshing machine, and it so frightened his pony that it bolted and collided with a van. The jury found for the plaintiff, and awarded him £12 10s. The owner of the van also brought an action against the Company, and he was awarded £5.

BUSINESS NOTES.

ONE of the first charging stations put down in England for the direct purposes of charging accumulators for electric motor-cars has just been completed at the White Hart Hotel, Reigate, by Mr. W. R. Wakley, the chief engineer of Maple and Co., the well-known Tottenham Court Road firm The dynamo is by John Turner and Sons, Denton, and the whole of the plant is of a high class.

MOTOR AWARDS OF MERIT.—The following notice was, with many others, crowded out of our last issue:—In connection with the exhibitiou of motor carriages at the Crystal Palace awards have been made as under: Diploma for gold medal—C. C. Burrell and Sons, for light compound traction-engine; Emile Delahaye, for benzoline-carriage; Mons. Serpollet, for steam-carriage; the Steam Carriage and Wagon Company, for steam-van. Diploma for silver medal—Société Franco-Belge, for steam-brake; L'Hollier, Gascoigne, and Co., for benzoline-carriages. Diploma for bronze medal—Arnold's Motor Carriage Company, for benzoline-carriage. The report by the jurors is signed by W. Worby Beaumont, M.I.C.E., Walter Hancock, M.I.E.E., H. A. O. Mackenzie, C.E., and Alf. R. Sennett, A.M.I.C.E, Hon. Executive Commissioner. "Although none of the vehicles exhibited approached that degree of perfection which would place them beyond adverse criticism," the jurors consider the prospects of benzoline motor-carts hopeful, and of steam motor-carts more hopeful. As to electric-carts, "the jurors considered it matter for regret that no electrically-propelled vehicle had been submitted for trial."

MR. CYRIL D. WARE, of Kimberley, has arranged jointly with Mr. Julius Harvey, of 11, Queen Victoria Street, London, a motor-carriage agency for South Africa.

THE DRAKE MOTOR.—The Drake patent motor, which will shortly be put on the market, is suitable for carriages, omnibuses, and vans of every description. A carriage may be seen at work in the course of a few weeks at Mr. W. Drake's private residence, South Road House, South Road, Clapham Park. The works, *pro tem*, are situate at 64, Westbourne Grove, W.

SOUTHAMPTON AND MOTOR-CARRIAGE BUILDING.—Acting in conjunction with a patentee who lives at a distance, but whose special type of steam launches is well known in Southampton Water, Messrs. Andrews, Brothers, of the Above Bar Carriage Manufactory, have now in hand the construction of a motor-car, which, whilst designed in strict accordance with the regulations of the Board of Trade, presents many features distinguishing it from any such conveyance yet built. It is intended for the carriage of goods, and will be fitted with a powerful motor. Oil will supply the motive power, but it is claimed that the method of its application in this instance will be free from the disadvantages observable in other cases, whilst the car will be capable of propulsion either backwards or forwards. The large capacity of the car will, it is thought, render it of great service for commercial purposes.

MOTOR-CAR REGULATIONS FOR SCOTLAND.

LORD BALFOUR, Secretary for Scotland, has issued regulations, applicable to Scotland, under the Locomotives on Highways Act, 1896, with respect to the use of light locomotives on highways and their construction, and the conditions under which they may be used.

Article 4 of the regulations states that a person driving or in charge of a light locomotive when used on the highway, "shall not, under any circumstances, drive the light locomotive at a greater speed than ten miles an hour. If the weight unladen of the light locomotive is one ton aud a half, and does not exceed two tons, he shall not drive the same at a greater speed than eight miles an hour, or if such weight exceeds two tons at a greater speed than five miles an hour. Provided that whatever may be the weight of the light locomotive, if it is used on any highway to draw any vehicle he shall not, under any circumstances, drive it at a greater speed than six miles an hour. Provided also, that this regulation shall only have effect during six months from the date hereof, and hereafter until the Secretary for Scotland otherwise directs."

OUR HORSE POPULATION.

THE inauguration of the new era in locomotion lends special interest to the live stock statistics contained in the latest returns issued by the Board of Agriculture. Farmers have been encouraged to devote a share of their attention and capital to horse-rearing, and the money which used to be wasted on Queen's Plates is now in fact as well as in name expended in promoting the improvement of the breed of horses. The change, however, does not seem to have been productive of any marked result. In 1895 there were in the United Kingdom 2,112,207 agricultural horses of one kind or another, including unbroken animals aud brood mares. In 1896 the total was 2,115,517, or only 3,350 in excess of the previous year. A growth in the stock of brood mares, however, seems to indicate that an extension of the horse-breeding industry was in progress. The figures for the four countries composing the union are as follows:—England, 1,190,038 horses of all descriptions, against 1,184,747 last year; Wales, 155,965, against 153,158; Scotland, 206,554, against 207,323; Ireland, 553,320, against 557,139. Scotland and Ireland, it will be seen, show decreases. It is in England and Wales that the development in horse-breeding has taken place.

H 4

NOTICES.

Contributions and articles likely to prove of interest to our readers will receive due attention, but in all cases the name and address of the writer must be given, not necessarily for publication.

All matter intended for publication should reach us not later than the 10th of each month. Stamped envelope must be sent if the manuscript is required to be returned.

All Advertisements should be sent to the Advertising Department, F. KING AND CO., LIMITED, 62, *St. Martin's Lane, London, W.C., where Advertising Rates may be had on application.*

The Annual Subscription is 7s., including prepaid postage to any part of the world.

Cheques and Post Office Orders should be made payable to F. KING AND CO., LIMITED, *and crossed London and County Bank; otherwise no responsibility will be accepted.*

THE AUTOMOTOR AND HORSELESS VEHICLE JOURNAL *can be obtained through* MESSRS. W. H. SMITH AND SON, *and at* WILLING AND CO.'s *bookstalls.*

When any difficulty is experienced in procuring the Journal from local newsvendors, intending subscribers can obtain each issue direct from the Publishing Office, by filling up and forwarding, with remittance, the Subscription Form accompanying the Paper.

The Automotor and Horseless Vehicle Journal.

A RECORD AND REVIEW OF APPLIED AUTOMATIC LOCOMOTION.

DECEMBER 16TH, 1896.

ANSWERS TO CORRESPONDENTS.

J. E. P. (Wolverhampton).—In all cases where applications are withdrawn before allotment the directors are bound to refund the money sent. After allotment a contract exists between the Company and the applicants, which, speaking generally, can only be dissolved by an action at law, when substantial misrepresentation must be proved.

S. A. (Toronto).—We will send the specification as you are so exceptionally situated.

I. ZINGARI (Leeds).—Impossible; it is highly inflammable and dangerous, even at ordinary temperatures. Its use is prohibited in this country, except under almost impossible conditions.

MERIVALE (Manchester).—(1) No. (2) We have inquired at the address given, but without any satisfactory result.

J. W. (Ebberston Lodge, York).—Thanks for your suggestion; which shall be carried out in an early issue.

MOORE (Camberwell).—The publisher will attend to your request.

J. DOUGLAS (Liverpool).—Write to Mr. Shrapnell Smith, Royal Exchange, Liverpool. He will give you every information.

BUTCHER'S CART (Darlington).—Our advice is to wait a little. Prices will be fixed shortly. You will find the addresses of agents in our advertisement columns.

JAMES G. (Bedford).—The local authorities have only the power to make recommendations—the regulations are, thank goodness, only issued by the Central Board.

P. G. (Faversham).—We cannot reply to such communications by post. The matter is one for a patent agent; the information sent is too meagre to enable us to advise off-hand, and you can hardly expect us to finish your vaporiser for you, and then experiment. We have returned it to your order.

HYDRO-CARBON (Portsea).—Write to Mr. Dugald Clerk, Chancery Lane, London. He can—and may—give you the information.

J. JOHNSON (Cardiff).—Always glad to consider any communication on special subjects, but cannot make any more permanent additions at present.

PETER M. (Fulham).—We have sent you the photos for use at your meeting. Return when done with.

FAIR MAID OF KENT.—Why not have the common courage to sign your name and give your address when writing a scurrilous attack upon one of your neighbours? The anonymous libeller is beneath contempt, and your letter—carefully type-written to avoid risk—has gone into the waste-paper basket.

ERNEST S. (Wolverhampton).—Do not pay the premium. Mushroom establishments for the sole purpose of obtaining apprentices to the new industry are growing up in several directions. The advertiser is a fraud.

ANTIQUITY (Belfast).—Thanks; but we are looking forward, and prefer to leave all but the most interesting of the old types buried in the ancient volumes you possess.

PATENTEE (London).—The statement is obviously incorrect.

MOTOR (Brixton).—As it is an old Company there would not be any statutory meeting; that was held long ago.

W. WYNSTANLEY (Plymouth).—You would find it difficult to get on without a properly-drawn partnership deed. Printed forms are cheap but nasty; consult a respectable local solicitor. The costs will not be great, and you will save both worry and expense in the end.

ALTER EGO (Devon).—Respect the rights of the other man—while maintaining your own.

W. GIFFARD (Salford).—Your best course would be to write to one or other of the agencies advertised in our columns.

H. J. STEVENS (Salisbury).—The time occupied would be about three-quarters of an hour (rather less in your district); weight about 15 cwt. For other particulars you had—if only for the sake of comparison—better write to some of our advertisers. We could only give you an approximate idea of the cost.

*** *Although this issue is mainly printed in comparatively small type, extreme pressure on our space causes us to omit or reduce many items which have been sent for publication. Several letters from correspondents, reports of meetings, and interesting articles have had in consequence to be either condensed, held over, or—where the matter was only of current importance—hopelessly crowded out. We are taking steps which will, we hope, obviate this necessity in the immediate future.*

THE BRITISH MOTOR SYNDICATE (LIMITED).

A Discreditable Prospectus.

THE promoters of public companies often—in fact, despite the unsavoury disclosures which at times take place as to their doings, we think we may replace the word "often" by "mostly"—do good service by bringing investments before the public in such a shape that the large mass of unemployed capital in this country may be beneficially used in developing some new industry or discovery to the general benefit of the community. No one has a right to complain that promoters occasionally make large profits, for they always run considerable risks. Again, too, if they make mistakes, and the reports of experts are not fulfilled, all but the investors in the particular company which has been unsuccessful are, as a rule, charitable enough to condone the failure with the remark that "those who seek for high dividends must be prepared to risk the losses."

All this—and even more—we are prepared to advance in the promoter's favour; but when a prospectus is issued teeming with mis-statements, bolstered up with assertions which are only made tenable for the moment by a deliberate suppression of facts—and when, too, the sums sought to be extracted from the pockets of investors amount to no less than three millions sterling, the mildest term which can be applied to those who have concocted such a document is that they have been guilty of discreditable conduct.

The British Motor Syndicate (Limited) was registered about 12 months ago with a capital of £150,000—out of which no less than 135,000 shares were issued as fully paid. This capital was afterwards—as shown in another column—raised, by the simple expedient of a resolution, to a nominal capital of £1,000,000. As we have not seen the memorandum of association of this Syndicate, we cannot speak positively of its objects; but we know from the public actions and expressions of those connected with it, that they made a show of purchasing a monopoly of all the patents connected with motor-carriage work, and of exploiting the new Act of Parliament for their own advantage. They undoubtedly acquired many patents — the approximate value of which we will presently deal with — and with the assistance of the splendidly-boomed trip to Brighton, they centred universal attention upon the industry in which we are interested.

For their energy and enterprise the shareholders in the British Motor Syndicate are entitled to all the profits they can legitimately make. One of the first statements made in the prospectus is that the shares are freely dealt in at £3, and that—to quote from another page—"**THE EXCITEMENT** (*sic*) in the share market, the immense premiums now being realised, and enormous dividends paid in kindred industries, sufficiently indicate what the immediate future of the Company is likely to become." This is a deliberate mis-statement; the shares in motor-carriage companies are almost unsaleable on the Stock Exchange, and a member of the Committee advises us that he does not know a single jobber who makes a "book" in them. Let that be as it may. We would ask one pertinent question, viz., does any sane man imagine that if the shares of the Syndicate were being freely dealt in at £3—or, in fact, at any reasonable sum—those connected with it would spend tens of thousands of pounds in advertising a prospectus to sell them at that price, when they could dispose of them on the Stock Exchange by merely paying brokerage to a member.

We next come to a line setting out "**SUCCESS CERTAIN. BUSINESS HOUSES DECIDE.**" The names of some half-dozen of the most noted advertising drapery houses are set out as having ordered vans. We know why. Not because they are convinced that the Syndicate's carriages are the best, but because they naturally desire publicity for their wares. They buy "living pictures" with the same objects. This argument, as an inducement to invest any part of the £3,000,000 asked for, may be dismissed with the contempt it deserves. In the next place we are favoured with an abbreviated list of patentees, and the chief names which would weigh with an investor in this country are those of our contemporary the *Engineer* and the well-known firm of Crossley Brothers, of Manchester, ostentatiously set out as the makers of the "Otto" Gas Engine. Needless to state, both of these, in a prompt and contemptuous manner, repudiated the slightest connection with such a misleading document.

With the directorate we have little to do. We may take it that, as a general rule, they have their own private ends to serve. We regret, however, to see on the front of the document the name of Prince Ranjitsinhji. His popularity with the great body of Englishmen has evidently been the attraction for the promoter, but his knowledge of automotors is an unknown quantity. As all-round sportsmen and cricketers, we heartily wish him out of the tight place he is in now that he has started to play at a game he does not in any way understand. At Lord's, the Oval, or Hove, he is—next to "W. G."—our idol, but in the region of Holborn Viaduct he will find that Mr. Promoter is trickier than George Lohmann, and that his pace is faster—if his delivery is not quite as fair—as Tom Richardson at his best.

We next pass to the dividends which have—as stated—been paid by the Syndicate. These are set out as follows:—

"May—10 per cent., or at the rate of 30 per cent. per annum.

"July—30 per cent., or at the rate of 60 per cent. per annum.

"September—100 per cent. bonus in shares of licensed companies, which, if taken at market prices, equals a total of over 100 per cent. per annum on the issued capital."

These figures, which are evidently intended to attract the unsuspecting public, are allowed to stand as stated. No certificate is given; the verification of the figures by an auditor is evidently considered as an unnecessary detail; while, whether these alleged dividends were paid on a capital of £3,000 or £3,000,000 is considered a matter of such an immaterial purport that the figures are not given. Again, whether the actual amounts were in cash or in shares in allied companies is not indicated. We could go on in this way through every page of our issue—the scheme sketched out is all in the air. "Immense Prospects," set out in big black type, is the keynote which pervades the whole document. Subsidiary companies have been formed; these, with their more or less paper capital, offer to pay huge premiums for the use of the Syndicate's patents, and on this slender basis we are to put up our £3,000,000—out of which £2,700,000 is to go to the vendors.

Two million seven hundred thousand pounds is a good round figure—even in this era of monthly millionaires. Let us endeavour to see what the shareholders are to obtain for the money. The only real asset which they acquire is certain patent rights, the dates and titles of some of the specifications being set out in the prospectus. We should have expected that under these circumstances some expert opinions would have been obtained as to the possible validity of the letters patent. Just as a certificate from a leading firm of auditors would have been advisable as to the profits which have been earned, surely an opinion from an expert patent authority might have been expected as to the value of the specifications. But, no. The list is in the prospectus, the Syndicate have bought the patents: the public must take it on their authority—their *ipse dixit* is sufficient.

It has seemed to us a pity that, for the sake of a little trouble and expense, this defect should remain; we have, therefore, obtained all the patents set out which can be procured, and, in addition to examining them carefully ourselves, have submitted them to the highest authorities at our disposal.

The opinion we have obtained is unanimous in its purport. The Syndicate state that they possess all the master patents in connection with motor carriages, and that they will resist all attempts at infringement. If they go into Court we will not directly attempt to anticipate the judicial decision, but counsel and patent agents are at one in the statement that master patents they have not — every oil-engine they work or lease on royalty has for its basis the well-known Otto engine, and can only, at the best, hold good for improvements in respect of details specifically as set out and claimed.

Practically the only point in reference to the oil-engine of to-day in which a master patent could be obtained would relate to a novel method of vaporisation, which would ensure the complete combustion of all the components of the heavy and safe hydrocarbons. It is certain that such a patent is not in the possession of the British Motor Syndicate. It is, however, very probable, from information which has been placed at our disposal, that one of the many private firms experimenting on this important point has been very nearly successful, and may reap a good reward for their pains. The Syndicate possesses many useful designs for various parts of motors and carriages, which have been patented. Whether they would be sustained in a Court of Law, however, is much more than doubtful in more than a moiety of those examined; but they would form an admirable nucleus with which to start a factory to build carriages on the Continental lines of to-day.

But is this uncertain asset worth £2,700,000? The promoters can answer the question for themselves. The Great Horseless Carriage Company (Limited), one of their own bantlings, is the owner of one half of the rights in these patents. In spite of the "furore on the Stock Exchange in favour of these ventures," the £10 shares in this Company can be bought for less than £3, so that as it was capitalised originally at £750,000, the market value is now reduced to some £225,000. Why should the public be asked to give £2,700,000 for exactly the same property as they could, at the date of the issue, obtain for one-twelfth of that sum? On that valuation the £3 shares offered would have been worth exactly 5s. each—and in our opinion would have been distinctly dear at that.

There is one important feature, however, which, beyond any question as to patents or figures as to paper profits, those concerned in this issue have either carelessly or wilfully omitted to consider—we refer to the extensive steps which are being taken by scores of the leading engineers in this country to graft this new industry on to their old-established businesses and reputations. While having this object in view, they have no intention of buying the Continental patents, or of slavishly following existing models either of motors or vehicles. We have recently had the privilege of seeing the strides which many celebrated firms are making in this matter, and must confess to being astonished at the enormous progress already achieved.

By simply utilising all the technical skill at their disposal and working in accordance with the ordinary routine of any well-organised engineering or electrical establishment, they have evolved new designs, often in conjunction with leading coach builders, and these are now being executed in workshops equipped with the best of modern appliances, operated by the most skilful of workmen. Some time must necessarily elapse before the full results of their efforts will be seen, because until full tests have been made and the manufacturing placed on a basis for effective output such firms will not publicly exhibit, but their motors when finished will be worthy of their reputations, and hold the field against any but their native competitors. On this point it must not be forgotten that to the present generation of English engineers this trade has been a sealed letter. What they will ultimately achieve is certain to be worthy of the birthplace of modern locomotion.

It is but little use pursuing the matter of this unfortunate prospectus further. We could dilate at length on its crudities, mis-statements, and bad taste—but enough has been done. It was so outrageously bad that the entire Press of the country—with a few notorious exceptions which might have been expected—unanimously exposed its hollowness, and by their timely comments must have prevented very many from being entangled in the toils, who might otherwise have been caught. If the promoters of the issue wish to give an earnest of their repentance for the wrong which they must be conscious of having attempted to commit they will voluntarily return the money which they have received. If they do not, their last state may be worse than the first—as a Court of Law may compel them to make the sacrifice.

AUTOMOTOR CONTESTS IN 1897.

WE announce in our columns the conditions of three sets of valuable prizes which are offered to be contended for in the coming year by automotor vehicles. The first of these in priority of offer, and perhaps of importance, is the one for 1,100 guineas offered by the proprietors of *The Engineer*—which it was originally intended should take place during the present year. Owing, however, to the legal restrictions, since removed by statute, a sufficient number of entries could not be obtained, and a postponement was made until May, 1897—which still errs rather on the near side if a representative list of the English engineers who have just commenced to manufacture is to be obtained.

The revised conditions, which are eminently practical, as might be expected from the source from which they emanate, are fully set out on page 118, but we may briefly state that the total sum is to be divided up into five prizes. The chief is of 350 guineas, and will be awarded to "the best mechanically propelled vehicle constructed to carry—including the driver—four or more persons, the total weight, when fully loaded, not to exceed two tons." The next is to be of 250 guineas, for the best to carry one, two, or three persons, the total weight, when loaded, not exceeding one ton. Another 250 guineas will be given for the best to carry, in addition to the driver, not more than one ton of goods, the total weight fully loaded not exceeding two tons. A sum of 150 guineas will be given for a vehicle carrying five cwt. of goods, the fully loaded weight not exceeding one ton. Any method of mechanical propulsion may be used, but if oil be adopted for supplying motive power, either for the production of an explosive mixture or for fuel, it shall not have a lower specific gravity than 0·8, or a lower flashing point than 73° Fahr., Abel's test.

The remaining prize, of 100 guineas, will be devoted to "the vehicle, whether for passengers or goods, propelled solely by a motor actuated by the vapour of oil or spirit having a lower specific gravity than 0·8, or a flashing point lower than 73° Fahr., Abel's test, and constructed to satisfy the requirements of any Act of Parliament and the rules to be made thereunder for the time being respectively in force."

It will be noted that all the chief prizes go, as they should, to motors using safe explosives or fuel, while only a comparatively small sum is devoted to the class using the more volatile, or dangerous, oil or spirits. The speed trials are also to be carried out in a reasonable manner, a run of 100 miles out and home, in which the minimum mean speed to qualify is five miles an hour, while no greater speed than 10 miles an hour is to count will be sufficient for all purposes, and will remove the contest from any suspicion of being a race—in which the prize goes to the vehicle engined in the most powerful manner, without any reference to its other qualifications or drawbacks for road traffic. The judges are Sir Frederick Bramwell, Mr. J. A. F. Aspinall, and Dr. John Hopkinson, and it is certain that the vehicles selected by them for the premier awards will be the best of those entered. Our contemporary is to be congratulated on its enterprise, and for the business-like way in which it is proposed to carry it out.

The next contest in order is that arranged for by the Automobile Club of France, the official conditions to govern which are given in another page. We warmly approve of the new position taken up by the leading Continental club. It has—at any rate, on this occasion—decided to abandon mere racing, and submit all vehicles to tests which will try the many other qualities besides speed which are necessary in a motor-carriage which is to meet the exigencies of every-day use and traffic. The competition is to be an international one, and it is proposed that it shall commence on July 1st of next year.

The vehicles are restricted to those carrying one ton or over, and the judges are briefly to take into consideration the cost of running the motors, the ratio of weight-carrying capacity to the weight and power of the vehicles, and several other points, such as the utility of the brakes used and the ease of steering, which, as we have stated in reference to the previous contest, are often of infinitely greater importance than mere speed. Of course, that factor cannot be neglected, but in the past it has been made to assume such inordinate proportions in judging the merits of a motor-carriage that in this article we intentionally seek to minimise it. However, as the competition will last for some days, during which the vehicles will have to run a distance of some 186½ miles—running twice over distances of approximately 25 miles, 31 miles, and 37 miles respectively, one journey on each day, stopping at every kilomètre (·6214 of a mile), five kilomètres (3·1 miles), and ten kilomètres (6·2 miles), to test the brakes and auxiliary gear, their road efficiency will be fully tested. We heartily wish the Automobile Club every success, and trust that some at least of the entries will come from this side of the Channel.

The third competition emanates from the Motor-Car Club, and the leading characteristics of it may be found in Mr. C. Harrington Moore's letter, which appears in another column. The Club intends to offer £2,000 for a contest to take place in May next, but we greatly regret to find that the principal point which will be taken into consideration is speed, which the Club is "of opinion affords the most satisfactory test as to the excellence of construction of a mechanical vehicle." With this view we emphatically differ. The Club asks owners of suburban racecourses to communicate with its officials, as the place of trial must be near London, and the course should be a level straight mile. From the more or less officially inspired interviews which have appeared in the Press we learn that a special prize will be reserved for the motor vehicle which first succeeds in accomplishing a mile in one minute, and that the Club intends to institute a Motor Derby.

If this is to be simply an experiment undertaken with the object of providing a new form of sport we can only prophesy that the public will hardly be weaned from horse-racing by the spectacle of more or less cumbrous motor-carriages making the best of their way over a length of ground. To compare it with chariot-racing is to leave out all the virile interest which made such contests popular. The sight of plunging, living horses straining every nerve, guided by the skill of man to defeat all antagonists, is something to appeal to and excite mankind; but when the result of any race is to be determined mainly by one point, viz., which vehicle is propelled by the motor developing the largest amount of horse power, the public, at any rate after the first essay, will severely let such contests alone.

If, however, the officials of the Motor-Car Club seriously consider that such a contest can in any way beneficially assist in making motor-carriages popular, we would ask them to reconsider their position. The Club, with its resources, has the power of doing great good or harm—and we are certain that only the latter can result from the encouragement of speeds at any sacrifice—speeds, too, which can never be allowed, even if possible, on any road in the United Kingdom; while, if they devoted £2,000, or even a quarter of that sum, to a competition to be carried out on scientific lines they would accomplish more real good than by holding fifty Motor Derbies.

"ENGINEERING" AND MOTOR-CARRIAGES.

Our contemporary—*Engineering*—in the course of a well-reasoned article which appeared in its issue of the 27th ult., deals with the objections of those who held the opinion that the Editor of that journal was by no means favourably disposed towards the new industry. Referring to the remarks which appeared in our last issue on the subject, the Editor states: —

"Among the more gentle of our critics is The Automotor and Horseless Vehicle Journal, which thinks we have 'altogether failed to grasp the position taken up by those who are seeking to introduce the new industry into the country.' We trust not; but what we do fail to grasp is the utility of those who are seeking to trade on the credulity of the public, and extract money from the pockets of the ignorant under the pretence of establishing 'the new industry.' Every penny thus misdirected is a loss to 'the new industry,' and robs those who wish well of the motor-car of the sinews of war. It will take a very large sum yet to evolve a practical motor car, and there is no maxim which the average investor acts more strictly upon than 'once bit twice shy.'

"The company promoters—amongst whom we must not include our contemporary, to judge by his moderate and courteous language—are the chief enemy of 'the new industry,' but there is another serious foe, the reckless amateur or 'mechanical crank.' 'No one,' continues The Automotor and Horseless Vehicle Journal, 'wishes to place vehicles of from one to three tons in charge of incompetent men to drive through crowded streets at the rate of some 14 miles an hour. . . The keynote of the advice given by all concerned in automotor work is to go slowly at first.' How has this advice been followed? On the Brighton race, which was to have been the very first legal appearance of the new vehicles on the Queen's highway, the speed reached as high a rate as 30 miles an hour; and, again, we have complaints that motor-cars are restricted to the speed of the bicycle. 'What,' says one ingenious reasoner, 'is the use of going to all the expense of machinery when one is not allowed to travel at a greater speed than can be attained by the bicycle without machinery? Why should we be restricted any more than the bicycle?' The reason is obvious. The bicycle is a light machine. In a collision with a pedestrian the rider is in a more dangerous position than the person struck, whilst against other vehicles it is all but powerless to do damage. With the motor-car the opposite conditions prevail.

"The Automotor and Horseless Vehicle Journal concludes its courteously expressed article with an appeal to us. 'In all friendliness,' it says, 'we would ask *Engineering* to look a little more kindly towards the new industry.' In all friendliness we would assure our contemporary that we will look very kindly towards the new industry—when it arrives. Our friendliness is such that we are ready to do battle on behalf of the embryo industry against its arch enemies, the company-monger and the mechanical crank."

We have quoted this much from the article in order to take an opportunity of emphasising two sets of views which we have never failed to express. The first is that, like *Engineering*, we are prepared to denounce in the strongest terms any attempts which may be made to bring out companies with inflated capitals. The promoter is entitled to a fair profit, but his demands must be reasonable, while his statements should, before all things, be kept within the bounds of truth. The second postulate in which we concur is as to the paramount necessity which exists for all interested in the progress of road motors to rigorously keep within the limits of the law. There are enough natural difficulties in the way without creating fresh ones by a wilful infraction of regulations. If anyone infringes, there should be no hesitation in suing for and enforcing the penalties incurred. It is only fair, however, to add that those referred to in the article were doubtless fascinated by their new-found liberty, and indulged in spurts on clear roads which they are not likely to repeat.

WANTED—A WORD.

Under this title we, in the last issue, discussed the various phrases which have been used to describe motor-carriages, and invited correspondence from those who were of opinion that they could coin a better word than any generally in use. Letters have, in consequence, come to hand in large numbers—in fact, we regret that we have not, in consequence of the quantity, space to print them. We have summarised below the words submitted, but cannot express an unqualified approval for any of them, while some are extremely objectionable. They are as under (of course, many have been submitted by several correspondents) :—

Autokinous.	Automotives.	Go cars.
Automobiles.	Horseless.	Motes.
Moto.	Mobus.	Self-Propelled.
Movers.	Autos.	Mo's.

WHAT BETSY-ANN MAKES OF IT.

DEPARTING GUEST. "WILL YOU CALL ME A CAB?"
BETSY-ANN. "ANSOM, FOUR-WHEELER OR MOVER, SIR?"

(A TIMES CORRESPONDENT SUGGESTS THAT THE HORSELESS CARRIAGE BE CALLED AN "AUTO-MOVER")

PNEUMATIC TYRES FOR MOTOR-CARRIAGES.

An extremely interesting lecture on pneumatic tyres was delivered on Monday evening, the 1st instant, by Professor H. S. Hele-Shaw, M.I.C.E., M.I.M.E., &c., before the members of the Liverpool branch of the Self-Propelled Traffic Association. Mr. Alfred Holt, M.I.C.E., one of the vice-presidents, was in the chair, and there was a good attendance.

The Professor's paper, of which we give an abbreviated report, was exceedingly interesting, and we regret that pressure on our space prevents us from doing it full justice by illustrating it with the appropriate diagrams which were used. After exhaustively setting out the history of the wheel and explaining in full its mechanical action and theory, he said: No one would dispute that to walk upon a yielding surface, such as mud or sand, requires an appreciable effort, which is greater the softer the material, so that heavy snow may be toilsome beyond endurance. The same cause is at work in the case of the wheel rolling upon a soft road and (here, I imagine, I may again excite some possible disbelief) of a soft wheel rolling upon a hard road. To understand this we must study the actual motion of the parts of the wheel as they approach the ground, and we will first consider that of the spokes themselves. Let us follow the behaviour of a particular spoke, and we shall see that until it nearly reaches the ground it approaches it at an oblique angle. If it does not find an obstacle it will come down upon the ground and rest there. If it meets any yielding substance, which is raised above the point of support, it will not only compress it underneath, but push it before it, as shown in the diagram, and will therefore cause a corresponding effect backwards, which is greater the deeper the rut which it is making. This is seen to be true both for a soft wheel and hard road, as well as a hard wheel and soft road. This seems obvious where a permanent compression and distortion is taking place, as, for instance, in a rut in the road, but it does not appear so evident when the material is of an elastic nature, and returns to its original shape again after the compression has taken place. When the tyre is elastic the same thing occurs. If the elastic material is of a nature that requires a distortion at every point, it is clear that the work which is being done continuously to distort this material is an absolute loss of power and a cause of resistance to the motion of the vehicle. In considering the best form of tyre, it is clear that if the only resistance was rolling, a hard wheel would be better than a soft one. The reason of the success of the introduction of the railway is due to the principles I have now made clear. Hence those who only consider rolling, were very naturally sceptical of the earlier attempts to make soft tyres serve for any other purpose than to merely protect the road, for although the theory of rolling which I have explained has not been generally understood, still the mechanical intuition of many men would tell them the facts to be what they are without their understanding, perhaps, the true cause. Again I may remark that crowds of inventors in connection with the soft tyre of vehicles, particularly for bicycles, have often gone entirely on a wrong track, with the natural result of failure. We come now to the real cause of the benefit of the pneumatic tyre which requires preliminary explanation. Suppose a body to be in motion, as this pair of wheels and axle, and it meets any obstacle over which it has to rise and loses a portion of its energy. Suppose it meets the same obstacle but is not compelled to rise to the same extent, the loss of energy is not so great. This is exactly what happens in the case of a soft, yielding tyre. It meets an object which it may cause to sink into it, hence the body as a whole is not checked in its onward course. This behaviour on the part of the tyre is made obvious by some photographs which I have recently taken of the tyre in the various positions which I now show, and also some photographs of the tyre given by M. Michelin in a recent paper, and this effect he has shown by a series of curves which indicate the deflection in meeting obstacles under various conditions and circumstances. If the reasoning which I have given is true, then the remarkable fact will come out, that at very low speeds the resistance to soft tyres is actually greater than that to hard tyres, and this benefit is only apparent as speed is increased, the greater the speed the greater will be the benefit of soft-tyred vehicles. I made a series of experiments myself which must be regarded as supplementary to the experiments of M. Michelin in the paper I have already mentioned, and they were made by my assistant without any previous idea of what might be expected, so that his inclination was, if anything, to obtain a better result with the pneumatic tyre. Instead of this, the experiments came out exactly as theory would lead us to expect, and at first, I must confess, surprised me. The experiments were conducted at the works of Messrs. Lawton and Co., who kindly placed three broughams at my disposal with—(1) steel tyres, (2) rubber tyres, and (3) pneumatic tyres. These were drawn over the floor, and over a series of obstructions, drawings of which I have already shown. The following is a statement of the results :—

Three similar vehicles—whose exact weight was not known. The tests were made in the show room of Messrs. Lawton and Co.'s works, Hardman Street, and in each case the pull required to start the vehicle was measured by a spring balance. The mean effort required was estimated by the average reading of the balance, whilst the vehicle was pulled at a uniform speed over a track about 6 feet long. The results were as follows :—

The first track was across the floor, the second, with obstructions, 1 inch apart, the third, with an interval of 2 inches, and the fourth with 3 inches between the blocks.

Track.	Steel Tyre.		Solid Rubber Tyre.		Pneumatic Tyre.	
	Starting Effort.	Mean Pull.	Starting Effort.	Mean Pull.	Starting Effort.	Mean Pull.
Floor ..	31·2	21·4	24	17·0	30·25	22·0
Second ..	37·4	22·0	27·4	18·7	29·0.	22·25
Third ..	43·8	21·2	36·8	19·8	30·75	23·25
Fourth ..	?	21·0	36·8	20·2	40·5	25·5

It is extremely interesting to study the various views on the subject by those who have been interested in the adoption of the pneumatic tyre. Thus Mr. Dunlop, of Belfast, who is a comparatively recent patentee of pneumatic tyres, writes as follows :—

"My improvements are devised with a view to afford increased facilities for the passage of wheeled vehicles—chiefly of the lighter class, such, for instance, as velocipedes, invalid chairs, ambulances—over roadways and paths, especially when these latter are of a rough or uneven character, as also to avoid sinking of the wheels of vehicles into the ground when travelling over boggy soil or land, and likewise for the tyring of wheeled vehicles generally, in all cases where elasticity is requisite and immunity from vibration is desired to be secured, and at the same time ensuring increased speed in travelling owing to the resilient properties of wheel tyres according to my invention."

From these words it cannot be seen that Mr. Dunlop appreciates the direct connection between the saving of power and the pneumatic tyre, as he only talks about increased speed owing to the resilient properties of his wheel tyres. We must go back a good many years, when the pneumatic tyre was first invented by Mr. R. W. Thomson, who seems to be nearer the mark, and who says :—

"The nature of my invention consists in the application of elastic bearings round the tyres of the wheels of carriages, for the purpose of lessening the power to draw the carriages, rendering their motion easier, and diminishing the noise they make when in motion. I prefer employing for the purpose a hollow belt composed of some air and water-tight material, such as caoutchouc or gutta-percha, and inflating it with air, whereby the wheels will in every part of their revolution present a cushion of air to the ground or rail or track on which they run."

This invention was actually carried into operation, and led to a good deal of correspondence and interest at the time, a brougham fitted with pneumatic tyres by this inventor attracting considerable attention in the London Parks exactly 50 years ago. The views which were then held are well expressed in an article in the *Mechanics' Magazine*, which is as follows :—

"The most obvious advantage—indeed, the only one which at first sight would seem likely to result from the substitution of an elastic for a non-elastic tyre—is a diminution of noise, and hence it was that we were led, in our former notice of these wheels, to characterise them as 'silent,' rather than as being distinguished for any other property. It has been so long regarded as a settled thing that friction is least with hard substances and greatest with soft, that by a natural though not perhaps strictly logical course of induction, we inferred that, though in this case the noise might be less, the friction, and consequently the tractive power required, would be greater. We must candidly own that we little expected to find the very reverse of this to be the fact. Yet so it is. Experiments very carefully conducted, and which we have ourselves repeated and verified, prove incontestably that the friction and draught are diminished to a very great extent by the use of these elastic wheels."

This led to a letter by a Mr. Heather correcting the Editor in talking of the reduction of friction, and making a mis-statement himself, as follows :—

"Sir,—The importance of disseminating by means of your journal correct mechanical principles induces me to suggest to you that the traction of a carriage is independent of the friction of the tyre and the road, and is due to the friction between the wheel and the axle, and to what may be called the resistance to rolling at the circumference of the wheel, which resistance is in no way analogous to friction."

All these facts show that the matter is not an easy one to understand at first sight, and I will briefly sum up the matter by saying that soft tyres do involve more friction than hard ones, but that the loss of power on an ordinary hard road is due in a much greater degree to the loss from concussion than to actual friction, that the order in which the loss of power takes place in the cases respectively of the pneumatic, rubber, and iron tyres, is directly in the order of the hardness of the tyre.

Having studied the theory of the subject as fully as time permits, we now pass on to certain practical considerations in the construction of the pneumatic tyre. The pictures which I now throw upon the screen are those which were running in the year 1845, and the further views which are now shown you will, perhaps, be surprised to hear are those of the tyre mentioned in the specification of Mr. Thomson of the same date. It is interesting also to note that Mr. Thomson's patent included the inner tube as well as the outer protecting case, the inner tube being indiarubber, strengthened with folds of canvas, and the outer covering itself being of leather either riveted or sewn, so as to make it strong and durable. Mr. Thomson advocates the use of pneumatic tyres to the traction engines and autocar in the following words :—

"The comparatively small amount of power required to propel carriages, the wheels of which are fitted with these belts, the steadiness of their motion, the absence of all jolting and consequent security of the machinery from injury, the small damage the carriages will do to roads, the absence of nearly all noise, the high speed that may safely be attained, and the great gentleness of the motion will, I think, enable steam carriages to be run on common roads with great advantage both for carrying passengers and goods." We must all regret that Mr. Thomson's genius did not, as far as I ascertain, meet with a fitting reward which seems to have been in reserve, judging from the present scale of company promotion, for more fortunate individuals, who at any rate cannot claim more originality of mechanical insight than the original inventor. Other slides were then shown describing the modern development in the mechanical details of the pneumatic tyre. Improvements in the arrangement for inflation, and particularly devices for getting at the inner tube in case of repairs being required.

This portion was discussed under the following heads :—

(1) *Attachment.*—(*a*) The early system ; (*b*) the early Dunlop ; (*c*) other forms of attachment ; (*d*) Welsh wire rim ; (*e*) Fleuss tyres ; (*f*) vehicles—points of difference between vehicle tyres and bicycle tyres.

(2) *Wear.*—(*a*) Ordinary wear, material, tread ; (*b*) puncture, repairs ; (*c*) dirt and wet.

(3) *Inflation.*—Pressure used, valves.

I cannot conclude without saying how much pleasure the preparation of this lecture has given me, for I regard it as a slight acknowledgment of the enjoyment I have experienced in the use of the modern bicycle. But the services of the pneumatic tyre are not limited to cyclists, and we may safely look forward to its increasing introduction to vehicles of every kind, both for light and heavy traffic ; and lastly, not to leave the impression that I have forgotten the object of the Association before which I have lectured to-night, I venture to assert that if the autocar, which 50 years ago was running by scores over the country, and were afterwards discarded, are to become universal in their adoption, and are to attain any reasonable rates of speed, this development will depend upon, and be almost entirely owing to, the invention and perfection of the pneumatic tyre.

An animated discussion followed the paper, and in this Messrs. A. Bromley Holmes, John A. Brodie, E. Shrapnell Smith, and Mr. James took part. On the motion of the Chairman a hearty vote of thanks was accorded to Professor Hele-Shaw, who, after acknowledging it, replied to several questions which had been raised. Messrs. Dunlop and J. A. Lawton and Co. kindly lent materials for several of the experiments which were made.

An interesting syllabus in connection with the first session of the Liverpool and District centre of the Association has been issued. The programme drawn out is a most comprehensive one, extending from December 1st up to March 30th. Papers will be read by Mr. G. F. Thompson, Mr. W. W. Beaumont, Mr. H. Percy Boulnois, Mr. Rhys Jenkins, Mr. Dugald Clerk, and Mr. Legros. A meeting took place last evening when a paper was read by Mr. Wm. B. Cook and Mr. Fred. Willoughby, on "A New Method of utilising Canals for Traffic—with Special Reference to the Canals of Lancashire and Yorkshire." The authors are the joint patentees of the scheme discussed, which is one of great interest to the shipping interest of Liverpool. The next paper will be read on January 5th, 1897, by Mr. G. F. Thompson, consulting engineer, on "The Motor Wagon Scientifically Considered."

All who are interested in motor traffic and reside in the neighbourhood of Liverpool should write to Mr. Shrapnell Smith, the Hon. Secretary, for the full prospectus of the Association, and join the enterprising local centre.

A VERY satisfactory test was made last week with one of the carriage trucks of the London Electric Omnibus Company's new omnibuses, which are soon to be placed on the streets of London. The streets on which the trial was made were specially selected on account of their severe gradients. The carriage ran up Trafalgar Square opposite Morley's Hotel, and through Craven Street, with ease. Stoppages were made on the inclines for the purpose of testing the re-starting capacity of the motors, and in each instance the re-starts were made without apparent effort, though less than half the available power was used. The steering was also managed with ease.

A MOTOR-CARRIAGE WHEEL.

THE Coupé Company, carriage builders and wheel makers, of Britannia Road, Fulham Road, London, are the sole manufacturers of Harrington's patent steel carriage wheel. We venture to predict that these wheels will be very largely employed in automotor work—for which, in consequence of their strength, lightness, and elegant appearance, they are pre-eminently suited. From the illustrations which accompany this article it will be seen that, although somewhat similar in appearance to the familiar bicycle wheel, they differ from it radically in one important point, viz., that it is practically impossible to buckle them. By securing each couple of adjacent spokes together by a band of steel riveted over them, at a point near the periphery of the wheel, great strength is secured, while the elasticity inherent in this form of wheel is at the same time retained. The wheels have been subjected to rigorous and practical tests throughout a very long period, as the Coupé Company as a matter of economy have fitted them to all the varied forms of carriages which are turned out from their extensive establishments. They have found them as cheap to make in the first instance as good wooden wheels, while presenting a much more artistic appearance, and at the same time lasting for a considerably longer period, without any incidental outlays being required for repairs. We have examined very many of these wheels, which have for years past been subjected to the rough wear and tear of the London streets without renewal, and in no case could the slightest shake be observed in any of the spokes. In many cases the condition of the paint on the wheels showed that they had been in collision sideways with heavy vehicles, but that their elasticity had readily enabled them to resume and keep their original form unimpaired. The estimation in which the wheels are held by the carriage trade proper may be judged by the many repeat orders which are received from builders not only in this country but from the Colonies and India. Any form of tyre—pneumatic or solid—can be fitted to the wheels, and examples of all types in every-day use may be inspected at the works. To sum up, we may state that the wheels are stronger, more durable, and more sightly than others, while they weigh considerably less, and are subject to a minimum of windage and vibration. We may add that the managing director of this Company—Mr. Courtauld Thomson—is a son of the Mr. Thomson who, as fully described in the first issue of THE AUTOMOTOR AND HORSELESS VEHICLE JOURNAL, invented and used the pneumatic tyre fifty years ago, and who was one of the most practical exponents of the utility of motor-carriages of his day. It is only fitting that a descendant of his should be numbered amongst the pioneers of the revived industry.

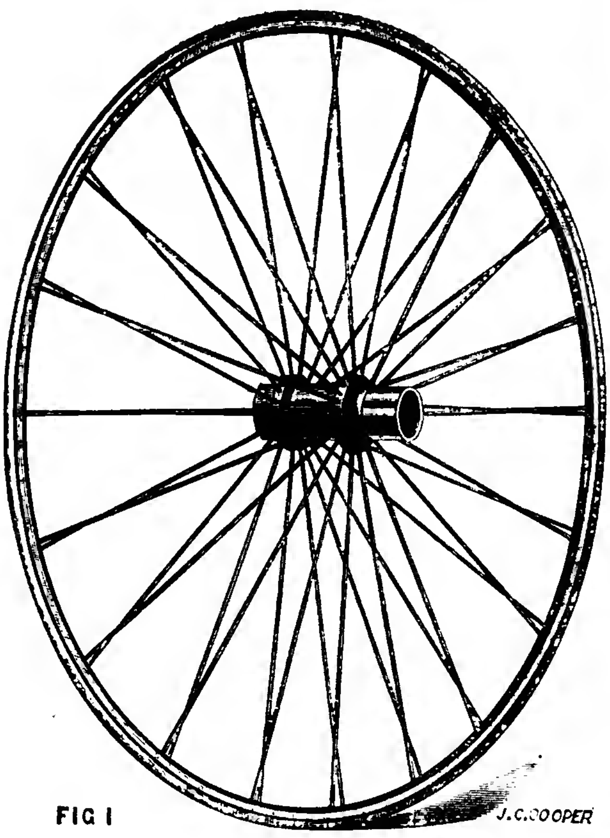

FIG I

J.C. COOPER

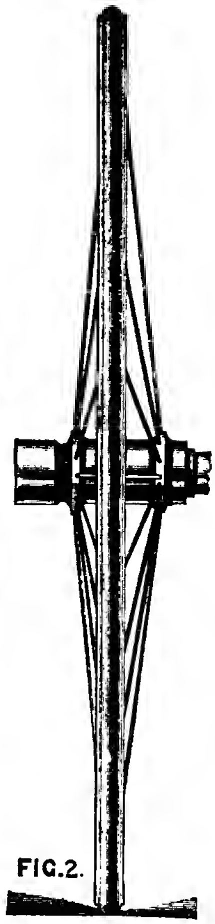

FIG. 2.

TAXES ON MOTOR-CARRIAGES.

THE regulations for the taxation of motor-cars have been issued. All weighing less than one ton will have to pay one guinea or 15s. annually, according as they are used for private purposes or as public conveyances. The same rule will apply to motor-cars over three tons in weight, but those between one and three tons will be charged heavily. All with four or more wheels, and weighing between one and two tons, will have to pay four guineas yearly unless they are used as hackney carriages or omnibuses, in which case the amount for each one will be £2 17s., while for those over two and under three tons the amounts will be five guineas and £3 18s. respectively. For cars of this class with less than four wheels and between one and two tons in weight the annual licence will cost £2 17s., whether used as private or public conveyances, and if they weigh over two and under three tons the amount will be £3 18s. The motor cabman of the future will have little to complain of if these charges are maintained. He will continue to pay 15s. so long as his cab is under one ton, while his rival, the omnibus proprietor, instead of, as now, paying the same amount for each self-propelling vehicle, will pay at least £2 17s. The proceeds of these licences will, as in the case of other carriages, be passed over to the local authorities. The new rules do not come into force until January 1st, when licences for the year ending December 31st will be issued. It is provided that in the case of a car not being used for the first time until October 1st in any year a reduction of a guinea if for private and of 7s. 6d. if for public use will be made. It will be understood that no charge of any kind is to be made for the expiring year. The regulations are vague as to the licence duty on private vehicles with four or more wheels and under one ton weight. They say they will be subject to the ordinary provisions as to carriage licence duty. The ordinary provisions are that the owner of a four-wheeled carriage, which is fitted to be drawn by one horse, pays one guinea, and if it is fitted to be drawn by two horses two guineas annually. The amount of duty, therefore, depends upon the "fittings." If a carriage has a socket in which a bar is or can be inserted for a second horse it is charged for at the two-guinea rate. How this rule can be applied to a motor-car is not obvious. Probably it is intended that only one guinea shall be charged. The self-propelled cycle will be subject to a duty regulated by the number of wheels, though this question also has not been grappled with.

EDINBURGH COACHMAKERS AND MOTOR-CARS.

The annual soirée and concert of the Edinburgh coachmakers was held on the 27th ult. in the Oddfellows' Hall, Forrest Road, when there was an attendance of over 700 people. Mr. Norman G. Croall occupied the chair, and amongst those present were Messrs. Stordy and J. Drew. In the course of the evening the latter, who is lecturer on carriage building in the Heriot-Watt College, gave an address on "Moto-Cars." He said that now that an Act had been passed permitting their use on the highways, under certain restrictions, they might confidently look forward to large and interesting developments before long. What was wanted, especially in their large cities, was not great speed, such as had been attained, but quick-stopping, turning, &c. The best claim for the electric motor was that it was noiseless. Electric omnibuses and carriages were excellently adapted for city use, and it was interesting to note that an electric cab company had recently been formed in London. He had had an opportunity of trying several oil-driven motors in London that season, and it was anything but pleasant. In time, no doubt, improvements would be carried out. With a motor-car the expense incidental to horses was avoided. There could be no rearing or kicking or running away. This new and great and important industry he looked upon not as enemy to their trade, but as an associate. (Hear, hear.) The cycle industry ought to have been in their hands. (Hear, hear, and applause.) By this time some of them might have been millionaires, instead of looking forward to spending their declining years within the cool portals of the workhouse. (Laughter.) It was both their interest and duty to keep in touch with a movement like that, so that if their services were required they would be able to use them most effectively. (Applause.)

PEUGEOT PHAETON (THE HON. C. S. ROLLS).

PEUGEOT PHAETON.

The phaeton illustrated on this page is one which its owner, the Hon. C. S. Rolls, had arranged to travel down to Brighton with on the 14th ult. We reproduce it for the purpose of illustrating our article describing the ride, but, along with a great deal of other matter, it was crowded out. The phaeton is a very comfortable vehicle for four persons, built by M. Peugeot, and fitted with an inverted Daimler motor developing about three and three-quarter horse-power. The wheels run very lightly, the spokes are of steel, and the rims are fitted with rubber tyres. The vehicle can run 15 miles an hour comfortably. Owing to inadvertence in starting from Cambridge, the Hon. C. S. Rolls did not arrive at the Hôtel Métropole in time to start.

SIR DAVID SALOMONS AND THE SELF-PROPELLED TRAFFIC ASSOCIATION.

In view of recent motor-carriage company developments, the secretary of the above Association has issued a statement setting out Sir David's connection with the matter. After giving particulars as to the Exhibition at Tunbridge Wells, he relates the history of the formation of the Self-Propelled Traffic Association, and in reference to it states:—

An attempt was made by many gentlemen to be placed upon the Council, to whom Sir David objected, on the ground that it was their wish to make the Association little more or less than a company-promoting concern. As he had no interest financially in the movement, nor any desire to take such a part in the future, Sir David resented such tactics, and the result was a division in the camp, the company-promotion section separating themselves from those who were anxious solely to forward the movement for the good of their countrymen and of English industry.

The Association was eventually formed with a very strong Council, consisting of gentlemen well-known in public life, science, and engineering.

Sir David Salomons was elected president, and such a strong support gave him great power to push the movement to a conclusion.

Then came the deputation to Mr. Chaplin, and to Sir David's astonishment, although the former gentleman had written to him previously, sympathising with the movement, it was the first occasion that Mr. Chaplin had stated publicly it was his intention to introduce a Bill.

Throughout this period Sir David Salomons travelled to and fro to Paris, and obtained information from all parts of the globe in order to be well posted in the new movement and further its objects, towards which he published various pamphlets and articles to show the advantages to be derived, and to meet various arguments which had been raised on the subject.

There was the difficulty also that, if the Bill became law, the Petroleum Acts would prevent benzine being carried when required for fuel.

In one of the pamphlets issued Sir David suggested the form of the Act of Parliament, which was eventually adopted to all intents and purposes. At an interview with Lord Harris the difficulty as to carriages to be drawn was raised, and he was present at the second reading of the Bill in the House of Lords, when great stress was laid on the wisdom of not permitting this point. Sir David did his best to get this reversed by showing that the danger alleged existed only in the minds of non-technical persons, and that heavy loads combined with great speeds were impossible under the limit of the weight of engine mentioned in the Bill. He also assisted to secure the raising of the two-ton limit to four tons, to meet the question of electric traction. This was supported by resolutions of the Self-Propelled Traffic Association, and the London and many other Chambers of Commerce.

In dealing with these questions Sir David had the advantage of having the results of a number of experiments which he had made many years ago on the subject, when he first took an interest in the improved means of locomotion on highways.

The Bill was amended in a few details in the House of Lords, which set up the control of many authorities, which would have been unworkable. No doubt when the amendments were accepted this point was not sufficiently considered.

Sir David Salomons then attended the second reading in the House of Commons, and was able to gauge the nature of any opposition from the discussion which took place. This enabled him to draw up a very careful Memorandum showing the various effects which would arise if certain proposals were adopted, and pointed out where modifications could be made with advantage to the Bill, and at the same time offering concessions to the opposite force. This Memorandum was sent into the Local Government Board and the Home Office (the two departments which have a voice in the matter under the Bill), and Sir David was requested to attend personally, which he did, and made a number of suggestions which he had the satisfaction of seeing adopted as amendments in Committee.

The point which there was the greatest difficulty in securing was that an unladen vehicle might be defined in the Bill as one without water, fuel, petroleum, or accumulators, as it was thought the words "unladen vehicle" met the point. Sir David's contention was that no Judge would hold that an unladen vehicle was otherwise than one ready to start to pick up its load. On this point he had not the slightest doubt. Sir David, therefore, suggested on his part, as a concession, to reduce the four ton maximum to three tons weight, providing an unladen vehicle was defined as one without fuel, water, or accumulators. Another point was the width of wheels, which so many members thought desirable to deal with in the Bill. Sir David preferred that all questions of construction be left to the Local Government Board, and this was eventually accepted.

He also obtained the concession to add to the words "no visible steam or smoke" the words "except from an exceptional or temporary cause." He obtained the further concession that if local authorities should stop any roads or bridges for this class of traffic, an appeal might be made to the Local Government Board.

Sir David sent a long Memorandum on the petroleum question, as it affects this class of traffic, to the Home Office, and was called to give evidence before the Petroleum Committee of the House of Commons, of which Mr. Mundella is the Chairman. The evidence appeared to be favourably received as far as he was able to judge, and he has reason to believe that the Rules which will be issued shortly will practically be based on the evidence given by him on that occasion.

No less than 50,000 letters have been written on the subject since last October, and possibly not less than 500 interviews, apart from meetings. A large number of articles and other publications to the Press and in other quarters have been sent out, which gives some idea of the labour expended by Sir David Salomons, to say nothing of an expenditure reaching many thousands of pounds.

The sum total of all this work has been, that there has hardly been an Act passed containing more liberal clauses, and with more unity of action, which is so desirable where the roads are continuous and local authorities so numerous.

The Act will secure complete control from a central point, the Local Government Board for rules and regulations as regards construction and use, while the Home Office controls all questions dealing with petroleum of low flash point, regardless of any Acts of Parliament which may exist.

No bridge can be closed without reasonable cause. The weight of three tons without fuel, water, petroleum, or accumulators renders it possible to construct a better class of carriage, and, above all things, it renders electrical traction on the roads an actual possibility. The exemption of the production of steam or smoke due to temporary and occasional causes will obviate vexatious prosecutions, and the regulations to be expected in regard to mineral spirits will be as liberal as is possible from the nature of the liquids.

The main object to be attained, by using every endeavour to transfer powers for regulating this class of traffic from Parliament to Government departments, was to enable amendments to be easily made to meet practical requirements, without the cumberous operation of appealing to Parliament. The system has worked well in the case of the electric light industry, and there is no reason why it should not prove as successful in the case of self-propelled traffic.

Sir David has sacrificed a considerable amount of time in assisting by every means in his power in framing the Local Government Board regulations

Sir David has already pointed out that it only remains for users of horseless traffic to do nothing on their part to destroy the confidence which the Legislature has placed in them, by committing any act likely to be of annoyance to others.

Throughout all the negotiations and communications between members of the Government and the officials of Government departments, Sir David Salomons bears witness to the fact that he was treated with every courtesy and consideration, which was, no doubt, due in a large measure to the circumstance that it was within their knowledge that the company promotion business had been completely separated from his side, and that the Self-Propelled Traffic Association was recognised by the Government as the official representative of the movement, so that it was felt that all he said was not in any way influenced by the slightest personal consideration or intention of extracting money from the pockets of the public.

"THE ENGINEER" 1,100 GUINEAS ROAD CARRIAGE COMPETITION.

CONDITIONS OF COMPETITION.

The proprietors of *The Engineer* have agreed with the Crystal Palace Company, who have offered facilities at the Crystal Palace for showing the carriages in work there, and for holding the subsidiary trials hereafter referred to.

Judges.

The following are the names of the judges :—

Sir Frederick Bramwell, Bart., F.R.S., M.Inst.C.E.

Mr. John Audley F. Aspinall, M.Inst.C.E., Chief Mechanical Engineer to the Lancashire and Yorkshire Railway.

Dr. John Hopkinson, F.R.S., M.Inst.C.E.

The competition is to be international.

Classes.

The vehicles will be divided into four classes, and one supplemental class, in each of which a prize will be given, as follows :—

(*a*) For the best mechanically propelled vehicle constructed to carry, including the driver, four or more persons, the total weight, when fully loaded, not exceeding two tons, a prize of 350 guineas will be given.

(*b*) For the best mechanically propelled vehicle constructed to carry either one or two or three persons, the total weight, when fully loaded, not exceeding one ton, a prize of 250 guineas will be given.

(*c*) For the best mechanically propelled vehicle constructed to carry, in addition to the driver, not more than one ton of goods or parcels, the total weight, when fully loaded, not exceeding two tons, a prize of 250 guineas will be given.

(*d*) For the best mechanically propelled vehicle constructed to carry, in addition to the driver, five hundredweight of goods or parcels, the weight, when fully loaded, not exceeding one ton, a prize of 150 guineas will be given.

Supplemental.—For the vehicle, whether passengers or goods, propelled solely by a motor actuated by the vapour of oil or spirit, having a lower specific gravity than 0·8, or a flashing point lower than 73° Fah., Abel's test, and constructed to satisfy the requirements of any Act of Parliament, and the rules to be made thereunder for the time being respectively in force, which, in the opinion of the judges, best satisfies the purpose for which it is built, a prize of 100 guineas will be given.

The judges are to have the power to divide any prize in case of vehicles proving of equal merit. At least two vehicles in a class must complete the whole journey, or no prize for that class will be given.

Propelling Power.

Any method of propulsion other than muscular power may be employed, provided it be contained in the vehicle.

Quality of Oil for Power Purposes.

Except in the supplemental class, no oil or other liquid used in any engine, whether for the production of an explosive mixture, vapour, or for fuel, shall have a lower specific gravity than 0·8, or a lower flashing point than 73° Fah., Abel's test.

Entries.

Entries are to be made on printed forms—to be obtained at the offices of *The Engineer*—at any time prior to 6 p.m. on the last day of March, 1897, being forwarded by registered letter, addressed to the Editor of *The Engineer*, 33, Norfolk Street, Strand, W.C., and accompanied by a deposit of £1 for each entry, this deposit to be forfeited if the vehicle entered is not submitted for competition.

Delivery.—Description and Descriptive Drawings.

The competing vehicles must be delivered at the Crystal Palace, Sydenham, between the hours of 10 a.m. and 6 p.m. on some day in the week prior the 24th of May next. Prior to the delivery of each of the vehicles, there must be forwarded to the Editor of *The Engineer*, 33, Norfolk Street, Strand, W.C., a docket showing the weight of the unloaded vehicle, in complete running order, with its store of fuel and water—if these are to be used—this docket being furnished by a weigh-master of some public weghing machine. At the same time there must be forwarded six, at least, type-written or printed descriptions of the machines, setting out, as briefly as possible, any peculiarities of construction or of working to which the competitors desire to draw the attention of the judges, and also six sets of clear blue-print drawings or sketch tracings, to a scale of not less than 1½ inch to the foot, illustrating the construction. These documents will not be returned, but on their receipt, a printed Form of Request to the Crystal Palace Company, to accept delivery of the vehicle, will be forwarded to each competitor by the Editor of *The Engineer*, and this Form of Request will have to be produced to the authorities at Sydenham when the vehicle is delivered.

Opening-up of Machines.

After delivery and before the practical working run, hereinafter referred to, each vehicle is to be opened up by a skilled attendant representing the competitor in the presence of one or more of the judges, or their representative, for their information.

Preliminary Runs.

Preliminary runs in the grounds of the Crystal Palace will be made with each of the vehicles in succession by the competitors in the presence of the judges or of someone representing them.

Practical Working Run.

This will consist of a run on the public roads of not less than 100 miles out and 100 miles home, or a total of not less than 200 miles, over a course to be announced three days prior to that fixed for the run. It is impossible at present to fix the exact date for this run, but it will probably be arranged for Monday, the 31st day of May next. On starting for this run from the Crystal Palace, each vehicle is to be fully loaded and is to have its full store of fuel and water, if these are used, and is also to carry the number of adult passengers for the class in which it is entered, one of whom is to be a representative of the judges, who will be counted as part of the load.

Route Map.

There will be provided for each competitor, on making application at the office of *The Engineer*, three days before the practical working run commences, a route map indicating the course which it is suggested the vehicles should take; but the competitors will be free to take any road they think proper between the Crystal Palace and their destination and back.

Order of Starting.

Lots will be drawn to determine the order in which the vehicles are to start. It is intended that the first shall leave at or about 10 a.m., and the remainder at intervals of 10 minutes. During the run the representative of the judges shall keep, on a printed form which he will have with him, a "log" of the run.

Change of Drivers.

Any competitor may change his driver at any place *en route*, if he should think proper.

Inspection of Vehicles on Return.

After the return of the vehicles to the Crystal Palace, it shall again be opened up by the competitor and submitted to the inspection of the judges, or their representatives, and this prior to anything being done to the vehicle in the way of repair or renewal, except such as may have been effected during the run.

Further Runs.

Should the judges so determine, further runs are to be made on subsequent days by all or any of the vehicles in the premises of the Crystal Palace Company or on the public roads.

Disqualification.

The judges reserve to themselves the right of absolutely disqualifying any vehicle or competitor from the competition for any infraction of these rules or for any cause whatsoever, and without in any way being bound to state the reason or reasons for which such disqualification is made.

Number of Vehicles to be Exhibited by each Competitor.

No competitor, either directly or by any agent or otherwise, is to enter for competition two similar vehicles in any one of the classes above referred to, and each vehicle is to be entered by not more than one person, that is to say, in the name of one individual or firm.

Responsibility.

While obeying in all respects the instructions of the judges, it is to be fully understood and agreed by every competitor that no responsibility, legal or otherwise, is to attach either to the judges, to the proprietors of *The Engineer*, or to the Crystal Palace Company in respect of anything or for any damage or injury caused to any person or thing, but all responsibility of every sort and kind, whether pecuniary or otherwise, is to attach to the competitor and is to be borne by him.

Length of Practical Working Run.

Any vehicle which does not complete the "practical working run" at a minimum average speed of five miles an hour, to include all stoppages, shall be disqualified. The distance upon which such time allowance will be computed will be fixed by the judges and stated on the route map.

Note.—As the attainment of high speeds is not one of the objects sought, it has been determined that nothing in speed over 10 miles an hour will be placed to the credit of any competitor, but, subject to this condition, and to any law or regulation made by any local or other competent authority, the competitors may go as they please, at any speed they think proper, running continuously day and night, or stopping as they think best. If at the date hereafter to be fixed for the trials the state of the law or of any local regulations should make it impossible, in the judgment of the proprietors of *The Engineer*, to hold the competition as at present contemplated, no blame or responsibility shall attach to them, or the judges, or to the Crystal Palace Company.

The following are the points which will be taken into consideration by the judges in awarding the prizes:—

(*a*) Distance run without taking or receiving supplies of fuel, oil, gas, electrical or chemical materials or electrical current, or of any agent employed for actuating the motor. Freedom from stoppages for repairs, adjustment, or for oiling, or any other purpose or cause.
(*b*) Suitability of design and excellence of workmanship, not only of the actuating machinery but of the carriage.
(*c*) Safety.
(*d*) Simplicity, durability, accessibility, and facilities for repairs, absence of offensive smells, and of excessive vibration.
(*e*) Time occupied in getting to work and ease of starting.
(*f*) Speed—up to ten miles per hour—and hill climbing.
(*g*) Completeness of control by, and certainty and decision of, steering and steering gear, and efficiency and durability of brakes and brake gear.
(*h*) Weight of carriage and motor machinery and appliances.
(*i*) First cost and—to a limited extent—the cost of working.
(*j*) General efficiency.

Note.—The quantity of fuel, oil, gas, or power-giving material or electricity used during the long duration run will not be specially taken into account, although observations will be made by the judges on this subject, but trials of short duration of the vehicles selected for further tests will be made if deemed necessary for the purpose of ascertaining the cost of working of the vehicles.

Judges' Decision to be Final.

The decision of the judges expressed in writing on any point shall be final and binding on all parties, and from such decision there shall be no appeal.

Copy of Rules to be Furnished to each Competitor, and Signed by Him.

Three printed copies of these rules will be supplied to each competitor or his accredited representative, and no competitor will be allowed to deliver his vehicle at the Crystal Palace until he has signed one of these copies, and it has been handed in to the Editor of *The Engineer* and formally acknowledged and accepted by him. In signing and forwarding this copy of these rules, the competitor shall accept all the conditions herein imposed upon him, and shall agree to be bound in all respects by them.

Official Number and Stamp on Vehicles.

Prior to the start for the long-distance competition, there will be attached to each vehicle, in some convenient place, a card stamped with the judges' seal and bearing upon it the number assigned to that particular vehicle for the purposes of the competition. The seal must not be broken, otherwise the vehicle will be disqualified.

Paragraph to be Signed by Competitors.

I agree to abide, and be bound, by the above rules and conditions, or any modifications of them which the judges may think desirable or necessary.

DOINGS OF PUBLIC COMPANIES.

New Beeston Cycle Co. (Limited).

The Future of the Motor-Cycle.

The first ordinary general meeting of the shareholders of the New Beeston Cycle Company (Limited) was held on the 18th ult. at the Institute of Chartered Accountants, Moorgate Place, E.C., under the presidency of Mr. Harry J. Lawson (the chairman of the Company).

The Chairman having explained that this was only the statutory meeting, stated that the amount subscribed by the public was about £180,000, out of which some £80,000 or £90,000 would form the nucleus of working capital. As they knew, the share capital was £1,000,000, and if at any future time further issues were made half of what would be raised would go to increase the working capital. After dealing with the ordinary cycle trade, with which we are not specially concerned, he said:—I am happy to be able to tell you that in that famous ride on Saturday, which will form one of the historic pages in the history of England (applause), we showed the world that we can go by ourselves unassisted, with self-acting carriages and cycles, from London to Brighton or anywhere we please. I am pleased to tell you that on that ride one of our motor-cycles was the only one of its class that got through. (Applause.) It was ridden by, I might almost say, a boy, and I believe he had never ridden in a race, and I do not believe he had had any experience whatever of a long journey. We saw him on the machine; we saw him get along without working, and he went up and down the hills with the greatest facility, beating all the trotting mares which were out to join in the procession. He arrived in Brighton, notwithstanding the thickness of the mud, a dead head wind, and a pelting rain, in a little over four hours, and the British Motor-Car Club awarded him a gold medal for his exploit. (Applause.) I go out before breakfast every morning when the weather is fine on one of these Beeston motor-cycles, and I can assure you it works wonderfully well. Now, in the matter of the sale of these machines we want you to assist us, and in connection with this there is one man who wants to be worried—I pity him more than anybody else—and that is our much respected manager. I am sure that if you had experience of them there is not one of you gentlemen who has £50 or £60 to spare who would not obtain one of these Beeston motor-cycles. In it you have a horse under you which will do whatever you wish, and you can regulate it very easily. It does not matter whether you are old or young, or male or female; you have a willing servant which will carry you anywhere. You can go to Scotland with it, and you are thoroughly independent of horses or vehicles if you possess one.

Dr. C. W. Iliffe followed, and in the course of his remarks said:—As to the motor-cycle, I may say that Mr. Lawson sent down a telegram to the works on Thursday, with regard to Saturday's tour to Brighton, desiring that a motor-cycle should take part in the journey. The result was that Mr. Gorton's son, who had not ridden the cycle more than four or five times, was selected to ride it, and it is now a matter of history how well the little machine came out. It started under the most unfavourable circumstances from the Hotel Métropole. It reached Reigate in the most respectable time, being fifth in the line of arrivals there. After a quarter of an hour's delay, it proceeded to Brighton, which it reached in the unprecedented time of four hours and three-quarters. (Applause.) At Reigate and Brighton electricians and engineers of very great competency examined the machine, and one and all pronounced this verdict: that it was the very best machine on the road. I may say it was the only one of British manufacture there. (Applause.)

A Shareholder: Do you make the motor-carriages?

Dr. Iliffe: No; only the motor-cycles. Our department is that of manufacturing ladies' and gentlemen's motor-cycles, together with the general cycle industry.

A vote of thanks was accorded the chairman and directors, and the proceedings closed. Shareholders afterwards inspected one of the motor-tricycles which had been brought into the room.

Anglo-French Motor-Carriage Co. (Limited).

THE statutory general meeting of the shareholders of the Anglo-French Motor-Carriage Company (Limited) was held on the 24th ult., at Winchester House, Old Broad Street, E.C., under the presidency of Mr. E. B. Ellis-Clark. The Secretary (Mr. F. H. Firth) having read the notice convening the meeting,

The CHAIRMAN said:—Gentlemen,—You know that the Company was formed to exploit the system of M. Roger, who had small works in France. These works, as was stated in the prospectus, were altogether inadequate for the carrying on of a large business, and one of the first things that the directorate did was to look about for fresh works in France. The French directors found very suitable premises, and Mr. Barrett and I were deputed to go over to see these works. We thought them admirably adapted for the purpose, but of course they were simply works without any of the necessary machinery to carry on our operations. While negotiations were in progress for these, the French directors saw that considerable delay would take place in equipping an empty factory, and although they continued negotiations for this factory, they immediately set to work to see if they could not find works completely equipped for our purpose; and in the course of some little time they were successful in putting their hands upon works which they thought were very suitable. Mr. Barrett and I went over to Paris again, and I must say that in the course of a long experience I do not think I ever saw a factory that was so suitable for the purposes of our business. Not only the machinery that was there, but the order and the planning of everything was modern and up-to-date. It is just a place that we ought to have to carry on our business in Paris; in fact, if it had been designed for our works, it could not have been better. A great deal of time, thought, and money has been spent upon the place. Negotiations are still proceeding for the acquisition of this factory. These negotiations in England are often very protracted, but my experience is that they are very much more protracted in France. The negotiations, however, are now being actively carried on by the members of the board in Paris, and I believe, from information which we only received this morning, they will be successful in their endeavours to obtain this factory for us. All I can say is that if they do we shall have one of the best factories in France for the purposes of our undertaking. Meantime, we have not been idle in England. Messrs. L'Hollier and Gascoine set to work to try and find us a factory in Birmingham, which we consider the most central neighbourhood for our business. We have taken premises occupying about 3,000 square yards, which we are now equipping in what I think I may call a modest manner. We are not going to spend so much money there, to begin with, as we had anticipated, owing to the proposal to acquire this factory in Paris. Mr. Gascoine is here to-day, and he will tell you that we are very nearly ready to commence work there, and I hope that within a few weeks we shall commence to make our carriages in England. A good many of you—in fact, I suppose all of you—have been interested in the accounts of the recent motor-car tour to Brighton, and I daresay some of you may have been rather disappointed at our not having occupied first, second, or third place in what finally, although it was called a tour, came with some to be absolutely a race. Well, the fact is, that the leading vehicles in this race were not the ordinary motor-cars of commerce, if I may say so; they were specially-constructed for the Marseilles race, and they had 10 horse-power, whereas ours only had 5. We put into that tour the ordinary vehicle such as we should sell every day to our customers, and therefore we did not occupy that position in the race which probably some of you thought we should have done. That race, however, has taught us a great many lessons, and has been very useful to us in every way. For my own part, I am very glad that it took place, because it will enable us, before we make any other stock, to effect certain modifications and additions to our motors which, I believe, will enable us to have the very best motor-car in the market. After dealing at some length with the prospective value of their patents, and to the fact that they intended at first to build carriages of utility instead of vehicles of luxury, he concluded by saying:—We have got a great many orders and inquiries coming in every day—I had forgotten to say that the Paris house is making motors for carriages for the distribution of goods for the Louvre. I think all this shows that we have got a first-rate carriage. I may also say that there is a cab company at Bordeaux which has investigated all the motor-carriages, and come to the conclusion that ours is the best, and they are forming a company to put our cabs on the streets of that city. I shall be very glad to answer any questions that may be put to me by the shareholders, and will say, in conclusion, that I believe we have got a first-rate future in front of us. (Applause.)

At the request of some of the shareholders, Mr. GASCOINE (the manager) said:—It seems to be the opinion of everybody in the Midlands that we have been exceedingly fortunate in securing such first-rate works there. The rent is low; we are nearly all on the ground floor; we are right in the centre of the city, and we shall be able to combine show-rooms with the factory. As far as the Birmingham part of the business is concerned, everything is looking exceedingly favourable. We have been getting 50, 60, and up to 80 letters every morning, and although we find our difficulty at present is to secure orders, owing to the fact that we have nothing to show as samples of English-made carriages, or even of foreign-made carriages, in the course of a few days we shall have English-made delivery vans which we can show customers, and directly we do this we shall be able to secure numbers of orders. The question has been mentioned about the suitability of electricity as compared with benzoline. I am sure it is very satisfactory for us to see in to-day's Press that Edison, the eminent electrician, gives it as his candid opinion, that at present electricity has not a chance with the motors in the market worked with steam or gas. Our motor is practically a gas-motor, only instead of using coal-produced gas, we use gas which is generated by benzoline. Of course, our business is not a speculative business. As our Chairman has said, we are not making any attempt to puff it; we want to go slowly but surely ahead, and produce something which is really practicable, and then I am sure we shall have a great success; there will be no lack of orders. (Applause.)

A vote of thanks was then passed to the chairman.

NEW COMPANIES REGISTERED.

[Under this heading we intend in future giving a full list of any new Companies registered which take power to make, deal, or become interested in any manner in automotor vehicles. Where detailed particulars are not given under this heading we shall be pleased to reply to inquiries through the "Answers to Correspondents'" column. All communications should be addressed to the Editor. The only stipulation which we make is that where the inquiry involves a search of the records at Somerset House—as in the case of information on the subject of the holdings of shareholders—a postal order must be enclosed to cover the Government stamp of one shilling which is charged before a search is allowed to be made.]

	Capital. £
Armstrong-Dove Motor Syndicate	6,000
Anglo-French Cycle Co.	30,000
Australian Cycle and Motor Co.	75,000
A. B. C. Cycle Fittings Co.	50,000
Auxiliary and Light Railways and Tramways Co.	10,000
British and Colonial Cycle and Components Syndicate	10,000
Birmingham Tubes (Limited)....	250,000
Brainard's Pneumatic Tyre Machine Syndicate	25,000
Birmingham Pneumatic Tyre Syndicate	25,000

	Capital. £
Coventry Machinists' Co.	10,000
Chorley Railway Wagon Co.	20,000
Casswell (Limited)	50,000

Sanspareil Cycle Co.	30,000
Self-Adjusting Bicycle Support Co.	25,000
Traffic Syndicate (Limited)	10,000
Whitehead's Auto-Cycle Co.	2,000
Windham Pneumatic Tyre Syndicate	5,000
Woodley Co. (Limited)	125,000
Yeovil Motor-Car and Cycle Co.	1,000
Zenith (Folding) Cycle Syndicate	6,000

Motor Development Corporation (Limited).

Registered November 24th, with a capital of £25,000 in £1 shares, to adopt an agreement with John V. Sherrin, to manufacture, sell, and deal in motors, rims, cycles, and other vehicles, and carriages, and to carry on the business of engineers, machinists, fitters, founders, &c. The number of directors is not to be less than three nor more than five; the subscribers are to appoint the first. Qualification, £1,000; remuneration, £150 each per annum. Registered by W. T. Hick, 2, Church Court, Clement's Lane, E.C.

Hastings and St. Leonards Engineering, Cycle, and Motor-Car Co. (Limited).

Registered November 18th, by C. Doubble and Co., Serjeants' Inn, E.C., with a capital of £2,500 in £1 shares. Object: to enter into agreements with N. Chennells and W. Wingfield, and to manufacture and deal in cycles, motors, carriages, carts, bath-chairs, wheels, tyres, machinery, &c. The directors are R. H. Gaby, L. O. Glenister, N. Chennells (managing director), J. C. Miller, and W. Slade, junior. Qualification, £25; remuneration, £80 per annum, divisible. Registered office: 37, Havelock Road, Hastings.

English Serpollet Motor Syndicate (Limited).

Registered on November 18th by Ashurst, Morris, Crisp, and Co., 17, Throgmorton Avenue, E.C., with a capital of £100,000 in £1 shares. Objects: To enter into an agreement with George Hopkins, Gustavus P. Harding, John T. B. Sewell, and Charles O. Maugham; to make, sell, let, exchange, deal in, and dispose of engines for motive or other power, motors, motor-cars, cabs, cycles, omnibuses, trams, carriages, and vehicles; and to carry on the business of mechanical, hydraulic, and electrical engineers, manufacturers, and contractors, machinists, smiths, engineering tool makers, boiler makers, &c. The first directors (to number not less than three nor more than seven) are to be nominated by the subscribers. Qualification, £200. Remuneration, £500 per annum and a percentage of the profits divided between them.

Westralian Motor-Carrying Co. (Limited).

Registered on November 24th, by J. A. Maxwell, 97 and 98, Bishopsgate Street, E.C., with a capital of £7 in £1 shares. Objects: To carry on the business of carriers, transport agents, coach and carriage builders, cycle, motor, carriage, and autocar manufacturers, dealers, and repairers, machinists, &c. Registered without articles of association.

New Issues.

The British Motor Syndicate (Limited).

The issue of this Company's shares at a premium is fully dealt with in an article which will be found on page 108. With reference to the result of the venture the following statement, made by Mr. Harry J. Lawson to an interviewer, is the only official intimation which has been made:—

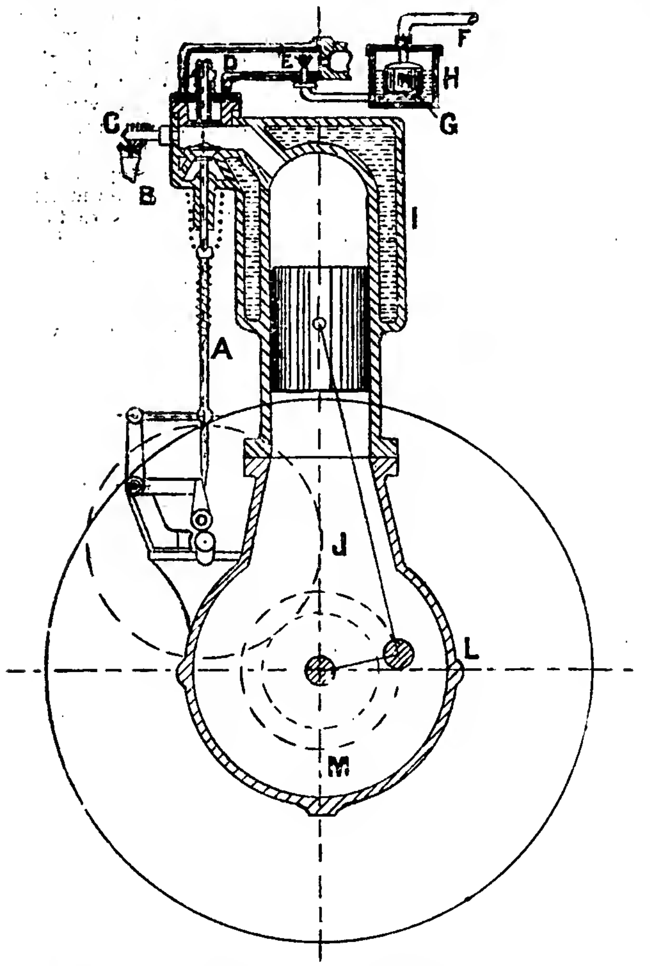
"The issue of the British Motor Syndicate was merely for a certain amount of increased capital. We didn't expect, nor do we need, the whole of the capital for which we asked the public to subscribe. The issue has been very successful indeed, and the most enthusiastic people in connection with it are the shareholders. As far as the position of the new shareholders is concerned, I am willing to make a public statement that, in my opinion, their shares will be, in a very short period, at a much higher price than £3. We have everything of the most improved character in electricity and steam, which we would not take anything for. My own belief in the system is shown by the fact that I have nearly all the money I have in the world—except some house and land property—invested in these motor patents and in the different companies owning them."

The Defiance Cycle and Motor-Car Company (Limited), Swansea, has been floated, with a capital of £10,000. It is understood that nearly all, if not all, the shares have been taken up by a few local gentlemen, and the manufacturing operations will commence at Swansea in January next. Suitable premises on the Strand are available.

A few days ago Sir David Salomons, the President of the Self-Propelled Traffic Association, was to be seen driving in the Park, in Fleet Street, and other crowded thoroughfares, in a new Serpollet carriage which he has just received. Considerable improvements have been made upon the original design, and an early opportunity will be given for inspection of the carriage in London.

THE DAIMLER MOTOR.

AT the request of several correspondents, and in pursuance of our arrangements to publish sectional views of typical motors, we illustrate the details of the celebrated Daimler engine. The patentee, Herr Gottleib Daimler, was for a considerable period associated with Dr. Otto in the work of perfecting the well-known gas engine which is identified with the name of the latter. Since Herr Daimler commenced business on his own account he has gained the unquestioned position of being the leading designer of oil-engines for motor-carriages on the Continent. His first application to a bicycle was made in 1886—and his then effort was illustrated in our last issue—while in the following year he applied the same principle to a motor-carriage.



His engine consists in its main essentials of two cylinders cast together, the operations involved, viz., the drawing in of the explosive mixture, its compression, explosion, and expulsion of the waste products, following exactly the "Otto cycle," which is so well-known to all interested in the matter.

The automatic system employed to supply the requisite charge of oil to form, in combination with air, the volatilised explosive charge is very neat and simple. The float chamber is connected with the reservoir containing the main supply of oil, the float H regulating the inlet of petroleum so that it cannot rise above the fixed level in G. The oil is in consequence conveyed to the jet E at a constant pressure, being vapourised at that point by the induced draught, caused by the suction of the piston. The carburetted air passes through the valve into the cylinder freely until the piston reaches the end of its stroke. The amount of compression to which the gas is subjected on the return stroke of the piston, can be regulated in accordance with the spring employed. It varies, as a rule, between 42 and 56 lbs.

The explosion takes place immediately after compression as the piston is starting on the second forward stroke. The firing is effected by means of the platinum tube C, heated to incandescence by a burner B, the contact being effected by means of an automatic movement actuated by a reciprocating member of the engine.

On the return stroke the burnt gases are discharged through the bottom valve, which is lifted by the rod A, raised by a cam working on a small shaft, which only rotates at half the speed of the main shaft, so that the rod A is only operated every other revolution.

The cylinder I is cooled by the water-jacket, while the disc M, and the rods are enclosed in air-tight casing L, to protect them from dust and dirt. The shell is partially filled with oil, so that the crank shaft, rods, and disc are perfectly lubricated. The ordinary rate of working is high, viz., 700 revolutions per minute, but in consequence of the efficient oiling arrangements, there are no difficulties in this respect.

"AUTOMOTIVE" VEHICLES.

AT a special meeting of the members of the London Chamber of Commerce, held on the 1st inst., in the Council Room, Botolph House, Major Flood Page delivered an address upon "Motor Vehicles."

Mr. W. H. WILLANS, Chairman of the Council, presided, and the large audience which assembled on the occasion included the Count de Torre Diaz, Baron G. de Reuter, Mr. John M'Call, Mr. Boverton Redwood, Mr. W. Mowat, Mr. Alexander Sclanders, Mr. J. Lulham Pound, Mr. A. R. Bennett, Mr. George J. Jacobs (President of the Institution of British Carriage Manufacturers), Mr. A. R. Sennett, Mr. J. H. Mace, Mr. L. Epstein, Mr. W. B. Leaf, Mr. C. J. Wharton, Mr. J. M'Andrew, Mr. F. S. Tomkins, Mr. Walter Hancock, and Mr. Kenrick B. Murray (Secretary).

The CHAIRMAN, in opening the proceedings, remarked that the attendance that afternoon was a clear indication of the interest taken in the subject of the lecture.

Major FLOOD PAGE, in the course of his address, stated that since the Act of Parliament relative to the subject of his address had referred to motor-cars as light locomotives, they would, so far as they were concerned, have to use that most unfortunate name. But they must have one word for everyday use, and since locomotive had been monopolised by steam he would suggest the word "automotive." He continued to give a history of the various means of locomotion, observing that the first omnibus appeared in Paris in 1828, and in London one year later. In 1823 there were only 12 cabs in London, and in 1886 there were 25,000 hackney carriages, while at the present time there were 115,000. France had ever been before England, and was now in advance of her in respect of the automotive. That was, he remarked, to a great extent due to the restrictions placed upon their use. Continuing, he dealt with the regulations laid down by the Local Government Board, the stringency of which was, to some extent, again due to the words "light locomotive." He believed that experience, however, would soon alter the present regulations, and he ventured to prophesy that before many years had passed there would hardly be any restrictions other than those at present in force with regard to horse traffic. They would find that but one of the rules drawn up by the Local Government Board would be sufficient, and that would be the one regulating the speed to a "reasonable" and "proper" rate, having due regard to the safety of foot passengers and other vehicles. The automotives would be found to be of great commercial value, and he firmly believed that in the near future quite different regulations would be in force. There was one very satisfactory feature in the regulations, and that was that they should only have effect for six months, and during that time he trusted they would be able to overcome the public nervousness, and that of the authorities. He would like, however, to protest against the action of the Chancellor of the Exchequer, who had caused to be inserted into the Act a clause which was iniquitous. It was to come into force on the 1st of January next, and stipulated that in Great Britain every automotive should be subject to an additional duty of Excise, in the case of an unloaded vehicle weighing under one ton to the amount of two guineas, and under two tons three guineas. They would thus have two classes of omnibuses in London, one paying a tax of 15*s.* and the other of £3 18*s.* With regard to the commercial results of the introduction of the automotive, he anticipated they would affect the petroleum trade, mechanical engineering, the carriage trade, railways, and by no means least of all, the war departments of every country in the world. The new industry would find work for thousands of men, though some, of course, would be displaced. Most of the automotives at present in this country were of French construction. He saw no reason why this should not be a purely British industry in every particular, for he believed it had come to stay. He continued to criticise the various methods at present employed in regard to the motive power used by the automotives, expressing the opinion that electrically-propelled vehicles would find favour in towns, inasmuch as the electricity could be easily supplied, while in the country districts he believed petroleum and steam would be more extensively used. He was of opinion that the automotive would in England supply the place of the canals of the Low Countries; and if the farmers did not, commercial men must organise the agricultural districts, so that they might, by the additional means of local communication afforded them, strive to retain within the United Kingdom a large proportion of that money now paid to the foreign farmer. There was plenty of room for improvement in the automotive, and he did not believe that the automotive of the future was yet built. They were at the beginning of a new era of internal communication, and he firmly believed that trade and commerce would benefit by it.

Mr. Sennett, in paying a compliment to the lecturer, said that he had clearly shown that there was much work before both engineers and carriage-builders of this country, and he thought it was quite useless for them or anybody else to waste time in the invention of a new name for self-propelling vehicles. If, however, they chose to do this, he thought the name should be one which carried its meaning on its face, which he certainly did not feel was the case in regard to the word suggested by Major Flood Page, namely, "Automotives"; for such a word could with equal appositiveness be applied to ordinary stationary motors, and also it would be necessary to tack on to this newly-invented word the name of the vehicle. If you called through your telephone, "George, bring the automotive," what could the groom do but "phone" back, "Which one, sir?" (Laughter.) Now, if you simply made use of the word "motor" in front of the vehicle you desired to refer to, all trouble was at an end. Thus you could call for your motor-Victoria, your motor-dog-cart, motor-van, motor-wagon, motor-omnibus, &c. Complaint had been made that the regulations of the Local Government Board were too stringent, and should be done away with to a very large extent. He thought that in introducing a new innovation it was better to err on the side of safety, at least until such time as it had been demonstrated that such stringency was unnecessary, when it could be with advantage removed. Mr. Sennett defended the employment of a double brake on self-propelling vehicles, pointing out that it was not only a means of increased safety but one of considerable convenience. He had driven various motor-carriages considerable distances, and, especially in the heavier types, he found it a great convenience to have two brakes, so that the wheel or hand-brake might be applied gently to take the weight off the carriage when descending a hill, and its speed and general control affected by the foot brake. If you had a simple brake so powerful as to comply with the regulations, you would find that brake a very inconvenient one for gently slowing up, and manipulating amongst traffic. What he thought was required, was a very handy brake for general use applied by the foot, and another and more powerful one for hill descending. Reference had been made to the difficulty of estimating speed. If this were necessary to be done, he did not see much difficulty in it; all you had to do was to take a measured distance, say, between one or more lamp-posts, and note the time occupied in the transit between them. It was certainly somewhat of an anomaly that Parliament should be practically unanimous in removing a burden from an industry, and then immediately go and tax it, but he thought, however, the immense economy which mechanical self-propelling traffic would shortly show over horse-drawn traffic, would not only neutralise the effect of the taxation, but would render it of small moment. One benefit to urban traffic should shortly be brought about, and that was the adoption of a sixpenny cab-fare system. This would probably be found of great advantage not only to the business man, but also to the proprietor and to the driver. One thing he would much like to draw the attention of the meeting to, and that was the reprehensible practice adopted in this country of leaving horses, from the mouths of which the bits had been removed, standing quite unattended outside wayside inns, and in other positions. This, he thought, amounted to culpable neglect, and should be dealt with by legislative enactment, if County Councils possess not the power to stop it. He had run a good many miles in France, and the petroleum motors certainly frightened country horses, although town horses took but little notice of them; accidents from this cause were there prevented by the prevailing practice of attaching all horses left by themselves to a ring in the ground by means of a rope. In the new Act provision, of course, had, very wisely, been made for the carrying of a light on motor vehicles; he was sorry that the word was used in the singular—which he understood was a slip on the part of the draughtsman—two lights should, undoubtedly, be provided for, for the use of a single lamp by cabmen and others without reference to the "near" or "off" side was decidedly a source of danger. He thought it would be a good thing for users of motor vehicles voluntarily to use *two* lights, and to put on the "off" side a small disc of green glass, about the size of a penny, in front of the flame, and another of red glass on the "near" side. By this means both the position and direction of going of the vehicles could at once be ascertained. This would obviate a vast amount of slowing-up in travelling on country highways, a thing which he hoped would shortly be practised to a very great extent for the transport of farm and market garden produce. The point, however, he wished to call attention to was, that if it were necessary on the part of motor vehicles to carry lights, it should also be made compulsory on the part of horse-drawn vehicles. (Hear, hear.) The latter were the most dangerous, from the fact that the animal's head projected some 10 feet beyond the point of support of the light, whereas with motor-vehicles these were almost invariably placed quite at the front of the vehicle. He regretted to learn that it was a moot point as to whether County Councils could enforce regulations for the universal exhibition of lights upon vehicles. Mr. Sennett thought this point should be cleared up without delay, and if any further legislation were necessary it should be entered upon at once. With regard to the best form of motor, he thought Major Flood Page had dealt with this matter with commendable impartiality. Undoubtedly, various forms of motors possessed advantages under various conditions, but with regard to electricity, it should be pointed out to the non-technical mind that electricity as used in modern motor-vehicle work was not a motive power at all; it was merely a vehicle for the reproduction of motive power which had previously been obtained from a steam-engine, therefore, if you could run, for example, an omnibus by means of steam power, without visible emission or noxious exhalations, it was clearly far more economical to use steam directly for that purpose than through the intervention of electricity. He felt, however, that there was a great future for electricity in urban traffic, and he hoped it might not be long before we had an efficient electrically propelled cab system. With regard to petroleum, undoubtedly there was a vast field open for this in the future, but at the present moment petroleum and gas motors had not been made sufficiently adaptable to motor vehicles, that it might be said their employment in this relation was an unqualified success. The shortcomings of steam-motors, indeed, were so much less important than those of petroleum-motors that it was more convenient to follow the unscientific course of using petroleum to raise steam and drive your vehicle by steam from petroleum than by petroleum direct by means of explosion or internal combustion; no doubt, however, developments would speedily take place now that our highways are open. With regard to the employment of motor vehicles in war, referred to by Major Flood Page, he thought there was a vast future open for them in regard to commissariat and transport work, but he begged leave to differ entirely from the Major in regard to horseless gunnery. The French Government had had transport vehicles built upon the Serpollet system, and these had been severely tested, and had fulfilled the requirements admirably, but the military authorities pointed out that, with regard to gunnery, if you had a gun drawn by half-a-dozen horses, and one were shot down, another could be quickly harnessed, whereas if you had a shot through your motor your gun was at once *hors de combat*. With regard to the formation of companies, he thought it was certainly necessary to form companies for the purpose of development, and although the lecturer had referred to the loss of millions in reference to the introduction of electrical lighting, Mr. Sennett pointed out, amid much laughter, that this money had not sunk either into the sea or the land, but had merely changed hands. The public must exercise discretion and look out for themselves, which he admitted was a very difficult thing, now that company-promoters were so much on evidence, and actually run their own newspapers.

Mr. G. J. Jacobs, Master of the Institute of Carriage Manufacturers, made some very amusing remarks, pointing out that constructors of petroleum motors should hasten to perfect them, because it would be decidedly *infra dig.* to see a coachman in his pig-skins, pink tops, and cockade, working away with hammer and chisel on his carriage by the roadside. He said coachbuilders of this country were waiting for the engineers to decide what motor was to be used, for they had to make the body, whilst the latter made the soul. They indeed were more concerned in the making of things of beauty, and they were quite prepared to make an elegant equipage when the matter of the motor had been settled, for it was that which determined the general design.

Baron de Reuter having spoken, and brought figures to show that in the running of automobiles in Paris the fact had been demonstrated that they were safer than horse-drawn vehicles in that city, in which he believed the driving on the part of the French coachman was the worst in the world.

Mr. Walter Hancock spoke as to what steam had done in this relation, and was likely to do, and gave some interesting particulars concerning the work of his uncle, the Mr. Walter Hancock who had been so very successful in regard to the running of steam omnibuses in London about 1830.

The proceedings terminated by a vote of thanks to Major Flood Page, proposed by Mr. W. H. Willans.

THE STANLEY AND NATIONAL CYCLE SHOWS.

These famous exhibitions of cycles and accessories which have just taken place have been greater successes than ever—whether judged from the standpoint of attendance or exhibits. It is out of our province to specially describe the exhibits, as they mostly consisted of pedalled machines, the merits of which have been fully discussed in the newspapers specially devoted to that ever-growing industry. The British Motor Carriage Syndicate (Limited) had a capital exhibit, which proved one of the principal attractions, consisting as it did of some of the leading types of vehicles which took part in the run to Brighton. It is not necessary to fully describe any of these, as they were illustrated in previous issues. The New Beeston Cycle Company and the motor-driven Olympia type of tricycle were also well to the fore. Amongst miscellaneous exhibits the Silvertown detachable tyre and the Fleurs tyre deservedly attracted a large share of attention; while the Dwarf Cycle Company showed a well-made chainless bicycle, which we understand they intend to adapt to motor purposes at no distant date. The National Cycle Motor-Car Insurance Company (Limited), of King William Street, London, did a thriving business at both the Agricultural Hall and the Crystal Palace—the secretary, Mr. Willson, informing us that he had booked several good lines.

A MOTOR RUN TO LIVERPOOL.

Mr. Wall, a stockbroker of Cork Street, Liverpool, contributes an interesting description of a journey which he recently undertook from London to Liverpool in an Arnold carriage. As the journey was primarily intended for pleasure purposes, no attempts at high speeds were made. The chief difficulty which was experienced was in obtaining supplies of oil of the requisite quantity to use in the engine; but this will doubtless soon be remedied by organisation. The following were the daily runs:—

			miles.	h. m.
Monday,	Nov. 23,	London to Barnet	11¼	1 30
Tuesday,	„ 24,	to Towcester	48¼	6 32*
Wednesday,	„ 25,	„ Drayton	52	8 29†
Friday,	„ 27,	„ Stafford	28¼	3 55
Saturday,	„ 28,	„ Whitchurch	34	6 50
Monday,	„ 30,	„ Birkenhead	34	4 15‡
			203¼	31 31
		Breakages	....	2 40
				28 51

* Hills and stones. † Hour lost in byroads in dark.
‡ Good road.
70 or 80 miles travelled in the dark.

PROPOSED MOTOR-CARRIAGE AND TRAMWAY COMBINATION.

The removal of the restrictions on the use of mechanically-propelled vehicles is likely to result in the motor-cars making their appearance in Dundee at an early date. When it became definitely understood that the cars were to be legalised the directors of the Dundee Tramway Company took up the question of making use of the new vehicles for the purpose of developing their traffic in the districts where at present there are no car lines; and it is now more than likely that the question of tramway extension in the city will be dealt with by means of the motor-cars. The only part of the present tramway system on which horse cars are run is the Perth Road line, and under the present regulations mechanically-driven cars cannot be run on that line. The intention is, however, to make use of them in the districts where there are no tramway lines, and which are at present entirely neglected by the Company or only served by 'buses. It has been suggested that motor 'buses might be put on the Downfield route, and that Birkhill and other country districts might have regular communication with the city. It is also proposed that Fairmuir and Lochee termini might be connected in the same way.

The *Daily Chronicle* of Saturday last has a wonderful reproduction of "a print on a silk handkerchief which has been in the possession of one family for 70 years." It is entitled "The Century of Invention, A.D. 2000," and some of the motor-carriages represented are very apposite to-day.

ELECTRIC TRAMWAYS ON HEAVY GRADIENTS.

The unsuitability of electric traction for tramways with heavy gradients has been so often urged that some details may be given of a line at Lausanne, newly opened and now working successfully, where the maximum gradient of 11·3 per cent. extends for 300 yards, probably the heaviest in Europe. Moreover, the line is hilly for its full length of 7½ miles. The cars weigh empty six tons, carrying 26 passengers, increasing the load to eight tons, and they have each two motors of 20 h.p. to give a speed of from 12 miles an hour to 7 miles on the heaviest gradient. The motors are of the four-pole type of 85 per cent. efficiency, and when developing 15 h.p. run at 540 revolutions. Emergency brakes are fitted to the cars, consisting of a piece of iron with sharp teeth, which may be lowered down and forced against a wooden rack rail, by which means the car can be stopped within two yards on the 11·3 per cent. gradient. The overhead system is adopted, and the six-pole dynamos at the central station are driven by two Crossley gas-engines, each of 130 effective horse-power when working at 160 revolutions. They have fly-wheels of six tons weight. The current produced can be varied from 100 ampères at 152 volts to 140 ampères at 50 volts, and accumulators are provided at the station.

AN ELECTRICAL STREET-CLEANING CAR.

A vehicle of this description has just been completed and will shortly be introduced to the various municipal authorities. It is 22 feet long, 8 feet wide, and 9½ feet high. Instead of being placed at the side the motors and brakes are above the wheels and axles, so as not to impede the action of the dust brushes. Three large rotary brushes, fixed on the centre of the car, do the sweeping and loading work on the same principle as a carpet sweeper, and are covered with steel casings, which have proper outlets for discharging the sweepings into the body of the car. As to the car itself, it can be worked either backward or forward without any change of machinery, the whole arrangement being reversed by the simple pressure of a lever. The brushes make five revolutions to each one made by the car wheel, and this high-brush speed forms a powerful suction which takes up all refuse matter and deposits it in the car. It is stated that the car has a loading capacity equal to 50 carts; can travel at the rate of nine miles per hour while performing its work; and that it can cleanse 45 miles of road in a day besides disposing of the refuse gathered, the cost per mile of working being about 12*s*.

CYCLES AND MOTOR-CARS IN PARIS.

The fourth Salon du Cycle was opened at 2 o'clock on Saturday afternoon in the Palais de l'Industrie. There was an immense number of visitors, and several slight accidents resulted from overcrowding. Many people found it impossible to gain admission. So great was the throng that when the Minister of Commerce arrived on a visit to the exhibition a way had to be made for him by a considerable body of police. At one time exit was a matter of great difficulty, and to make matters worse at dusk the electric light suddenly failed and people had to grope their way out into the Champs Elysées. There are altogether 550 exhibitors, and the stands occupy not only the entire ground-floor but also a portion of the first storey. France is represented by fully 450 exhibitors. Since the last show the number of motor-car exhibits has quadrupled. The leading English firms are well represented, and the excellence and finish of the work displayed on their stands receives general praise. American exhibits occupy a very prominent place this year.

THE DURYEA MOTOR.—A £5,000 CHALLENGE.

The Duryea Company—an illustration of one of whose carriages appears on this page—are fully confident that they have one of the best motors at present on the market. Mr. McKim, the owner of the patents, is, however, not for the moment inclined to sanction the publication of any details as to his special claims, as he prefers to wait until everything is, in his opinion, complete, instead of publishing points piecemeal. We hope, in an early issue, to be able to publish in a concise form all information which is likely to be required in respect to these patents. In the meantime we hear that Mr. McKim has demonstrated in a very practical way that he is not afraid to back his good opinion of his Duryea motor, by sending a challenge to the Secretary of the Motor-Car Club, suggesting, purely as a test of endurance and suitability for road traffic, that he should enter one or more of his carriages to compete (not for speed necessarily) against any other carriages that the Motor-Car Club may possess or control, the suggestion being that they should start from St. Martin's-le-Grand and travel to Glasgow and back. The stakes suggested were £5,000 a side, to be deposited with an official of one of the leading financial institutions. This test was to be entirely as to endurance and suitability for ordinary road traffic, and was in no way to be a race, but, of course, the limit allowed by law of 12 miles an hour would have been permissible in the ordinary way. The suggestion of Mr. McKim was, as we understand it, that the stakes were to go to the winner, and the loser was to hand over the losing vehicle for the winner to utilise in whatever manner he might think fit. We believe the Secretary of the Motor-Car Club has declined the challenge for several reasons; one being that the Club does not own any motor-cars, and another that the Club and its members, headed by its President, do not, in any way, countenance racing on the public highway. But, as we have pointed out, the question of speed beyond the legal limit was absolutely specified as not to have any bearing upon the issue, we hardly think the latter reply was necessary. We believe the challenge was specially extended to the President of the Club or any other members who might possess vehicles which claim to be superior to or as good as the Duryea. In reference to this latter extension of the challenge, we understand that the same was laid before the President, and also handed to Mr. Lawson, to deal with as representing the British Motor Syndicate, but so far, we believe, he has not taken up the gauntlet.

REVIEWS OF BOOKS.

"Phil May's Gutter Snipes." (London: Leadenhall Press.) Price 6*s.*

ON another page we reproduce, by permission of the publishers, an illustration from this book. It is, unfortunately, not one of the happiest of Mr. Phil May's endeavours, as the subject is not a very promising one. All who wish to see our great pictorial humorist at its best should get this book; the artist simply revels in the scope for his pencil which is afforded by the vicissitudes of life amongst street children. He is mostly amusing; but, when he chooses, his grim pathos brings the tear to the eye. The 6*s.* edition has been exhausted; but the publishers intend to make a popular edition at half-a-crown. As a Christmas work it should have an enormous sale.

"Carriages Without Horses Shall Go." By A. R. SENNETT, M.I.M.E., M.I.E.E., and M.I.C.E., &c. (London: Whittaker and Co.) Price 2*s.*

THIS is a marvellous cheap and able book. It has for its basis the paper which Mr. Sennett read before the British Association on "Horseless Road Locomotion"—a notice of which has already appeared in our columns; but Mr. Sennett, who is undisputably an authority on this subject, has elaborated upon the paper, and by the aid of some 40 admirable illustrations he traces the evolution of the motor-carriage from the types in vogue in the early days of the century; and while doing ample justice to the progress which has been made by our Continental friends, points out the lines on which future improvements are almost certain to proceed. The Locomotives on Highways Act, 1896, and the regulations which have been made under it, are fully set out and commented upon. The book cannot fail to be of service to all concerned in the manufacture and purchase of these vehicles; while all general readers who wish to be "up-to-date" in this matter will consult this most reliable guide.

"Auto-Cars." By D. FARMAN, M.I.E.E. Translated from the French of Lucien Serraillier. (London: Whittaker and Co.) Price 5*s.*

THIS is one of the most practical books yet written on automotor work, and, as might be expected, it is the production of a Frenchman. The author is well-known on the other side of the Channel as an expert on the matters of which he writes, and the Baron de Zuylen de Nyevelt, president of the Automobile Club of France, in writing the preface to the work has emphasised this fact. After an admirable chapter upon theoretical matters and formulæ, in which the theory of engines in general is sufficiently explained and investigated, the author describes in detail the whole of the leading motors and carriages. All necessary details are fully described and illustrated—the engravings, of which there are 112, being very clear. M. Farman, while being a keen advocate in favour of petroleum, is fair in his remarks; and his book should not only be perused—but studied—by all who wish to take up the subject at the point to which Continental engineers and carriage builders have carried it. A sufficient index is contained in the book, and tends considerably to its utility as a work of reference.

"The Law of the Motor-Car, with the Regulations of the Board of Trade." By GRIMWOOD MEARS, of the Inner Temple, Barrister-at-Law. (London: Messrs. Reeves and Turner.) Price 3*s.* 6*d.*

ALMOST coincidently with the coming into force of the Light Locomotives Act we have an able legal authority and an enterprising firm of publishers ready to hand to interpret it. All who use motor-cars or who contemplate employing them should obtain the book. In case anyone is inclined to underrate the pitfalls which may present themselves to the layman who attempts to interpret the law, we prefer to let Mr. Grimwood Mears speak for himself. In the course of an interview he said:—

"From a lawyer's point of view the accidents will group themselves mainly under three heads. There is, first, the inevitable accident; then that due solely to the negligence of the party causing the damage; and the third instance in which the party injured himself contributed by his negligence to the damage he sustained. This classification does not pretend to be either scientific or exhaustive, but it presents the familiar divisions usual to this class of work. In each of our three heads the principles of law are clear and well defined, the difficulties that arise are mainly on account of the facts being complex and controverted. A few simple illustrations will present the definite rules which tend to establish the liability or immunity of the parties. And, first, inevitable accident. Appropriately enough we may call our illustration a "hard case." A is crossing the road; a runaway horse belonging to B turns the corner rapidly and knocks A down. What is A's remedy? Briefly and bluntly he has none, providing the accident is not due to the negligence or lack of skill of B or his servants. At the time of the accident both were in possession of equal legal rights. B had as much right to ride or drive a horse along the highway as A had to traverse it on foot. The mere fact of a horse bolting is not, *per se*, evidence of negligence. Before A can recover he must show that B or his servants did some act inconsistent with the standard of prudence required from a reasonably competent and careful man. By thus showing that B might have avoided the accident had he used more care or been reasonably expert, the case is at once removed from the category of inevitable accidents, and, therefore, does not impair the general rule that for an inevitable accident there is no remedy.

"A plaintiff who is suing either for injuries to his property or to his person by reason of collision or running down must give evidence of negligence before his case can be submitted to the jury. This must, of course, be understood to be true of those cases only in which there is no contract between the parties. We are taking the ordinary instance where A collides with a vehicle belonging to B or runs over B, a person previously unknown to him. B then must, as we have said, prove that A was negligent, and he must further show that the negligence and resulting damage are clearly and uninterruptedly connected. The mere fact that an accident has happened is not enough. Occasionally there are presumptions raised by the law in a person's favour. One of the most important of these is that which in a sense protects the person crossing the road from the vehicle which knocks him down. The foot passenger needs less evidence of negligence to support his case than if he were a plaintiff seeking to recover damages by reason of a collision between vehicle and vehicle. We have, therefore, seen that when an accident takes place the person injured must prove that the defendant was guilty of negligence, and that it was from this negligence that the damage ensued."

Many warnings and admonitions are given in the volume, but our advice is buy the book and save money in litigation.

"Power Locomotion on the Highway." By RHYS JENKINS, M.I.M.E. (London: Wm. Cate, Limited.) Price 2*s.* 6*d.*, nett.

THIS is a practical bibliography of all matters pertaining to locomotion on common roads, with an interesting preface and sketch of historical matters. To the student it affords a ready means of finding the sources from which information can be obtained; but we expect that with the great increase in interest taken in the subject the author willl find it very difficult to keep it up to date. The motto of the book is very apt, viz., "Sir, mark me, ere long we shall see a pan of coals brought to use in place of a feed of oats."—Bishop Berkeley.

THE *Glasgow Herald* has recently published a very able series of articles on Mechanical Tramway Traction: and we hope that they intend to republish these in book form. The issue should be a very successful one.

MOTOR-CARRIAGE CONTEST.

To the Editor of THE AUTOMOTOR AND HORSELESS VEHICLE JOURNAL.

SIR,—I am directed by Mr. Harry J. Lawson, the President, and by the Committee of the Moto-Car Club, to notify to you that it is the intention of the Club to hold a great motor-car competition some time in May next year. The tests will be given on the point of design of the motor-car, consumption and cost of fuel, and other points, but the principal point will be speed, which we are of opinion affords the most satisfactory test as to the excellence of construction of a mechanical vehicle.

It is proposed to offer for competition £2,000 in prizes. Notice of this competition is given thus early in order to enable English manufacturers to be prepared with their productions in good time. If sufficient entries are received, the Committee will confine the competition to British-made motor vehicles. In order to carry out this competition satisfactorily, the Committee will require special ground within easy access of London, and containing at least a full level and straight mile. A special prize will be offered to the first mechanically-propelled vehicle which accomplishes a mile in a minute.

Owners of race-courses and other large enclosed spaces are invited to communicate with me if they are prepared to co-operate in providing the necessary course. There is no doubt that this marvellous and novel competition will attract an immense concourse of people, and will excite an interest not less than that aroused by the classic races. All communications on this subject should be addressed to me, at the offices of the Motor-Car Club, 40, Holborn Viaduct, London, E.C.—I am, Sir, your obedient servant, C. HARRINGTON MOORE,

Nov. 21st. Hon. Sec.

THE PROPOSED MOTOR-CAR CLUB CONTEST.

To the Editor of THE AUTOMOTOR AND HORSELESS VEHICLE JOURNAL.

SIR,—I observe that it is proposed to have a Motor Derby. To this none can have any objection. It is merely a question for those who run in the race, to consider how far they care to risk their lives with no compensating advantage.

But in the announcement, the following words occur :—"The Committee will require a special ground . . . . at least a full, level, and straight mile." Elsewhere there appears the following—" but the principal point will be speed, which we are of opinion affords the most satisfactory test as to the excellence of construction of the mechanical vehicle."

In these two quotations lie the danger of the proposed race, so far as the public safety and the pockets of purchasers are concerned.

The Local Government Board, in order to meet the desire of the local authorities to limit the speed, have fixed 12 miles an hour for the maximum, and the Act itself permits no rate beyond 14 miles an hour, and no one can hold out the smallest probability that this rate of speed will be increased in any future Act.

Therefore, any attempt to place self-propelled vehicles on the market capable of making a pace much greater than that permitted by law, will simply act as an incentive to their owners to do that which is forbidden when hurrying to keep an appointment for which they are late.

But the worst feature in the announcement is the statement that speed is the best test for a carriage, because a level track is to be selected for the trial. Experts know perfectly well that the power required to propel a light motor-carriage on the level when the road is good, is exceedingly small, while such a carriage on an incline might be a complete failure for want of sufficient power.

No test could be more delusive than the one suggested. It would place the present petroleum motor-carriages on a par with steam, whereas, on meeting an incline, the steam carriage would in a few moments be out of sight, whilst the petroleum-driven one was struggling to climb the hill.

This I can vouch for from what I have seen in connection with motor-carriages and those in my possession, as well as from theory.

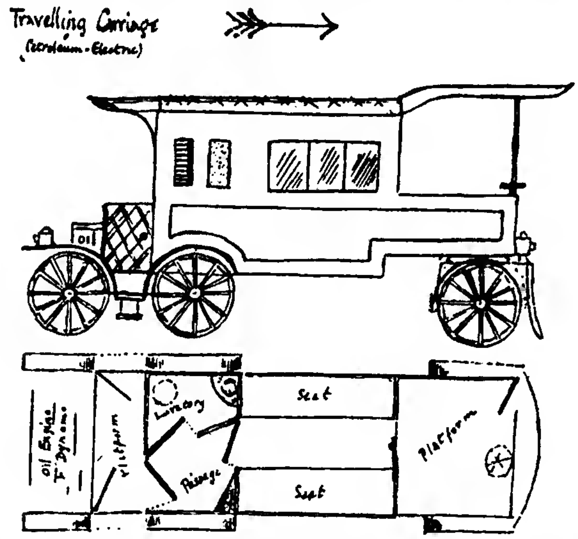
It is not fair that the public should be made to believe that the proposed test is likely in any way to produce a satisfactory vehicle. Anyone who purchased a carriage based on such a notion, would soon regret his bargain.—Yours ever faithfully,

DAVID L. SALOMONS.

DESIGN FOR MOTOR-CARRIAGES.

To the Editor of THE AUTOMOTOR AND HORSELESS VEHICLE JOURNAL.

SIR,—I venture to send you a rough sketch of a design for a motor-carriage, which is at least not on horse-drawn lines. As a member of the Self-Propelled Traffic Association I am much interested in the subject, and have gone so far as to advocate in the *Electrical Review* and other papers a combination of petroleum and electricity—an oil engine with a dynamo



being carried on a *separate* tender, and the current generated passing to the front of the vehicle and thence to an electric motor connected with the driving wheels. The tender is preferably two-wheeled, and attached to the driving axle of the vehicle by elastic shafts, so that the vibration of the engine is practically unfelt. At the same time the well marked advantages of an electric motor are obtained without the weight, cost, and trouble of storage batteries—though it may be desirable to have enough battery power to start the dynamo and engine without load.

(I enclose a rough sketch of a cab to show the arrangement and functions of the various wheels, the effect being that of *one* vehicle, though there are technically two.)

I should suggest four cylinders for the oil engine, giving an impulse every half revolution ; perhaps six if weight would allow.

Please note, wheels all same size.

So much for the "engining" of the carriage.

A plan is given of the "travelling carriage," showing deck arrangements, so to speak. A novel feature is the lavatory accommodation, the various doors being so arranged as to secure the greatest possible privacy.

Should you care to publish this as a crude design you are very welcome to it, as I am not competing for any of the prizes now being offered, and have no wish for copyright.—I am, &c.,

ALFRED J. ALLEN.

LONDON INSTITUTION, FINSBURY CIRCUS,
December 2nd, 1896.

P.S.—With regard to the sketch for a petroleum-electric carriage which I had the honour of sending you recently, it should, perhaps, have been mentioned that the oil used is supposed to be of the lighter variety, the heavier oils presenting (in spite of their greater safety) some serious disadvantages, notably a very pronounced odour. Another point with regard to the provision of an electric current as a means of transmiting the power of the engine, is the possibility of driving *all* the wheels supporting the carriage.—I am, &c.,

A. J. ALLEN.

December 5th, 1896.

MAPLE'S AND MOTORS.

To the Editor of THE AUTOMOTOR AND HORSELESS VEHICLE JOURNAL.

SIR,—The attention of my directors has been called to the fact that the name of Maple and Company, Limited, is being extensively used to advertise motor-cars. It is also stated that this company has placed large orders for motor delivery vans. I am requested to inform you that my company has not given any order for motor-cars, nor for any such description of vehicle.—I beg to remain, dear Sir, yours truly,

THOS. FINLAY, Secretary.

Maple and Co. (Limited), 149, Tottenham
Court Road, W., *Dec. 3rd.*

THE NEW PETROLEUM REGULATIONS.

To the Editor of THE AUTOMOTOR AND HORSELESS VEHICLE JOURNAL.

SIR,—We have pleasure in enclosing a copy of the letter we wrote to the Home Secretary on the subject of the new Petroleum Regulations, for publication in your colums.—Yours truly, CARELESS, CAPEL, AND LEONARD.

Hope Chemical Works, Hackney Wick, N.E.,
Dec. 2nd, 1896.

[COPY.]

Hope Chemical Works,
Hackney Wick, N.E.,
November 14th, 1896.

TO THE RIGHT HON. SIR MATTHEW WHITE RIDLEY, BART.

DEAR SIR,—We have just seen a copy of the new Petroleum Regulations for Autocars.

We are manufacturers of a doubly distilled mineral spirit called "petrol," which has been adopted by the Autocar Club as the best spirit for use in petroleum motors.

In the introductory statement referring to the regulations you state that "not only is the vapour from mineral spirit, which is given off at ordinary temperatures, capable of being easily ignited, but also when mixed with air of forming an explosive mixture."

We would respectfully suggest that these words as they stand do not fairly represent the facts of the case, and are calculated to create a wrong impression, and needlessly alarm the public.

Sir V. D. Majendie gave the Select Parliamentary Committee on Petroleum, which sat this year, an exact definition of the conditions which were essentially necessary to produce an explosive mixture of petroleum vapour and air (*see* p. 43 of No. 4 paper handed in by Sir V. D. Majendie) as follows :—

(*a*) A temperature sufficient to disengage from the petroleum appreciable amounts of inflammable vapours.

(*b*) The confinement of the vapour so disengaged in an unventilated or insufficiently ventilated space.

(*c*) The application of fire or a light, and he adds, "If any one of these conditions be absent an explosion is a physical impossibility."

We would submit, therefore, that the clause as it stands is calculated to make the public think that just in the same way as the mineral spirit gives off a vapour at ordinary temperatures which may be easily ignited, so the vapour given off may at any moment unite with air and form an explosive mixture which would be capable without any warning of causing a serious accident.

We think that such a statement, unqualified as it is, is likely very needlessly to prejudice the use of mineral spirit, and to inflict a serious injury on all those interested in motors, such as the Daimler motors, in which some form of light petroleum is employed.

As being manufacturers and distributors of this kind of spirit for over 25 years, since petroleum was first introduced into this country, we can speak positively as to the great ignorance and prejudice which exists amongst the public about it, and the very general confusion in the public mind between such explosives as gunpowder and the light petroleums, ignoring the fact that the latter are perfectly harmless, and cannot explode unless the three conditions mentioned by Sir V. D. Majendie are complied with.

Under the circumstances we hope you will be willing to amend the clause by adding the words "in a confined space," so that it will read thus: "Not only is the vapour therefrom which is given off at ordinary temperatures capable of being easily ignited, but also, when mixed with air 'in a confined space,' of forming an explosive mixture."

It is physically impossible for any explosive mixture to be formed in the open air; it could be produced only in a confined space.

All those interested in autocars feel that they owe a deep debt of gratitude to the Board of Trade for the liberal way in which they have modified the provisions of the existing Petroleum Acts so as to meet the changed conditions, and it is relying on your sympathy that we have ventured to make the above suggestion.—We are, dear Sir, yours faithfully,

CARLESS, CAPEL, AND LEONARD.

THE STUDY OF MOTOR TRAFFIC.

To the Editor of THE AUTOMOTOR AND HORSELESS VEHICLE JOURNAL.

SIR,—Judging by the frequent remarks and communications addressed to me during the last few weeks, and more particularly since the occasion of Sir David Salomons' visit, I fear that a wrong opinion has, in many instances, been formed regarding the scope and aim of this Association's work. It is to guard against the idea—apparently general—that commercial interests alone are to be provided for in our programme that I venture to claim a portion of your valuable space.

The specific object of this branch has been defined as "The scientific investigation of self-propelled vehicular and locomotive road traffic," and, in this city, circumstances have conspired to make it appear that the chief desire is to promote the circulation of heavy goods traffic by means of motor vehicles. Such priority has been considered expedient solely by reason of the pressing need for experiments and trials in this direction, and must not be taken as evidence that the papers, lectures, and discussions during our first session will be of limited interest and application. It seems to me that, since the successful "evolution" of a satisfactory vehicle for heavy work must embrace data suited to the construction of lighter types, no more inclusive method of treatment could be devised. This, therefore, may be looked upon as a fortunate development, seeing that the study of light conveyances only would be practically valueless when necessity arose to meet the exigencies of goods haulage.

In conclusion, I hope that all persons in this neighbourhood who intend to follow the movement in a scientific manner, whether they be interested from recreational or business motives, will communicate with me for particulars of the Association. On receiving a written application, I shall be most happy to send a copy of Sir David Salomons' inaugural address, together with our programme for the 1896-7 Session, to any of your readers.

E. Shrapnell Smith,
Hon. Local Secretary the Self-Propelled Traffic Association.

Royal Institution, Liverpool.

THE BRITISH MOTOR SYNDICATE (LIMITED).

Soon after the publication of the prospectus of the above Company we received several letters from those mentioned in it, or interested in its success. Some are published below, and we at the same time add one important communication which was not sent in direct, but which is of public interest :-

Sir,—I am directed by the proprietor of *The Engineer* to ask you to be good enough to allow me to state in your columns that the reference to this journal in the prospectus of the British Motor Syndicate (Limited) is entirely unauthorised by them, and that the gentleman named in such connection has resigned his post as their assistant editor.—I am, Sir, your obedient servant, S. White, publisher of *The Engineer*.

33, Norfolk Street, Strand, *Nov. 27th*.

Sir,—As statements having reference to this syndicate have been made by advertisement and otherwise which may do me considerable injury unless the obvious infereuces from them are contradicted, I beg that you will in fairness allow me to say that the reference to my name and to *The Engineer* in the prospectus of that syndicate was not only unauthorised by me, but was entirely without my knowledge. Further, that I have no interest of any kind whatever in the British Motor Syndicate or any other motor-carriage company or business. The reference to my editorial connection with *The Engineer* is also so made, I will admit inadvertently, as to do me harm by the inference that my resignation had some connection with this syndicate. I must therefore ask to be allowed to state that I resigned in July in consequence of pressure of private practice, and the announcement of this resignation has been made in the business columns of the principal technical journals in London.—I am, Sir, your obedient servant, W. Worby Beaumont.

Sir,—Will you be geod enough to allow us to state in your columns that the reference to Crossley Brothers (Limited) in the prospectus of the British Motor-Car Syndicate (Limited) is entirely unauthorised by us, and that the gentleman named in such connection is only acting as one of our consulting engineers, and the patent referred to in the prospectus must be his own, as it is in no way connected with this firm ?—Yours, &c.,

10, St. Bride Street, Robert Wilson.
Nov. 30th.

Sir,—A number of letters having appeared in certain journals on this subject, we trust you will afford us space to reply.

With reference to the names of two well-known patentees mentioned in our advertisements without, as it has been said, their first-obtained consent, we beg to state that our Syndicate actually paid to the said two patentees the very substantial sum of £12,000 a few weeks ago, and bought outright their patents with all future improvements they may make connected with this industry. We are advised that, having so purchased their inventions, we have a perfect right to advertise them as patentees in any manner we may desire.

As to the manner in which they are referred to, we have followed exact precedents, and described them in the same way as the public have hitherto been accustomed to see them styled. As to other statements, we are are quite prepared for, and, indeed, like some amount of opposition, for the whole subject is so entirely new and in advance of the times that it would indeed be singular if certain old-fashioned and undoubtedly respectable people, without a motor in their whole composition, were not to some extent shocked ; but it must be remembered that, rightly or wrongly, we believe we have in our hands a gigantic monopoly, nearly approaching in importance that of the railway companies of the United Kingdom.

Times and future events alone can prove how nearly accurate we are in our estimate, but in the meanwhile the public would do well to bear in mind that no successful monopoly has ever yet been established without similar opposition to that which is now manifested. We have only to refer to Crossley's themselves and their patent gas-engine, the Singer sewing machine, the Plimpton Skates, the Incandescent Light, and Dunlop Pneumatic Tyre, and other revolutionary inventions, which have now proved themselves, in spite of every scepticism, to be fully worth all the millions of money to the shareholders their founders once prophesied.—Yours faithfully,

Charles McRobie Turrell,
The British Motor Syndicate (Ltd.), Assist. Sec.
59, Holborn Viaduct, E.C., *Dec. 1st*, 1896.

[Among the many letters which are crowded out are communications from Sir David Salomons, Mr. A. R. Sennett, Mr. H. P. Holt, and Mr. Radcliffe Ward.]

Motor-Wagon Communication between Manchester and Liverpool.

As a forerunner to the adoption of this service between Liverpool and towns in the Manchester district, a complete survey of the roads has just been completed by Mr. Joseph Hawley, Assoc. M. Inst. C.E., acting under the instructions of Mr. Alfred A. Jones (Messrs. Elder, Dempster, and Co.), one of the vice-presidents of the local branch of the Self-Propelled Traffic Association. The report is most favourable, and may be regarded as the first step towards the accomplishment of this enterprising departure.

We hope, in an early issue, to be able to give full particulars of this important scheme. It is expected that by May next all will be in form for the beginning of operations. Mr. Shrapnell Smith (the hon. secretary) and Mr. Lawrence Jones (hon. solicitor), of the Liverpool branch of the Self-Propelled Traffic Association, are taking all necessary steps to further the movement.

Australia's Motor-Cars.—The Largest in the World.

Most of us no doubt thought that we were fairly early in the field over this motor-car business, but it turns out that Australia is well in advance of us. It already has the biggest one in the world.

The largest horseless carriage in the world has just been built in California. Some idea of its size may be gathered from the fact that it possesses 75 horse-power, an unheard-of amount for this new form of vehicle.

This particular car will travel between Coolgardie and the coast, and is intended merely for freight. It will pull over rough roads two other wagons. Coolgardie is 400 miles in the interior, and up to the present time all supplies for the men at the diggings have been transported by the old wagon system, a wearisome task. It was considered impracticable and too expensive to construct a railroad to Coolgardie, so the idea of a big motor-car was hit upon.

It was no small matter designing such a vehicle. For one thing water is scarce on the road to Coolgardie, and so the steam ought not to be exhausted upon the air, but saved, reconverted into water, and again used.

NEW INVENTIONS.

Compiled for "The Automotor and Horseless Vehicle Journal" by Herbert Haddan and Co., Registered Patent Agents, of 18, Buckingham Street, Strand, W.C., London.

Patents Applied For.

24,430. November 2nd, 1896. Sir C. S. Forbes. Improvements in or applicable to motor-cars, road-carriages, and the like.

24,526. November 3rd, 1896. W. A. P. Werner. Improvements in driving mechanism for self-propelled road vehicles.

24,699. November 4th, 1896. F. A. Sharratt and W. W. McLeod. Improvements in braking cycles, motor-cars, and like carriages.

24,848. November 6th, 1896. J. Birtwistle Improvements in and relating to power-driven vehicles for use on roads.

24,881. November 6th, 1896. J. B. Furneaux and E. Butler. Improvements in explosion engines, especially suitable for propelling vehicles, boats, and other bodies.

24,912. November 6th, 1896. V. E. Pretot. Improvements in and relating to speed and reversing gear for motor-carriages and other purposes.

24,953. November 7th, 1896. W. Rowbotham. Improvements in reversing and variable speed gear for vehicles, launches, and the like.

25,105. November 9th, 1896. H. Middleton. Improvements in steam propelled cycles and carriages.

25,140. November 10th, 1896. W. Rowbotham. Improvements in self-starting apparatus for explosion engines, in particular for those used in vehicles, launches, and the like.

25,202. November 10th, 1896. J. G. Stidder. Improvements in or relating to motor and other road cars or vehicles and cycles.

25,226. November 10th, 1896. J. Powell and H. Moore. An improved method of and apparatus for driving cycles and other road vehicles and machinery generally by the aid of liquids.

25,412. November 12th, 1896. W. Simpson, W. L. Bodman, and D. H. Simpson. Improvements in the construction of motor-driven vehicles.

25,480. November 12th, 1896. W. Banies, W. Norris, and J. Simkiss. Improvements in driving and reversing gear for oil and other engines, especially applicable to motors for common roads.

25,515. November 13th, 1896. L. S. Crandall and S. G. Mason. Improvements relating to the storage and utilisation of compressed air or gas on cycles and other vehicles.

25,516. November 13th, 1896. S. Gorton, W. Taylor, and The New Beeston Cycle Co., Ltd. Improvements in or relating to velocipedes, auto-cars, and the like.

25,628. November 14th, 1896. F. Parker. Improvements in motor and other road vehicles.

25,718. November 14th, 1896. F. K. Woodroffe. Improvements in and connected with road vehicles propelled by petroleum, and other motors.

25,735. November 16th, 1896. J. Marsden and M. Pearson. Certain improvements in and relating to the mechanism of locks for cycles, motor-cars, or for other suitable purposes.

25,844. November 17th, 1896. M. E. Thomas, W. F. Toops, J. M. Hulen, H. L Hendrick, E. L. R. Hendrick, and R. W. Hendrick. Means for storing up the electricity generated by the application of the brakes to the wheels of moto-cars or locomotives.

26,105. November 19th, 1896. R. J. Crowley and E. B. Payne. Improvements in or relating to the means for transmitting motive power applicable to motor-cars and other vehicles and the like, also for other suitable purposes.

26,114. November 19th, 1896. W. J. Wynn, A. E. Wynn, and W. J. Radford. Improvements in automotor vehicles.

26,180. November 19th, 1896. B. Coultas and J. V. Coultas. Improvements in and connected with mud-guards for cycles, motor-cars, and other vehicles.

26,232. November 20th, 1896. J. H. Ball. Improvements in automotive vehicles and in mechanism for the same.

26,302. November 20th, 1896. F. W. Greengrass. Improvements in and relating to self-propelling road vehicles.

26,316. November 21st, 1896. A. T. Ellis. Improvements in and appertaining to cycles and pneumatic tyred and such like vehicles.

26,362. November 21st, 1896. W. Gibson, W. H. Palmer, and A. J. P. Whitaker. An improved driving chain for cycles and other road vehicles.

26,415. November 21st, 1896. E. Pellas and S. Fossati. Improvements in and connected with steering gear for moto-cars.

26,563. November 24th, 1896. J. E. Wallis. Improvements in road locomotives, light road locomotives, or motor-cars.

26,595. November 24th, 1896. F. Smith. Improvements in motor road vehicles.

26,643. November 24th, 1896. H. S. Maxim. Improvements in motor carriages or vehicles.

26,688. November 25th, 1896. C. Willson. Guards for motor cars or locomotives.

26,721. November 25th, 1896. J. M. Starley. Improvements in driving chains, especially applicable to cycles, motor-cars, &c.

26,780. November 25th, 1896. F. K. Woodroffe. Improvements in or connected with motors for vehicles.

26,779. November 25th, 1896. B. M. Lindwall. A fender for motor cars.

26,850. November 26th, 1896. A. G. Melhuish. Improvements in and connected with gas or oil vapour motors, and their connection with motor vehicles.

26,886. November 26th, 1896. B. J. Jacobs and The Yeovil Motor Car and Cycle Company, Limited. A new or improved reversing apparatus for motor-driven vehicles.

26,907. November 26th, 1896. F. L. Merritt. Improvements in motor-cars.

26,956. November 26th, 1896. F. R. Frost. Improvements in connection with motor cars and like vehicles.

26,976. November 26th, 1896. C. M. Johnson. Improvements in and connected with motor vehicles.

27,054. November 28th, 1896. J. E. Dixon. Certain improvements in metallic tubes for the frames of bicycles and other velocipedes, motor carriages, and for other purposes.

27,104. November 28th, 1896. J. W. Davison. Improvements in or relating to the construction of wheels for carriages, motor cars, cycles, and other vehicles.

Specifications Published.

15,564. August 19th. Electro propulsion of vehicles or vessels. L. Epstein.

According to this invention the necessity of providing charging stations is obviated by providing means on the vehicle itself by which the secondary batteries can be recharged. For this purpose the motor is so arranged, which motor is driven by the electricity from the secondary batteries, that it can itself be used as a dynamo-machine, and means are also provided whereby the said motor can be easily uncoupled from the motor shaft and coupled to a small subsidiary engine, by which it can be worked as a dynamo to recharge the secondary batteries.

18,868. October 8th. Electric velocipedes. H. W. Libby.

Relates to a bicycle to be propelled by electricity, and consists of a frame with an electric battery and an electric motor secured to said frame, a longitudinal tube extending from the front to the rear fork for holding the exciting fluid for the battery, an electric controlling device, suitable connections between the battery, motor, and controlling device, and suitable mechanism for transmitting motion from the motor to the driving wheel.

Printed Copies of the above Specifications Published may be obtained by forwarding 1s. for cost of each copy and postage to Messrs. Herbert Haddan and Co. Applications not yet Published.

QUIPS AND CRANKS.

The British Flying Machine Syndicate.

Capital—Ten Millions. In Ten Million Shares of One Pound each.

Prospectuses of the above forwarded on application. You can only get the shares at a premium. The directors having acquired the rights in all the Flying Machines which have up to the present been invented, strongly recommend this enterprise to persons desirous of investing their capital in a highly prosperous undertaking.

The directors point with pride to the successful accomplishment of a public breakfast in London and the successful accomplishment of a public dinner in Timbuctoo, and rely upon these facts to convince the public that the suggestion which has been made by carping critics that the first necessity of a going concern is that it should be able to go is absolutely without foundation.

Pictures of Flying Machines earning a substantial dividend and travelling the skies in all directions have already appeared on the back pages of the daily and weekly papers.

Persons who desire more than this as a guarantee of the dividend-earning powers of the British Flying Machine Syndicate had better lock up their spare capital in the baby's money-box.—*The Referee.*

Prince Ranjitsinhji's name figures in the prospectus of the British Motor-Car Company as "owner of Indian patents." Can this (asks a curious correspondent) have reference to the Car of Juggernaut, which may be regarded as one of the earliest autocars ever patented?—*The Globe.*

VOL. I. No. 4. JANUARY 18TH, 1897. PRICE SIXPENCE.

CONTENTS.

THE KANE-PENNINGTON MOTOR.

IN compliance with the request of several correspondents, we give the following description of Mr. Pennington's Motor, taken from his Specification, numbered 23,771, and dated December 11th, 1895. As we have not had an opportunity of testing the efficiency and utility of this much-advertised motor, we at present withhold our opinion as to its merits, but hope to deal exhaustively with it in an early issue:—

Referring more especially to the invention with a motor having two cylinders, the bearing pieces, 35, for the axle of the propelling wheel are each provided with horns, 36 and 37, for the lower and back braces, which are of steel tubing. It is preferred to make these solid to fit into the hollow ends of the braces; but they could be made hollow to receive the braces. Further, each of said bearing pieces is provided with a seat, 38, for the front end of the engine cylinder, and the piece, 35, is also provided with a bearing, 39, for a valve gear to be described below. Each bearing piece could be provided with such bearings, but, as I find it advantageous to operate the valves of both engine cylinders from one gear, only the one piece is shown as so provided.

It is preferred to use a removable block, 40, under each end of the axle to allow this to be readily inserted and removed when desired.

In making bicycles and similar vehicles self-propelling, it is desirable to reduce the weight; and, in order to effect this, the hollow frame of the vehicle (or such portion or part thereof as may be thought available) is made to constitute or form part of the reservoir for the oil. As shown, the top braces, 41, 41ª, make part of such reservoir In order to carry a large supply of fluid, a can, 42, is mounted on the frame, and connected, by a nipple, with one of the fluid holding braces. A hollow cross piece, 43, forms a brace and also a pipe connection between the fluid holding braces at their lower ends. The couplings, 43ª, unite the cross pieces to the braces. At 44 is the filling opening of the can, 42.

In the cross piece, 43, is the conical orifice and threaded cylindrical opening for the needle valve, 45, which regulates the delivery of the oil. This needle valve has a threaded stem engaging the threaded opening and the tapering point within the conical orifice as is usual in needle valves, the turning of the stem inserting the point more or less deeply into the orifice to check or cut off, or to start or increase, the delivery from said orifice. The needle valve is formed at the end of a flexible valve rod, 47, which is extended forward and provided with a handle, or other operating means, within reach of the rider. Its forward end is upheld by the handle bar, the valve rod passing loosely through a loop, 46. The valve rod, therefore, does not interfere with the turning of the handle bar, nor with its vertical adjustment. Such a valve rod, as is described, might be used to operate any suitable form of fluid delivery valve, and the described arrangement of needle valve could be used with any suitable operating means; although it is an advantage and a special improvement to use the valve rod and the needle valve arrangement in connection with each other.

The oil drips from the orifice into the opening, 18, at the top of the arched pipe, 49, and is thence conveyed to the engine cylinders through the valve to be described below.

In order to reduce the weight of the engine and to favour the conduction of heat from the engine cylinders, 6 and 6ª, they are each made of a steel tube, cut away at one end to leave a projecting tongue, 7, for attachment to the bearing, 35, of the engine crank shaft, 10, which, as shown, is also the axle of the vehicle wheel, 2. The seats, 38, are curved (or concave on their faces) to fit the curvature, in cross section, of the tongues, 7. The curvature of the tongue increases its strength, as well as facilitates the manufacture of the tongued cylinder. The engine cylinder, being single acting, the front ends are left open. The rear ends are closed by the heads, 51, which carry the valves, 23, 23ª, 54, 54ª, and ignition tubes, 52, 52ª, and which also reinforce the steel tubes, at the explosive end, by means of a flange, 53, for each tube or cylinder. The ignition tubes are made of platinum, or other suitable material, each closed at its outer

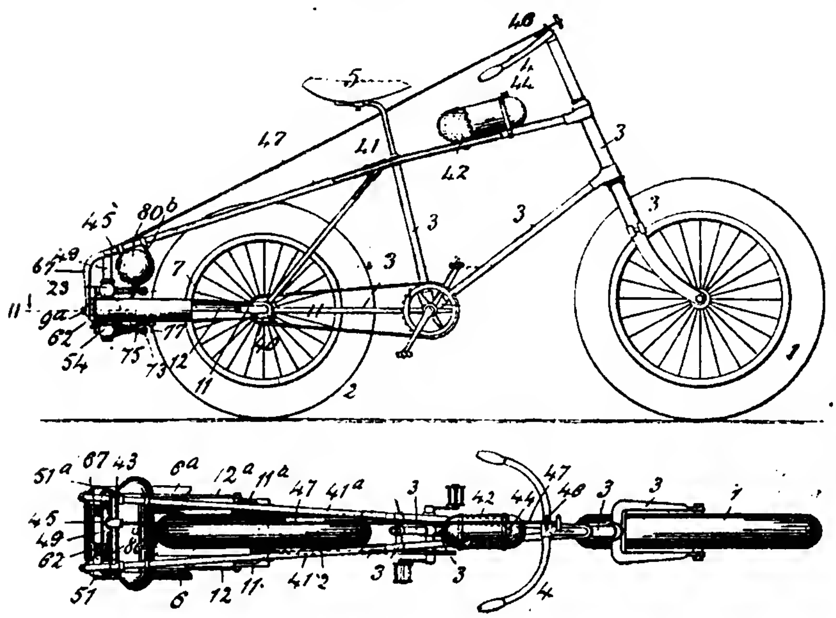

FIG. 1.

end and opening each into one cylinder at the inner end. They are kept hot at the proper point to insure ignition of the explosive mixture in the cylinders when fully compressed, as is well understood in the art.

In each cylinder moves a hollow piston, 13 or 13ª, which is connected by its pitman or connecting rod to the cranks, 11, 11ª, respectively at the corresponding end of the shaft or axle, 10. The pitmen are each best made of a small steel tube, 12 and 12ª respectively, with end pieces, 57 and 58, of a thicker material. The rear end piece, 58, fits between bosses, 59 and 60, on the inside of the hollow piston, with which it is connected by the journal-pin, 61. The front end piece is loosely connected with the pin of the crank, 11 or 11ª, a bushing being advantageously interposed. The bushing fits between the end piece and the crank pin with sufficient looseness to turn freely, and has inwardly and outwardly turned flanges which overlap the respective parts. A screw tapped into the crank pin holds all in place.

The rear ends of the cylinders, 6, 6ª, are connected with each other by means of the chambered cross piece, 62. This, as shown, has several functions; it forms a cross brace between the rear ends of the cylinders, and also between the rear ends of the top braces, 41, 41ª; it forms chambers for enclosing and protecting the ignition tubes, 52, 52ª; it forms supports and protectors for the burners, 63, 63ª; it forms a support for the rock bar, 64, pivoted at 65 to a boss on its under side, the said rock bar operating the exhaust valve mechanism, as explained below. On top, the middle portion of this cross piece is cut away so as to allow the escape of the products of combustion from the burners, 63, 63ª, if necessary, to supply air for their combustion. The burners, 63, 63ª, may take air from the outside through the burner tubes, as in the familiar Bunsen burners; and the orifices for the escape of the products of combustion need not be made just as shown. Ears, 66, on the piece, 62, fit over the projections, 68, between the bent pieces, 67, forming the lower ends of the top braces, 41, 41ª, and the heads 51.

The heads, 51, are each made double, the inner plate being integral with the projections, and also with the flange, 53, which enters the cylinder tube. The outer plate has projections, 69, which fit outside the cylinder. The inlet port and outlet port are each made through the flange, 53, the cylinder tube, and the corresponding projection; and so also is the hole for the ignition tube, 52 or 52ª; only there is, preferably, no outside projection corresponding to 69 for the ignition tube.

The inlet and outlet valves, 23, 23ª, 54, 54ª, are each screwed into threaded openings in the projections, 69. They each include a chambered body, with the opening and seat for the valve disc, 76, in the partition between the chambers, also with a lateral opening, 70, the full diameter of the valve disc, and in line with the valve stem, 75, and with an elongated hollow cylindrical extension, 71, also in line with the valve stem. The opening, 70, is provided with a closure, shown as a screw plug. A spiral compression spring, 72, surrounds the extension, 71, through which the valve stem, 75, passes and by which it is guided. It presses at its inner end against the body of the valve, and at its outer end against a disc, 73, on the end of the valve stem. In this disc is an annular groove, which receives the end coil of the spring.

The inlet valves, 23, 23ª, open inward (that is, toward the engine cylinder) and are opened by the atmospheric pressure when a sufficient vacuum is made in the corresponding engine cylinder, and closed by the spring when there is no such vacuum.

To the top of the valve one end of the arched pipe, 49, is secured by a union, 74, with a disc of gauze or perforated metal, 49ª, interposed. One end of the pipe, 49, is fastened to the top of the valve, 23, and the other end to the top of the valve, 23ª (*see* Fig. 3), so that the same fluid-delivery valve, 45, shall serve for both cylinders.

The exhaust valves, 54, 54ª, also open inward, and are opened by valve mechanism and closed by the springs. To open the valve, 54, there is a tappet, 77, on the valve rod, 78, whose rear end is jointed at 79 to the rock bar, 64, and which is guided by an eye of the guide piece, 83, fastened by a nut on the lower part of the valve.

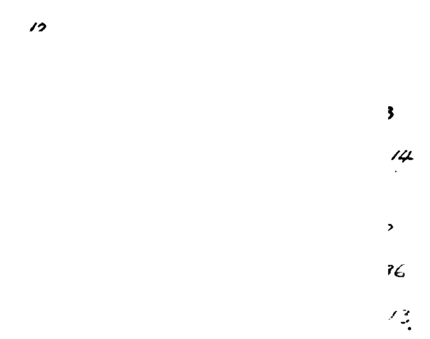

FIG. 2.

The tappet strikes the end of the valve stem and forces it and the valve disc inward against the pressure of the spring.

To open the valve, 54ª, a tappet, 80, is provided on the valve rod 81, whose rear end is jointed at 82 to the corresponding end of the rock bar, 64, and whose front end is loosely connected with the crank-pin, 73, of the valve gear, 15. This wheel is double the diameter of the pinion, 14, on the shaft, 10; so that the exhaust valves are opened once in every two reciprocations of the corresponding pistons, 13 or 13^a.

The gear as shown is provided with a boss, 76^b, to hold the valve rod, 81, away from the gear teeth, and to give a longer bearing in this gear to the crank pin. It is provided with an annular groove, 77^b, to receive the end of tubular bearing, 39, and with a pin, 78^b, to enter said bearing. A screw, 79^b, tapped into the pin, holds the gear in place, the under side of the screw-head bearing against the opposite end of the bearing. This special arrangement is advantageous, but it may be replaced

FIG. 3.

by another if its advantages are not desired, and the same remark applies to other particular constructions shown in the drawings and particularly described.

At 80^b is a can of oil for supplying the burners, 63, 63^a. It is upheld by straps from the top braces, 41, 41^a, and has a filling opening, 81^b. A feed pipe, 82^b, conducts the fluid to the branches, 83 and 84, which lead to the respective burners. Stop cocks, 85 and 86, in the branches control the supply to the burners.

The operation is as follows:—

The can, 80^b, being supplied with proper fluid, the burners, 63, 63^a, are lighted to heat the ignition tubes, 52, 52^a. Then the rider, adjusting the needle valve and mounting the machine, starts the wheel and shaft turning. Assuming that the parts are in the position shown, the pistons are both drawn forward

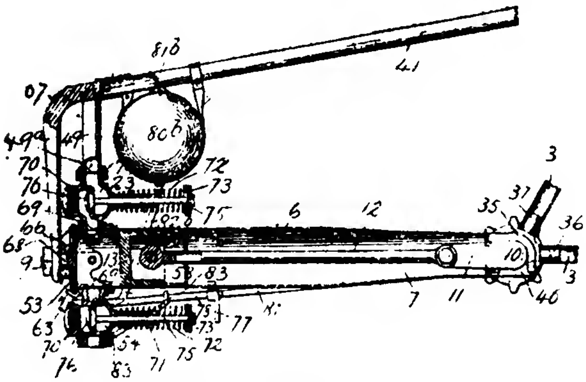

FIG. 4.

by the cranks, 11, 11^a, and pitmen, 12, 12^a. If both cylinders are empty, a mixture of air and oil is drawn into both cylinders through the arched pipe, 49, and the inlet valves, 23, 23^a. As the end of the forward stroke is reached, the springs close the inlet valves. During this movement, or half revolution, of the shaft, 10, the crank pin, 73^*, has made a quarter revolution, removing the tappet, 80, from the stem of the valve, 54^a, and so rocking the bar, 64, as to bring the tappet, 77, against the stem of the valve, 54.

The pistons, 13, 13^a, are moved back together, and the tappet, 77, forcing open the valve, 54, the contents of the cylinder, 6, are exhausted, while the contents of the cylinder, 6^a, are compressed because the valve, 54^a, is closed. The compression takes place also in the ignition tube, 52^a, and when it is complete the explosive mixture reaches the part of said tube which is sufficiently heated to ignite the mixture and to cause it to explode.

The pistons having now reached the inner (or rear end) of their stroke, the force of the exploded and expanded mixture in the cylinder, 6^a, forces the piston, 13^a, forward and turns the shaft, 10, propelling the vehicle. During this forward movement, the piston, 13, draws in from the arched pipe, 49, a charge of oil and air, its exhaust valve, 54, as well as the valve, 54^a, being closed during this movement.

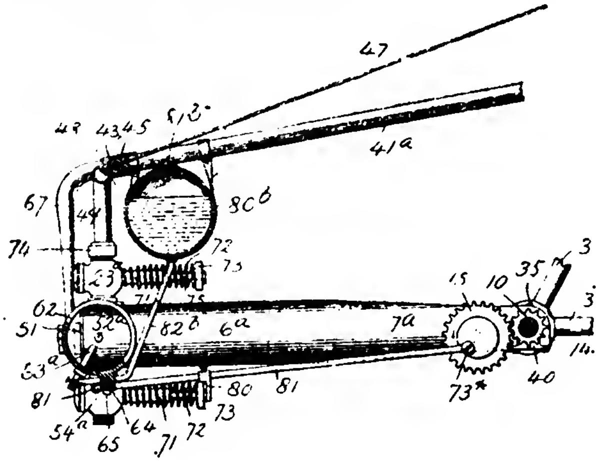

FIG. 5.

During the next inward movement of the pistons, 13, 13^a, the valve, 54^a, is opened and the valve, 54, closed, so that the contents of the cylinder, 6^a, are exhausted, and those of the cylinder, 6, compressed. The parts are now again in the position shown in the drawing. The compression of the explosive mixture in the cylinder, 6, forces it into the ignition tube, 52, until it catches fire and explodes, forcing the piston, 13, outward and through the shaft, 55, drawing the piston, 13^a, so as to draw an explosive charge into the cylinder, 6^a, to be in turn compressed and exploded.

In order to effect the compression of the explosive mixture in the cylinders, 6, 6^a, it is evident that some force is necessary. In ordinary gas engines, a heavy fly-wheel has been employed to store force for each explosion sufficient to effect the next

FIG. 6.

compression. Sometimes the force of an explosion has been made directly to effect the subsequent compressions. It is found unnecessary to use either of these expedients, and the vehicle may therefore be made lighter. The weight of the rider has been found available to store power for effecting the compression. This is an advantage, not only in saving weight, but it makes the vehicle self-stopping when the rider dismounts, the weight of the vehicle alone not being sufficient to effect the compression.

The illustrations accompanying the above article may be described as follows:—Fig. 1 is a side elevation of a vehicle having a two-cylinder motor, and a plan of the same; Fig. 2 is a view on the line 11—11 of Fig. 1; Fig. 3 is a cross-section on a line 12—12 of Fig. 2; Fig. 4 is a view on line 13—13 of Fig. 2; Fig. 5 is a view on line 14—14 of Fig. 2; and Fig. 6 is an enlarged view of a detail.

I 3

THE MECHANICAL PROPULSION OF TRAMWAY CARS.

Lecture at the Sheffield Technical School.

AT the Technical School, St. George's Square, Sheffield, on Saturday evening, the 19th ult., a lecture was given before a large number of the members of the Sheffield Society of Engineers and Metallurgists, by Mr. W. H. Watkinson, M.I.M.E., M.I.E.E., Professor of Prime Movers at the Glasgow and West of Scotland Technical College, on "The Mechanical Propulsion of Tramway Cars." The chair was taken by Mr. T. W. Sorby (president), and amongst the others present were Professor Ripper, Councillors G. Senior, W. F. Wardley, B. Chapman, J. C. Whiteley, Messrs. G. T. W. Newsholme, W. T. Beesley, and G. H. Mellor.

Professor WATKINSON, at the outset of his lecture, said it was not until comparatively recently in this country that there had been any great demand for rapid street transit, and on that account this branch of engineering had been too much neglected by engineers. In the United States the demand for rapid traction had been great, and engineers had risen to the occasion, and supplied the demand very effectively by means of the electric overhead system That night he purposed dealing with the relative merits of the various systems which at present seem most promising. The demand for rapid street transit had now become so pronounced, and the benefits which were to be derived from it were now recognised to be so great, and the loss to a city like Glasgow through the lack of it was so enormous, that the public would not long tolerate the present slow and cruel system of horse traction. Proceeding, he said steam, air, gas, and oil engines have the great merit that each car is independent, and therefore a general breakdown of the system is impossible. The underground cable and the electric (without storage batteries) depend for their success mainly to the fact that with them the prime movers at the central station can be very large and of the most economical type. This, however, is almost their only claim for supremacy. At present the electric battery system is not in a sufficiently advanced stage to prove commercially successful, and until recently steam cars had not been successful owing to problems involved in the design and construction of the boilers and engines. Now, however, they knew how to construct motors of that type, which for efficiency and lightness surpassed all others. It was now no longer necessary to provide a separate locomotive, as the whole of the apparatus can be placed on the passenger car itself. This possibility enables the total weight propelled to be enormously decreased. The great advantages of the steam-engine are due to its being able to exert great power with small loss of efficiency during the starting of the cars or on inclines, and also to it being able to work with maximum efficiency under the normal load and to the ease with which its direction of motion can be received. The principal drawbacks are the smell and dirt from the products of combustion when fitted with an ordinary boiler, but by the use of coke or oil these nuisances may be very greatly reduced, and by using forced draught and letting the chimney discharge downwards they may be almost annihilated. In connection with tramway cars these nuisances can be done away with altogether by dispensing with the furnace, the steam being generated by superheated water carried in suitable reservoirs beneath the car, they being replenished at a central boiler station. By means of the Serpollet boiler the condenser may be dispensed with, as the steam is still superheated, and, therefore, invisible on leaving the engine. When discharged beneath the car no nuisance is caused by the exhaust. Serpollet generators are now used of over 50 horse-power, and a number of cars in Paris are fitted with them. Compressed air, he further said, has long been used for the transmission of power, but the problems involved have, until recently, been far less appreciated than those connected with any other system. On this account the efficiency of the older compressing plant and motors was very low, and it is still generally believed by engineers that the system is necessarily inefficient; but a new era has commenced, and compressed air will probably play a most prominent part in the transmission and distribution of power. In this system there is no chance of smell or visible exhaust. The efficiency of an electric motor is higher than the air motor, but as the former runs at high speed gearing has to be used which reduces practical efficiency below that of an air motor. Mentioning here the McKarski system (used in Berne) and the Hughes and Lancaster system (tried experimentally at Chester), Professor Watkinson passed on to gas and oil engines, which, he said, at present seem to promise to become the most successful of all motors for tramcars and motor-carriages generally. Those in use have the great drawback that their direction of motion cannot be reversed, and, therefore, gearing has to be used for this purpose. In spite of this, however, gas-engine tramway cars are now working successfully at a lower cost than any other system. Most of the smell is due to lubricating oil sent out with the exhaust. The great drawback to the cable system is the initial cost, and the difficulty is in connection with the extensions. A disadvantage is that if the rope fails the whole system is thrown out of action, but an advantage is that it is practically impossible for a car to run away. He was of the opinion that the system has a considerable future before it. For hilly districts, he thought, it is better than the electric system, but he would not advise it to be laid in many cases. In the case of the overhead electric system, the wires do not annoy more than telephone wires, but if telegraph or telephone wires fell across them the user of the instruments might be injured. A fracture, too, might arise at any time by a slight accident, and whilst so far accidents have not been very great, frequent accidents have taken place. It is by far the most flexible system, and pays better than others, as the total cost of running cars is made up by a great many items. Although, however, these cars are such a great success in the United States, it does not follow that they will be so successful here, owing to the greatly reduced fares, and the distances passengers will travel. Recent changes in the system have made it far more efficient than it was a few years ago, and he did not think that Sheffield or Glasgow had lost anything by waiting. The Americans could not wait, and they had paid for the experience, which will be most valuable here. He did not think it wise to rush in for any of the systems, but rather advised one or two to be tried experimentally, so as to ascertain where a system is applicable to the requirements. The streets in Glasgow are narrow, and there are a great number of right-angled curves which absorb a great deal of power—far more than in the case of horse cars. The relative advantages and disadvantages of different types he summed up as follows:—Oil—Disadvantages: Vibration due to unsteady running, danger of fire or explosion, not self-starting, not reversible, easily damaged, complicated gearing. Advantages: No boiler required, automatic action, driver has not to look after coal or fire. In the case of steam, the disadvantages are: Stoking, water-level and pressure gauge to be attended to, weight of boiler and water; while the advantages are: Engine light, simple, and understood by most men, gearing simple, easily started and reversed, vibration less, no smell, danger less than with oil, inclines easily mounted. Gas shares all the advantages of oil and is less dangerous. It is more certain in action, but the disadvantage is the recharging of the reservoir. The advantages of electricity are, no vibration, no smell (except from acid fumes), and the disadvantages are heavy accumulators, rapid depreciation, costly, both initially and in working and the recharging of cells. The conclusions he had arrived at were that at present the steam-engine car is the best on the market so far as independent motors are concerned, because it is independent, and because there is no nuisance. It is the most reliable in every way, and until other oil engines are brought out it will continue to be the best one. The electric system possesses very great flexibility, and has the merit of novelty, and it has proved a financial success. He did not think, however, that they had arrived at a point at which definite steps should be taken which would involve a great outlay on any system. He believed they had pursued the wisest plan in waiting, and he thought they would continue to be wise in being patient in connection with the development of the various systems. The lecture, which was attentively listened to, was illustrated with lantern views showing the different machinery of the various cars which the Professor technically explained.

Professor Ripper proposed a vote of thanks to the lecturer. He said it would be nothing short of a great financial mistake at the present time to conclude from the observations of systems which already exist that one system is better than another, and he believed in Sheffield it would be a great mistake to think that what was best from Attercliffe to Lady's Bridge, would prove the best from the New Market to Broomhill. There were engineering matters which would require considerable working out, and it was important that they should not tie themselves to the system, so that when they had spent money on it they could not do anything else to carry it on. (Hear, hear.)

Councillor George Senior seconded the vote, expressing himself in favour of the overhead system or steam.

The vote was carried unanimously after a little discussion, and a similar compliment to the Chairman concluded the meeting.

SIR WILLIAM ARROL'S NEW MOTOR.

One of the most important proposals yet made with regard to tramway traction has been laid before the Glasgow Corporation. Sir William Arrol—the celebrated engineer—and Mr. George Johnstone, who are joint patentees of a new oil engine, have, through Messrs. Borland, King, and Shaw, writers, Glasgow, offered, within four months of acceptance, to equip any route in Glasgow with tramcars driven by mechanical power. This they are prepared to do at their own expense, on the express condition that, should the Corporation decide, at the end of two months' trial, that the cars are unsuitable for the purposes of the Corporation tramway system, they shall be withdrawn, and the community be in no way held responsible for the expenditure incurred, this being borne entirely by the promoters of the scheme. But the promoters anticipate an unequivocal success for their cars, and should their expectations be realised during the preliminary trials, they offer on behalf of their clients to equip every tramway route in Glasgow with cars driven by mechanical traction, and to run these for a period of seven years at a cost to the tramway department not exceeding what it at present pays for horse haulage. The cost of horse haulage is to be calculated on the basis of the past two years' working of the cars by the Corporation, which period admittedly was the cheapest on record for such a system. At the end of the seven years the promoters undertake to hand over to the Corporation as a free gift the whole of the cars, with their motors, in good working condition, and these latter to be held free of any charge for royalties which the patents owned by the promoters would entitle them to impose. As nearly as need be calculated for present purposes, horse haulage, without deducting anything for depreciation, costs the tramway department £100,000 per annum, so that, while Messrs. Borland, King, and Shaw's proposal practically amounts to offering to equip the city's tramway system with cars driven by a self-contained motor for nothing, the sum they would receive under the proposal would be in round figures something like £100,000 per annum for seven years.

Reporting on this offer, Mr. Young, the Corporation Tramway Manager, said :—"It is now about two years since we had communications from the same firm in connection with a forthcoming patent by the same inventor. These communications were quite as vague as the present one. Before the motor was produced or tested I was asked if I would entertain or recommend an agreement binding the Corporation to adopt the system, to some extent, in the event of a test being satisfactory. Of course, I did not see my way to do so. Facilities for testing the invention by conditionally using the rails were, however, frankly granted by the committee. The outcome was the Johnstone motor-car, which was, for a considerable time, tested in our Coplawhill Yard. It was afterwards tested on the city streets with members of the committee on board, and nothing has been said about it since. It is still standing in our premises at Dennistoun." In the present system the propelling power is kept secret, and one month's trial of the undivulged motor was to decide a contract for seven years. In his opinion the committee should not get mixed up in any speculative scheme of the kind, and more especially if it cannot be operated by men employed by themselves.

Acting on this report the Corporation declined to accede to the request made by Sir W. Arrol and his colleague.

THE SELF-PROPELLED TRAFFIC ASSOCIATION AND CANALS.

As briefly recorded in our last issue, an "extra session" of the Liverpool local branch of this Association was recently held under the presidency of Mr. H. P. Boulnois, the City engineer, when Mr. F. Willoughby read a paper entitled, "The Improved Method of utilising Canals for Traffic," with special reference to the canals of Lancashire and Yorkshire.

In the course of his remarks, Mr. Willoughby said it might appear out of place to introduce for consideration a subject so antiquated as canals, especially having regard to their financial condition and to the state of decay into which many of them appeared to be rapidly drifting, for, although some still yielded a dividend to their shareholders, others barely paid their management and working expenses, and some were actually derelict; but they must remember that before the railway era canals were very profitable undertakings and of great importance as a means of transport to the mercantile community, and the aim of his paper, he said, was to show how canals could now be so transformed and utilised as to meet the requirements of the age and to regain the popularity they formerly enjoyed. The cities and towns of Lancashire and Yorkshire were well supplied with transport accommodation by the several railways and canals passing through the district, and most of them had the advantages of both systems; but in consequence of the severe competition to which every trade and business in the country was now being subjected, a pressing demand had arisen for lower rates of carriage, which the railway companies appeared unwilling and the canal companies in their present state were quite unable to afford. He believed that one of the objects for which their association had been formed was to render some assistance in this direction, and he therefore ventured to bring to their notice the improved method of utilising canals for traffic, invented by Mr. Cook. He then enumerated the seven canals in direct communication between Liverpool and Manchester, and proceeded to point out the reasons for the failure of the present canal system, and afterwards explained the improved method of utilising canals for traffic. He said it was proposed to draw off the water from the long-distance canals, and lay down on the bed of them a standard main line of 4 feet 8½ inches gauge railway, constructed with stone foundations, timber sleepers, cast-iron chairs, and a single line of 90 lbs. to the yard steel rails, with gradients in the place of locks, retaining as waterways such portions as might be required to connect the rails with other canals which were not transformed, or with canalised or other rivers. A single line of rails, with sidings and turnouts, would be sufficient to transport ten times the amount of traffic at present carried over the canals, but there was ample room on all canals for a double line, which could be laid down when required. The essay also dealt exhaustively with the financial side of the question.

At the close of the address a discussion was carried on by Messrs. C. R. Dykes (Rochdale Canal Company), Maunsel C. Bannister, J. Walwyn White, A. Bromley Holmes, G. F. Ransome, A. Williams and E. Somerset (both of the Leeds and Liverpool Canal Company). The usual compliments to the reader of the address concluded the proceedings.

I 4

MR. J. E. TUKE ON OIL MOTORS.

MR. JAMES EDWARD TUKE, of Harrogate and Bradford, who has been recently exhibiting the Arnold motor-carriage in various parts of the country, last month delivered a lecture at the Keighley Drill Hall on horseless vehicles. Facilities were offered for a thorough inspection of the machine, and Mr. Tuke showed himself quite willing to explain the most minute details of construction and working. He also gave exhibitions of the car in motion, and negotiated the most difficult corners at a good speed without the slightest trouble. The front axle remains stationary and the steering wheels run on a pivot on the principle of the Olympia tricycle. The motor is driven by oil, and can be both started and stopped readily. It was remarked that the smell from oil so much complained of in connection with vehicles of this type was comparatively slight, notwithstanding the fact that the motor was running in a confined place. Mr. Tuke's lecture was given in a chatty style. He did not claim that the motor was perfect, not did he believe that it was a failure, but he pointed out that the vehicles were as yet in their infancy, just as bicycles were twenty years ago, only makers would have the not inconsiderable advantage of all those years of experience in the cycle trade. "Emancipation Day" had come before they were ready; makers had been caught napping, and the result was that at present they were not able to meet the demand which was springing up in various parts of the country. The lecturer traced, with the help of the lantern, the history of the motor from 1780, when a steam carriage plied about Paris, and he dwelt upon the barriers erected against its extension in this country by the law, owing partly to the antipathy of the railway companies and the ill-conceived objections of horse-breeders. He next discussed the relative advantages of steam and oil as a motive agency. He classed the principal advantages of steam as follows:—(1) Reduced vibration when the car was at a standstill; (2) the car was self-starting; and (3) elasticity of working. In regard to advantage No. 2, he said that to start the steam car they had simply to open the valve and the machine began, whereas with oil engines they had to set the fly-wheel and crank into swing position, with the cylinders filled with an explosive mixture of oil and air before they could secure the combustion necessary to get the first natural revolution of the fly-wheel. To set against the advantages of steam, they had the following advantages in the case of oil engines:—(1) Less mechanism and consequent less danger of the machine getting out of order; (2) less need of overhauling; (3) the simplicity of the oil engine would enable it to be driven by any person of ordinary intelligence, and would not require an engineer. Mr. Tuke dealt with several methods of ignition, and declared in favour of electricity, pointing out that the carriages would run 300 or 400 miles with one charge, and the cost of refilling the electric sparker would not be above 6*d*. Summing up, he said that for heavy work—such as vans carrying a couple of tons or omnibuses carrying 20 or 30 persons—he thought steam was desirable; but for light work—cars to carry 10 or 20 cwt., or to carry a small party—he had no doubt that the advantage was in favour of oil.

A COACHBUILDER ON THE FUTURE OF AUTOMOTORS.

A LARGELY-ATTENDED meeting of the Aberdeen Mechanical Society was held recently in Gordon's College, Aberdeen—Mr. Sproul, president, in the chair—when a paper on "Carriage Building" was given by Mr. Robert Shinnie, of Messrs. R. and J. Shinnie, coachbuilders.

MR. SHINNIE remarked that carriage-building included the construction of every kind of vehicle, from the luxurious Pullman car to the scarcely less important child's mail car, and had a passing glance at the motor-car movement. In dealing with carriage-building, he said they might well ask themselves where they stood. Were their past works about to become obsolete? Their present routine had received a sudden check, and large promises filled the air. If the eagerness with which the fulfilment of those promises was searched after, and if the anxious throb of expectancy raised with regard to gigantic horseless carriage and motor-car companies, with enormous wealth of money and possessions, were any true portents, the world was on the eve of changes vastly greater than occurred when railways were introduced. Meanwhile they might continue discussing the carriages with which they were familiar, and be ready to welcome the vehicles of the future—when they come (laughter and applause). Mr. Shinnie then noted that carriage-building grouped together a variety of diverse occupations or handicrafts, and these he enumerated in this order:—(1) Wood workers and "body" makers, (2) under-carriage makers, (3) wheelmakers, (4) blacksmiths, (5) trimmers, or workers in leather and cloth, (6) painters, (7) draughtsmen and designers. In addition to these, he observed that there are numerous auxiliary occupations concerned in the industry to meet the requirements of special makes of steel and iron, special timbers, fabrics in silk and cloth, fittings in silver, ivory, and other ornamental materials, colours, and varnishes, leathers of various kinds and colours, and he pointed out that the success of the finished article very largely depends on the skilful selection of the various materials of which the carriage is constructed. The lecturer proceeded to describe the various technical processes in carriage-building from the lithographed designs to the finished vehicle. After glancing briefly at the historical aspect of his subject, comparing the vehicles of the olden time with those of later days, Mr. Shinnie concluded with another reference to the motor-car, remarking that great improvements must necessarily take place in the present types, alike in the matters of gracefulness and weight, before they can become widely popular, but with development on these lines the carriage-building of the future may be conducted still more on the principles of true art and science.

In a discussion that followed the reading of the paper, the Chairman touched on these last points. It was his view that in seeking to attain the grace and lightness in the motor-carriage that were yet lacking, engineers and coachbuilders between them may effect such a structural change in the form of vehicles as to bring in a new type that shall be alike beautiful and useful. Very cordial thanks were awarded to Mr. Shinnie for his paper.

Tramway Motors for Light Railways.

THE Sydney Minister for Works has had a report from the Engineer-in-Chief for Railway Construction with regard to the utilisation of tram motors on light lines of railway. In view of the recent Light Railways Act the following *resumé* of that document will be of interest in this country:—It is intended to convert all the steam tramways to electric lines, and the use of the motors will of necessity be discontinued. It was Mr. Young's idea that the motors might afterwards be put on the pioneer railways. Mr. Deane points out that these tram engines have now to take in water every five or six miles. In the country, of course, such frequent stoppages would be an impossibility. To obviate the difficulty the motors would have to carry tenders holding a supply of water, and the weight of the tender with its burden would, as a consequence, have to be deducted from the haulage capacity of the motor. In a grade of 1 in 20 the motor carrying water enough for 10 miles and coke for 20 could haul 30 tons. With a tender carrying sufficient water and coke for a trip of 50 miles, the haulage would amount to 22 tons. For a grade of 1 in 50 the loads would be 85 tons and 77 tons respectively; for 1 in 80, 132 tons and 124 tons; for 1 in 100, 159 tons and 151 tons. While the motors can easily negotiate sharp curves, still, if curves such as there are about the city and suburbs were adopted in the country, the rolling stock, except the passenger carriages, would have to be specially built. Another drawback would be that a transfer of freight would be required when the main lines were reached.

MR. E. SHRAPNELL SMITH.

As hon. secretary of the Liverpool and District Centre of the Self-Propelled Traffic Association, Mr. Shrapnell Smith has been highly successful in his efforts to establish it on a firm basis. To quote Sir David Salomons on the occasion of his inaugural address at Liverpool, in October last:—"In Mr. Shrapnell Smith Lord Derby will find a clever, enthusiastic, and hard-working honorary secretary." He has been exceedingly energetic and tactful, while, judging only from the experienced manner in which he has worked, many who do not personally know him will be surprised to hear that he is not yet 22 years of age. Youth in his case has by no means been a disadvantage, and, judging from what he has done already at this early stage of his career, he should have a successful future in store for him.

Mr. Shrapnell Smith was educated at the Liverpool College (Modern School), St. John's College, near Preston, the Royal Institution School, and University College, Liverpool. When 16, as his father wished him to follow either electrical or chemical engineering, with a view to which he had been studying, he was apprenticed to the United Alkali Company (Ltd.), Liverpool, and has gone through their head offices and the Gaskell and Deacon's Works (Widnes) of this great Syndicate. At these works Mr. Smith is now stationed as assistant chemist and process manager.

The accounts of the Paris-Rouen race in 1894 led Mr. Smith to make an exhaustive examination of the early English records and exploits, which convinced him of the great possibilities of mechanical road-haulage, and when Sir David Salomons's now historic letter inviting communications appeared in the Press, he was one of the first to take advantage of this opportunity to join hands with those who were desirous of effecting the removal of the anomalous condition of things which then existed in this country. Attendance at the great meeting of December 10th, 1895, at the Cannon Street Hotel, when the Self-Propelled Traffic Association was formed, succeeded as a matter of course, and this was followed by an opportunity of enjoying Sir David's hospitality on the occasion of his entertaining the committees of the French and Belgian Automobile Clubs in July last.

On March the 2nd of last year Mr. Smith lectured in Liverpool on "Horseless Carriages and Motocycles; their History and Prospects," for which purpose he received much valuable help and the loan of slides from Sir David Salomons, Bart., Mr. W. Worby Beaumont, and Mr. J. H. Knight.

This lecture was the fourth or fifth out of London, but interest in Liverpool was so small that scarcely one hundred people were present, and the local Press allocated barely 20 lines to a report—a very different state of affairs to what obtained when he lectured at the Picton Lecture Hall eight months later.

The acceptance by Mr. Shrapnell Smith of the honorary local secretaryship of the Self-Propelled Traffic Association was delayed for some considerable time, on account of a projected visit to South America which was not concluded, and with the appointment his duties quickly increased. On September 9th of last year the first move of the Association was made in Liverpool, when Mr. Smith arranged for Mr. W. Worby Beaumont to go down there, under the auspices of the Self-Propelled Traffic Association, to address the Liverpool Incorporated Chamber of Commerce on the subject of "Motor Vehicles for Heavy Traffic." In taking steps to form a local council it was found that the objects of the Association readily commended themselves to all those who were invited to become members thereof, and, after several private interviews with the Right Hon. the Earl of Derby, on October 1st, 1896, a deputation formally waited upon the then Chief Magistrate of Liverpool and received his acceptance of the local presidentship.

Mr. Shrapnell Smith's idea of a programme for the local branch was to provide a series of papers on the various phases of the movement, and to arrange for an exhibition of modern self-propelled vehicles at the earliest date, when a variety of types might be hoped for. The former has been successfully carried out, and the latter rests with his Council. All the work, so far, has been carried on with encouraging signs of public interest.

In order to carry out the heavy detail work of his office Mr. Smith has had "to burn the midnight oil" by no means unfrequently, for all his secretarial duties have been discharged single-handed, and in no case has his "hobby" been allowed to interfere with the due performance of his engagements in the chemical trade. In the course of our interview with Mr. Shrapnell Smith, he said:—"At present, my interest in the matter is entirely scientific; from the first indication, the revival of road locomotion has exercised a peculiarly fascinating influence over me, and I was unable to refrain from identifying myself with the pioneer work in some capacity." We also gathered that the humanitarian aspect appeals very forcibly in Mr. Smith's case, and his sympathy in the matter is undoubtedly intensified by the exceptionally hilly nature of the Liverpool streets.

Mr. Shrapnell Smith is to be heartily congratulated on the excellent results which have attended his efforts; while the Council of the Association could hardly have found a gentleman more fitted in every way for the position which he so admirably occupies. Before accepting the post, we understand that he gave a written undertaking to the Association that he would not invest in or accept any commissions from motor-car companies. This is a very desirable guarantee, in that he is enabled to appear in public without fear or favour, but it need not preclude his one day becoming a leading spirit in some of the numerous large carrying undertakings that are likely to come into existence for the establishment of traffic routes between centres of commerce. We venture to assert that he would prove a great acquisition to any such enterprise.

MOTOR WATER-CARTS.

THE following notice of motion has been given by Mr. G. Yarrow Baldock for consideration at the next meeting of the Hackney Vestry:—"That, in consideration of the large and continually increasing amounts paid by this Vestry for horse-hire and cartage, and with a view to facilitate the work of 'slopping and dusting' being undertaken entirely by the Vestry without the intervention of a contractor, it be referred to the General Purposes Committee and to the Sanitary Committee jointly to report as early as may be:—(a) As to the practicability and possible economy of employing for the purposes of the Vestry carts and vans driven by electric or other automatic motors; (b) As to the advisability of fitting suitable motors to the water-carts and other vehicles at present the property of the Vestry; (c) As to the advisability of the purchase by the Vestry for experimental purposes of a motor-van or vans of the most approved pattern designed for the collection of refuse and scavenging. And further, that the said joint committee be and is hereby authorised to obtain all such necessary estimates, plans, drawings, and specifications as will enable the fullest possible information (specially as to the probable capital outlay and cost of maintenance) being embodied in the report for the guidance of the Vestry."

TRAMCAR PROPELLED BY HOT AIR.

IN view of the prominence which the question of street locomotion has assumed, a description of the motor-car which Mr. James Murrie, consulting engineer, 264, St. Vincent Street, Glasgow, has laid before the local Corporation Tramway Committee will be read with interest. The motive power is compressed hot air, which is compressed at a station by a gas-engine to a pressure of 2,000 lbs. per square inch. When heated it is stored in accumulators consisting of nests of solid drawn steel tubing, enveloped by a fluid maintained at a temperature of 800 degrees. Each station is placed as near a tramway terminus as possible, and the hot air is conveyed from the accumulators through small flexible metallic tubes to a pillar on the street. The car having been drawn up opposite this pillar, the end of the tube is attached to another coupling on the car, and the reservoir of the latter is charged, and the tube disconnected in less than half a minute. In cases where it is inconvenient to have fixed stations, the generating appliance may be erected on carriages which, having been charged, are run along the tramway rails to the motor-car into which the hot air is transmitted through coupled tubes resembling those used in connection with the Westinghouse brake on railway trains. The reservoir underneath the car consists of several solid drawn, mild steel tubes encased in asbestos with an outer metallic jacket. One of these reservoirs will store sufficient air to propel the car for eight miles, or, by adding to the weight, a reservoir can be made to contain enough to propel the car for 24 miles. The motor, which is fitted below the car, consists of six cylinders, each operating on an axle crank set at an angle of 60 degrees to its neighbour. It will propel the car in either direction, and works up to 25 indicated horse-power. The motor is arranged to act as an air compressor, and when the action is reversed it serves as a brake, energy being stored in descending a hill or in stopping. The car starts gently. A small independent motor coupled to a dynamo supplies the current to four 20-candle electric lights at an estimated total cost of a penny per hour. In front of the wheels at each end of the car is a revolving life guard. A dial in the interior of the car automatically shows the route and the streets that are being traversed. The tickets are stamped automatically with the names of the streets at which the passenger enters or leaves the car, so that the conductor does not require to leave the platform where he receives the fares from the passengers as they leave. Three brakes are attached to the car—the motor, a modified Westinghouse, and a lever brake. The weight of motors, reservoirs, &c., average 18 cwt. per car for a run of eight miles, or 28 cwt. for a run of 24 miles. Mr. Murrie estimates that the cost of running such a car will range from 1¼*d.* to 2*d.* per mile, according to the type of engine used at the station, these sums including all charges for energy, such as fuel, repairing of motors, depreciation, wages at stations and insurance, but making no allowance for management.

ROYALTY AND THE NEW INDUSTRY.

To Mr. Hugh Inglos, who is a son of General Inglos and a connection of Lord St. Oswald, is due the credit of introducing motor-carriages to Royalty. This event took place at a house party given by Lady Sheffield, when H.R.H. the Duke of Cambridge, K.G., availed himself of the opportunity of indulging in a drive in a carriage smartly driven by Mr. H. Inglos. The motor was an oil one of a modified Daimler type. Subsequently at Doncaster Mr. Hugh Inglos—who is interested in the Omnium Supply Company—gave a lecture on the horseless carriage, in the course of which he alluded to its many advantages, stating that it took up no stable room, and would run from 50 to 100 miles with one charge of fluid, and would attain a speed of from 12 to 30 miles an hour with ease, and continue it night and day. Motors could be made to any necessary horse-power, and could be fitted with specially constructed pneumatic tyres on the latest improved silencing systems; any part could be renewed at any time, and vehicles could be run either slow, half speed, or full speed, and could be replaced at once; and any youth could drive them with absolute safety. Compared with horses and carriages the motor-carriage was cheaper both in cost and maintenance, and he looked to the day when the farmer would have his own light railway, practically, and would go to market and back again, and send his produce with ease and economy. If wanted expeditiously, no time was lost in looking for the groom or harnessing the horse; a match was simply struck, and the auto-carriage began to move. To medical men he could conceive no greater boon, and how handy it was for running to and from the station with passengers and luggage? France and America had for some time been in the field in the making of these cars, but England was only just beginning to develop its strength. He further dwelt upon the various motive powers used—steam, oil, and electricity, and he said that he believed, and his own opinion was, that steam, notwithstanding its present disadvantages in the weight of machinery and so forth, would eventually hold its own, but, at present, steam was not nearly so suitable as oil or electricity. Electricity had the disadvantage of the weight of the accumulators, and oil practically was the best motor they possessed at the present moment. There was also compressed air, but this, so far, had proved unsuitable for the purpose. He remarked that there were various kinds of oil engines, and described the many valuable patents which were essential to the building of good oil engines, and, in conclusion, he expressed his strong conviction that English engineers, who could still build the best ships and the best locomotive engines, would hold their own in building the best and most economical motor-cars.

NOTES OF THE MONTH.

EXCITEMENT was recently caused in Oxford Street by tho taking fire of a motor-car which was proceeding along the street. The driver on discovering the mishap specdily brought the car to a standstill alongside the pavement. A cry of "Fire!" was raised, and a large crowd rapidly gathered ronnd the vehicle and assisted in extinguishing the flames.

QUEEN CHRISTINA of Spain is the only Sovereign who possesses an automotor. The carriage, which has been on view in London for some time, has now been forwarded to the Royal lady.

THE Tramway Committee of the Glasgow Corporation have agreed to postpone for a month consideration of the report by the general manager and his engineer in regard to the various tramway motors in use in American cities which they had visited.

THE Fifeshire County Council are not satisfied with the Scotch regulations for motor-carriages—although they are already more stringent than those in vogue in England. The alterations which they seek are as follows:—

Art II.—(2) That on roads under 16 feet wide, the width of light locomotives allowed to travel thereon be not above 4 feet 9 inches. That no light locomotive be allowed on any road under 13 feet in width. (3) That the width of tyre be made to correspond to the weight of a light locomotive when loaded. (6) That there be shown on each locomotive weighing 1½ tons or upwards, the weight of the locomotive unladen, and the maximum weight which it is to be allowed to carry or draw. (9) That there be two lamps, one on each side of each locomotive. Further, that provision be made that the person in charge of a light locomotive shall be not less than 18 years of age, and shall be certified as qualified to be in charge of light locomotives.

PARIS, like London, has been visited with a motor-carriage fire. It was five o'clock and just dark on a December night, when a sudden fire broke out in the middle of the street, flames shooting up to the second floor of the houses. People came running up from all sides, and a couple of minutes later the fire-engines appeared upon the scene and played their hoses on a burning motor-carriage. The reservoir, containing six gallons of oil, had caught fire, setting aflame the woodwork. The carriage, or rather van, belonged to a bootmaker of the Boulevard des Italiens, but the boots were cleared out in time.

THAT fearful and wonderful invention, the Keeley motor, is once more to the fore. Apergy is, we are told by an American correspondent, the name of the "force" claimed for the motor. It is thus defined:—"It is obtained by simply blending negative and positive electricity with electricity of the third element or state, and by charging a body sufficiently with this fluid, gravitation is partly reversed, and the earth repels the body with the same or greater power than that with which it formerly attracted it, so that it may be caused to move away into space." Tho beauty of the explanations as to the Keeley motor is that they are all so simple and so beautifully clear that anyone—even the most unscientific—can understand them at a glance. When will that motor work?

THE Hon. Chas. Rolls, youngest son of Lord Llangattock, the Hendre, Monmouth, has been perambulating the country during the holidays with his Peugeot motor-phaeton, which we illustrated in onr last issue. He made an exceptionally good journey from Gloucester to Ross, which compensated him for his disappointment in not being able to take part in the historical trip to Brighton.

M. LÉPINE, Prefect of Police, is a convert to the practical utility of the automobile. He has written to the Paris Municipal Council asking permission to take from the money at his disposal about £140 for the purchase of a machine worked by petroleum for the traction of a fire-engine, ladders, and so forth, and for the conveyance of the necessary staff of pompiers. If the experiment prove successful, as is anticipated, horses will eventually be entirely replaced by automobiles in the firo brigade. This is a very significant move, and it speaks volumes for the progress which is being achieved on the Continent.

ABOUT £100 damage was done by firo recently in the office of Mr. Georgo Johnstone, Hope Street, Glasgow. There were some patented drawings of motor-cars in the office which were, fortunately, saved from destruction.

THE new electrical system of tramways now in course of construction in Leeds is to be ready for the use of the public by Whitsuntide.

THE Corporation of Halifax have lodged a Private Bill empowering the authority to construct motor tramways. They ask for powers to work the system themselves, and to charge a passenger fare at the rate of a penny per mile or fraction of a mile. They also seek authority to use the tramways for sanitary purposes, "and for the conveyance of scavenging stuffs, road metal, and other materials required for the works of the Corporation free of all tolls and charges in respect of such use." Officers of the Corporation when on duty are to be carried free of charge, fares are not to be raised on Sundays and holidays, and borrowing powers for the purposes of the Act, to the extent of £20,000, are taken.

THE Neath Corporation seek Parliamentary powers to work all tramways within their jurisdiction.

THE Huddersfield Town Council have adopted similar resolutions—so that the day of the promoter in the provinces seems to be waning.

PERTH tramways have been a great success, and the directors have a substantial balance after allowing for dividend.

K 2

WE are very pleased to hear that the young girl Dyer, who was injured by being knocked down by a motor-car at Crawley during the motor-car parade last November, has been discharged from Crawley Hospital qnite recovered from the mishap.

IN a recent issne we commented upon Mrs. Wood's invention of a motor-horse. But as this idea comes from the opposite sex, we allow our contemporary, *Woman*, to supply a further commentary upon it :—

Women, it has often been said, seldom excel in the business of original creation or invention, for their faculties are chiefly imitative and not inventive, bnt the lady who will shortly exhibit a remarkable patent at the Crystal Palace proves that even a woman's brain is occasioually capable of flights of mechanical and inventive genius. The invention is a petroleum motor in the shape of a horse, which can be attached to any vehicle and be controlled by a driver from the box-seat of the carriage or ridden as an ordinary steed. A small waste-pipe is run under the carriage to the rear, where all the vapour and smoke is given off, thus saving all inconvenience to the passengers from that source. The inventor of this motor-horse is Mrs. Wood, of Mitcham, and she claims by it to have appropriated all the advautages of the motor-carriages, which will so soon be seen in our streets, without any of their numerous disadvantages. I shall be interested to seo this invention, but it is to be hoped that Mrs. Wood has not really attempted to imitate the outward form of the horse. The result of such a proceeding could only be comic.

Woman is, of course, illogioal. Take away tho "outward form of the horse" and what remains of the novelty? Surely onr friend from Mitcham conld not be expected to design an ordinary traction-engine!

THE members of the Cardiff Conuty Conncil have been for some time past almost equally divided in their opinion as to how the tramway lines should be owned. As a natural consequence, debates have been many while the decisions were bnt few. At last, however, they have come to a resolution, which runs as follows :—

That the Corporation buy the lines and depôts for £61,500; that they lease them to the Company for 15 years at a rental of 5½ per cent. of the purchase money; and that the existing lines be made equal to new at the cost of the Company, that the lines be doubled where necessary and convenient, that the fares be not raised, that the Company introduce electrical or any other mechanical traction when desired by the Corporation, and that all extensions and newly constructed lines be rented on the basis of 5½ per cent.

THERE have been somo convictions during the month for furious driving, more particularly in the Midlands. When, however, a policeman or anyone else swears that a speed of 20 miles an hour has been exceeded, it by no means follows that it has. We should like to take X 2410 along a country road on a frosty day at 10 miles an hour and ask him for his estimated rate of running—the probabilities are that he would state a record-breaking pace.

IN fact, there is nothing so hard to estimate as the speed of a passing vehicle when it travels at anything over nine miles an honr. Let half a dozen men, taken at haphazard, stand at a corner and see a carriage driven by at top speed, and we will venture a fairly heavy wager that if they state their honest opinions they shall differ in their opinions as to the rate of progress by nearly 25 per cent., while the lowest figure mentioned will in nearly every case be higher than that at which the vehicle is moving.

WHEN the time comes for revising the law, driving to the danger of the public mnst be the factor which is to determine a man's guilt or innocence and not any presumption as to the actual speed at which one progresses.

MENTION of the fact that motor-cars are prohibited from passing np or down the Long Walk in Windsor Park has already been made. A further notice has been posted to the following effect:—"Motor-carriages and other locomotives are not allowed on the private roads in the Park."

ANY Corporation which may contemplate taking over the undertaking of a tramway or other company, &c., within its borongh bonndaries, will do well to follow the prndent example of Sheffield. The Corporation of that town have managed to come to a private agreement with the Tramways Company to purchase the whole of their undertaking for £27,500, and when it is known that the original demand of the company was £31,000, and the original offer of the Council £27,000, it must be admitted that the latter have made a very good bargain. Speaking from the point of view of public bodies, and consequently of the ratepayers, we may say that it is decidedly the best policy in such matters to arrive at a compromise without arbitration.

THE Streets Committee of the Middlesborough Corporation have appointed a committee to meet and consult with their neighbours—the Councils of Thornaby and Stockton—as to the conditions npon which electric tramways are to be jointly allowed in the districts mentioned.

"ANECDOTES" is responsible for a statement that a qnick-firing gun which can discharge 700 rounds a minute and travel 45 miles an hour has been perfected, and is in truth a reality of war. The writer continues:—"The effect of 50 or 100 of these machines of war charging into a large body of troops, or run through a city at a high rate of speed, firing their deadly missiles on the inhabitants as they rushed through, can readily be imagined." Well, yes, Jules Verne has long ago imagined all this—bnt when will the reality come? It is easy to edit a newspaper of the popnlar *Bits* order. One has only to describe an absolnte achievement of the apparently impossible and the trick is done.

AS reported elsewhere, the Glasgow Corporation have considered the proposal of Sir William Arrol and Mr. George Johnstone to eqnip, free of cost, a section of their tramway system for the demonstration of the Johnstone motor-car. The proposal was rejected, and the Corporation adhered to their decision to give a fair trial to any motor which may be exhibited for inspection, and, generally, to give all inventors reasonable facilities to do so. It was also resolved that Mr. Young's report on his American investigations should be circulated.

ALTOGETHER 11 applications have been made to the Light Railway Commissioners from the promoters of light railway schemes throughout the country, and preparations will be at once made by the Commissioners for considering them.

IN order to carry out an improved system of electrical working, the South Staffordshire Tramways Company is to be reconstructed. A sum of £140,000 is to be raised on 4½ per cent. debentures, while the interest on the preference shares is to be reduced to five per cent. The charges thus created will amount to £10,600 per annum.

WE learn, on the authority of such a competent judge as Lord Lonsdale, that motor-cars are not likely to interfere with coaching as a form of sport. Some day, he says, motor-cars may replace omnibuses, vans, drays, and carts, though he holds the opinion that enormous improvements will have to be effected before the new vehicles can do that; but he confidently says that "they will never oust the carriages and traps in general, except in the way of night work in London, or heavy work in the country." Asked to give a reason for his confidence, Lord Lonsdale replied: "Well, just for the same reason that men do not go grouse-shooting with Maxim guns—because there is no sport in the other thing."

THE introduction of the motor-car into Wales was marked by an unfortunate but unavoidable accident. One of Thornycroft's horseless carriages had been purchased for conveying ship's stores, &c., from Cardiff to Barry Dock, and was brought by road from London. When near Cardiff Infirmary Mr. W. Duncan, the secretary to the purchasing company, in attempting to remount the car while in motion, slipped, and before the carriage could be stopped, had one of his big toes crushed, and amputation was necessary.

THE New York Post Office authorities believe that horseless wagons will prove cheaper and more expeditious than the vans at present in use. Their success in this respect has been demonstrated elsewhere, and it is expected that ere long the new vehicles will entirely displace the old-fashioned horse-drawn Post Office vans. The chief advantage claimed for the motor-car is that it runs so smoothly in the streets and roads that the letters and other mail matter can be sorted and stamped in transit, as in a travelling Post Office on the railway. In this way the mails can be taken from the points of collection direct to the train; and thus a considerable amount of time is saved. For parcel post purposes, in this country, horse vans, in some places around London especially, are utilised instead of the railway during the night. Should the American experiment of road and street sorting motor-carriages prove successful, we may by-and-bye see them introduced into England.

THE Bradford Corporation have deposited in the Private Bill Office of the House of Commons for consideration during the ensuing session a "Tramways and Improvement" Bill. The measure will give the Corporation power to raise money for the purpose of constructing tramways—£83,050—and will enable them to work the tramways themselves or by their lessees, and to use steam locomotive, cable, electric, or other mechanical power.

THE Company which has recently laid down in New York an improved underground trolley conduit for working their electrical tramway system is, as might be expected, in difficulties, owing to the cold weather and snowstorms which have recently prevailed in America. The engineers concerned, however, say they are confident that they can keep the conduits clear. It is well for us that the experiment should be tried in the States; for if they can ever, which is more than doubtful, get an underground system of electric mains for tramway purposes which will work satisfactorily in all weathers it would soon be universally adopted in this country. Of course, always premising that the cost is kept within reasonable limits.

THE Blackburn Corporation have agreed to renew the lease of the local Tramways Company on their substituting electric for horse traction on two of their three routes. The Corporation will supply the Company with electricity at the price of 2½*d.* per unit up to 140,000 units, and 2*d.* per unit above that quantity, and will provide overhead wires and poles, the Company to maintain their own motors and electrical plant.

AN ingenious excuse was recently made by a West Ham farrier for neglecting to maintain his wife and family. He said that since he saw a motor-car he had not the heart to shoe any more horses. The Bench thought he was suffering from that species of "motor-ataxy" which ordinary people call laziness, and sent him for a month to a place where exercise on the treadmill has usually an exhilarating effect.

THE Sale District Council have decided to oppose the tramway scheme of the Manchester Carriage and Tramways Company, solely on the ground that the proposed overhead electrical wire system is unsightly, and objectionable in many other respects.

THE officials of the London Road-Car Company enjoyed a very successful dinner on the 7th inst. Of course the subject of motor-carriages could not be kept out of the speeches, and while regretting the "loss of their fellow four-footed labourers"—as some present called them—they were all ready to welcome any improvements which might be brought forward.

OUR cab strike can hardly be said to have produced much of a revolution in London locomotion. But in New York they are just at the expectant stage at which we were some two or three months ago. The New Yorkers are also indulging in the luxury of a cab strike. It is a more formidable affair in the land of freedom than in London. There the striker pulls out his revolver and shoots at sight.

THE SERPOLLET STEAM SYSTEM OF MOTORS.

A DEPUTATION from the Aberdeen Town Council recently came to London for the purpose of inspecting motor-carriages, with the object of recommending to their colleagues which system would be most suitable for the purposes of the Board. As a powerful vehicle capable of carrying some 20 persons to and from the beach is required in Aberdeen, none of the oil motor-driven vehicles were in any way suited to their wants, but conducted by Mr. G. Hopkins, of Parliament Street, and Mr. Julius Harvey, of Queen Victoria Street, to the Serpollet depôt at Willesden, they there saw two diverse vehicles which enabled them to thoroughly test the merits of the steam-carriage. One was a small vehicle like a phaeton to hold four persons, and the other was a large tramcar to carry 50 passengers.

As it is understood that the members of the deputation reported favourably on steam, as represented by M. Serpollet's invention, we quote as follows from the statement of one of the representatives. He writes:—

"We had not many minutes to wait until Mr. Cust, the engineer, representing M. Serpollet, announced that he was ready to demonstrate the capabilities of the tramcar. In the rails leading out of the shed there is an awkward double curve like the letter 'S,' and it was a point of interest with the

FIG. 1.

deputation to observe how the car would negotiate the curve. As a matter of fact, it turned easily, if not elegantly, and was promptly switched on to a private line extending for about 200 yards along the side of the commodious premises. The visitors having entered the vehicle, it glided down a slight gradient to the end of the line at the rate of about five miles an hour. On reaching the bottom, the engines were immediately reversed, and the car made its way back again, climbing the hill with no apparent effort. The journey was repeated again and again, more power being applied at every fresh start until a speed of about 10 miles an hour was attained. There was very little noise, and no smell. The use of coke prevents smoke, and the steam escapes as if by stealth.

"The car, which was built a few months ago, was for some time in use on the streets of Paris before being taken to London for exhibition purposes. Although the vehicle we saw differs in many respects from the sort which would be suitable for traffic in Aberdeen, a brief description of it may be interesting. It is built to accommodate 20 persons inside, 24 on the top, and six on the front platform, the outside passengers being protected from rain by a roof. The front of the tram resembles an ordinary car, except that six seats are placed under a kind of verandah. At the back are the appliances for driving and regulating the car. Here may be seen the furnace, the automatic oil pump, the handles by which the motive power is applied, and, in short, all the paraphernalia of a locomotive on a small scale. There is room at the back for only one man to attend to all the functions of regulating and driving, while the conductor is placed on the front platform. The boiler consists of a group of tubes so arranged that the heat of the furnace can play freely round them. Water, injected by means of a powerful hand-pump, is immediately converted into steam, and it is one of the features of the Serpollet system that an increase of several horse-power can be obtained in an instant by one or two strokes of the hand-pump. The advantage of this is evident. When a vehicle reaches a hill or a road along which travelling is heavy, additional power is required, and the use of the hand-pump in the case of a Serpollet car has been described as analogous to an application of the whip in the case of horses.

FIG. 2.

Another material advantage claimed for the Serpollet boiler is that it cannot burst. The tubes are filled, not with water, but with steam merely, and, in the case of a negligent driver allowing the tubes to be overheated, all that can occur is an escape of steam and a stoppage of the car for the time being. The engine—a very powerful-looking little thing—is subtly concealed between the two pairs of wheels. Motive power is applied to the running wheels by a series of cogged wheels, the pistons and connecting-rods so conspicuous in a locomotive being absent here. Were it not for the compartment at the back of the car, and a suggestion of unusual solidarity, there would be difficulty in distinguishing it from the ordinary tramcars we see on the streets every day."

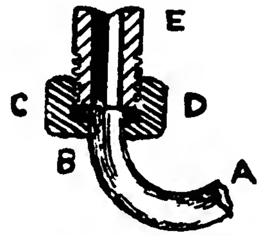

FIG. 3.

Apropos of this visit, and of the favourable comments made by Sir David Salomons as to the future prospects of steam as represented by the Serpollet boiler, we append a few illustrations showing the details of tubes and some views of carriages which have been recently constructed in France. We have received so many queries from correspondents on this subject that we are pleased to have an opportunity of affording the information which we have been repeatedly asked for.

Fig. 1 shows a section of the form of tube which has been adopted after several trials. It is made out of steel tube, the slit in the centre being all the water or steam space which is provided, so that it has an enormous reserve of strength. The boiler is, in fact, constructed on the principle of a practically instantaneous conversion of the water supply into steam of the pressure required—the supply of water being automatically supplied as steam is used in the cylinders. These tubes are coupled up as shown in Fig. 2, while Fig. 3 shows in detail the method in which the joints are made.

The combination of stamped sections of the shape shown in Fig. 1 and the drawn tubes of the joint marked A in Fig. 3 are arranged in the fire-box, so that only the stamped section is exposed to the full force of the hot gases; the tubes A are only subjected to much lower heat; while the threaded ends, E, are altogether outside of the fire-box. In this way great safety and strength-pressures of 1,500 lbs. and upwards have been frequently applied at very high temperatures without any distortion of the tubes. This has been demonstrated repeatedly, and an instance may be given: — One of the extremities of an element (an element being the group of tubes shown in Fig. 2) was closed, and the other was connected with a test pump. When the element had been heated in a forge fire to a temperature of from 780° F. to 900° F. water was injected into it at varying pressures up to 3,000 lbs. without any perceptible distortion. In practice the Controle des Mines of France certify these tubes as safe at 1,500 lbs., and this is done by virtue of a Ministerial order issued after an elaborate series of experiments in 1888. It will be readily seen that the tube elements, as they are called, can be readily grouped in prism arrangements, so that they can be used as horse-power varying between two horse-power and 50. One enormous advantage of the thickness of tubes used—besides that of safety—is that a considerable amount of heat is stored in the tubes, and this is taken up by the cold water as it is pumped in. If they were thin in section the great disparity in temperatures would soon lead to a disruption in shape from this cause alone, without any reference to the poor efficiency which would ensue. With regard to the general details of the Serpollet engine and carriage, we hold these over until we have an opportunity of illustrating and describing in detail a new carriage which is about to be placed on the market. In the meantime, however, we avail ourselves of the courtesy of Mr. A. R. Sennett, who has lent us blocks with which we illustrate, on this page, various forms of Serpollet steam carriages, which may be taken as types of those hitherto introduced by the maker. We may mention that these views will appear in a book which will be shortly published by Messrs. Whittaker and Co., entitled "Horseless Road Locomotion: its History and Modern Development." This work is from Mr. Sennett's pen, and from the advance proofs which we have had an opportunity of examining, we can safely state that this volume will become one of the standard authorities on motor matters.

COACHMAKERS and MOTOR-CARRIAGES.

The annual social gathering of Messrs. Atkinson and Philipson's *employés*, their wives and friends, to the number of nearly 200, took place at Newcastle-on-Tyne on New Year's Eve. At the concert which succeeded the tea, Mr. John Philipson presided, and presented the prizes to the deserving apprentices. He remarked that it was the 38th anniversary of the first presentation, and he believed his system had the desired effect, in encouraging improvement in work and the habit of punctuality. The motor-carriage would take a certain place on the roads which were now open to it, but he did not think it would interfere to any marked extent with the manufacture of English pleasure carriages and of harness. Motor-carriage building would be a distinct branch, and he hoped shortly to have a wing of their manufactory devoted to the purpose. The greatest caution was necessary in the selection of a motor, as, up to the present time, the engines were far from perfect; but he and his sons were working and watching carefully, so that they might, at the earliest possible moment, be able to offer something reliable to the public. This, he believed, was the best way to keep the industry in their hands, as the coachmaker, owing to his special knowledge of carriage construction and suspension, was the proper and most capable person to produce a carriage which would work without noise or vibration, and would run smoothly, and be comfortable and durable. The concert was followed by a dance, in which Messrs. William and John Philipson, junr., took part.

Motor Vehicles to Convey Produce in Queen's County.

Some further particulars are to hand as to a service of automotor vehicles which will be shortly established in the southern portion of Queen's County. It is proposed to run vehicles both for goods and passenger traffic from Johnstown, in the county Kilkenny, to Ballybrophy Station, calling at Rathdowney and continuing to Borris-in-Ossory. The district is an important one for grain and green crops, and there is almost a continual line of heavy vans on the roads in the harvest time conveying the produce to the Ballybrophy Station. It is also an important line for cattle conveyance. Nearly all the young cattle brought up to the Queen's County for fattening come from the south and west portions of Limerick County and from Kerry. They are nearly all discharged at the Ballybrophy Station, and after a large fair in either of these counties the roads round Ballybrophy are studded with lots of cattle for the different graziers living about. A great many of the cattle have from time to time to be brought from the station to their destination on cars and carts. The motor-cars will be fitted up for the purpose of taking over that traffic also as well as the conveyance of sheep and swine.

The country which the new service will open up is a rich and important one. There has been almost a continual movement amongst the people there for a railway line through it. The proposal to run motors for the light traffic of the district has given a great deal of satisfaction in the locality. The project originated with a wealthy resident in the neighbourhood of Johnstown, with whose name more than one enterprise in the district is associated.

The Fifth Avenue Stage Company has, says Dalziel, ordered one hundred motor 'buses, of 20 horse-power each, and expects to have them running in a few months.

BUSINESS NOTES.

Cardiff Adopts Motors.

The South Wales Motor-Car and Cycle Company (Limited), has been registered with a capital of £5,000 in 1,000 £5 shares, and the whole of the shares issued have been taken up by merchants, shippers, and traders connected with the Cardiff Docks. The directorate consists of Mr. E. L. Downing, Captain Hamilton Murrell, Mr. T. R. Thomas, Mr. R. T. Duncan, and Mr. H. Thomas. The headquarters of the Company will be 119, Bute Road, Cardiff. The premises are now undergoing extensive alteration, and will soon contain a varied assortment of motors and cycles. The Company's engineer submitted an exhaustive report on the different types of motors, and in the first instance recommended the purchase of a steam motor van, steam being the best and most easily managed motive power known up to date. The Company adopted the recommendation, and forthwith placed an order for a steam motor-van with the Steam Carriage and Wagon Company (Limited).

The type of van built at the Chiswick works is well known, as we have fully described and illustrated it in our columns, especially in our last issue. The van was run down to Cardiff by road, the distance traversed being 158 miles, while the total time under steam on the journey was 25 hours—the load carried being about half a ton. The roads between London and Oxford were in very bad condition, being up for at least one-third of the distance. From Oxford the second day's journey was on rather better roads, while the last run from Gloucester through Chepstow to Newport and Cardiff was over very hilly roads, but every acclivity was successfully climbed. Not the slightest stoppage was necessary on the way for either adjustment or repair, and the van arrived at Cardiff in as good a condition as it was in when it left Chiswick.

The new van will not be a mere advertisement, but will have to earn its own living. It will be a familiar object about the docks collecting and delivering, and when convenient making trips to Newport and Barry on the same mission. A large amount of work has already been promised for the van by shareholders, who calculate upon effecting a great saving over the present system in vogue. It will be decidedly interesting to watch the outcome of the experiment, which may lead to an extensive industrial development in the district.

We have recently had an opportunity of minutely inspecting and testing the driving chains manufactured by Messrs. Brampton Bros., of the Oliver Street Works, Birmingham. It is rather late in the day to testify to the excellence of finish which this firm have achieved in their products, but the exquisite finish of their manufactures and the consistent strength which is maintained by them in all their varied output are worthy of the highest praise which can be given. In their own speciality they are without rivals.

Motor-Cars in the Isle of Man.

In view of the fact that the Imperial Parliament has passed a Bill authorising the use upon certain roads of motor-cars, there has been introduced into the Manx Legislature, at the instance of Mr. James Mylchreest, who represents Castletown in the House of Keys, a Bill to legalise the use of light locomotives, not to exceed in weight four tons, and so constructed that no smoke or visible vapour is emitted therefrom. Fourteen miles is fixed as the maximum speed of travel along public highways. It is provided that yearly duties shall be charged. After some discussion the Bill was adopted by 14 votes to four.

AN INTERVIEW WITH MR. McKIM.

His £5,000 Challenge, and Opinions on Motor-Vehicle Matters generally.

In our last issue we announced the fact that Mr. J. L. McKim, of 81, Cannon Street, E.C., had challenged the Motor-Car Club generally, and its president particularly, to a contest, offering to back the Duryea Car, in which he is interested, against any other four-wheeled vehicle of equal horse-power for the sum of £5,000.

Nothing having come of this (as the authorities at Holborn Viaduct elected to stand down), a representative of ours recently waited on Mr. McKim to ascertain how matters stood, and to gather his opinions in general on motor affairs.

After some difficulty an appointment was obtained with Mr. McKim, in his handsome offices, which are noteworthy as an example of furnishing in the most tasteful of American styles—everything that can secure comfort to the visitor, and at the same time facilitate the rapid transaction of the work in hand, having been studied in the arrangements, which *en passant* are models of what the surroundings of a high-class business establishment should be to-day. The door having been locked to keep out for ten minutes the thousand and one applicants for admission to the presence of a successful organiser of commercial undertakings, our representative at once asked Mr. McKim whether he had heard anything more from the Motor-Car Club as to his challenge. To this he replied:—

"No; and the most peculiar part of the transaction is, that while the secretary of the Club tried to obscure the real issue by asserting that speed trials are not allowed in this country, he was at the same moment sending letters to the Press offering a prize of £2,000 for a Motor-Car Derby, and a special prize for the vehicle which could accomplish a mile in one minute. I cordially agree with The Automotor—the opinions of which I like as much as I dislike its title—that speed is by no means the only, or even the chief, test of a motor vehicle, and that such a competition as proposed by the Club could only, if carried out, bring the industry into contempt and discredit."

"Your aim then was?"

"Simply this. I believe—in fact, I know—that the Duryea, judged by all the practical points which will appeal to the engineer and the commercial man, is a long way ahead of any other motor-vehicle, and I wished to prove that by an open challenge to the President and all other members of the Motor-Car Club to run it against any other vehicle over a course sufficiently long and varied to settle the matter and for a stake large enough to make it worth the winning."

"Nothing has come of your offer?"

"No, and I do not think Mr. Lawson could take it up—if he did, defeat for him would be certain, and he is hardly likely to risk another Waterloo just at present. At any rate, I think the honours remain with me by forfeit."

"Well, as I cannot make 'copy' out of a contest which is not likely to take place, will you tell me something of your connection with the vehicles in which we are both concerned and of which my readers would learn all that can be known?"

"My interest in the motor-car industry first received birth during a conversation which I had many, many years ago—almost more than I care to remember—with the inventor of Perkins's steam boiler, which, by the way, was the father of all those made recently for very rapid evaporation, and the engineering world is to-day perhaps hardly aware how energetically Perkins followed out his system and how fully it has been copied by others. Since then, of course, the conditions of English law made it impossible for anyone to carry out very full experiments in public, and it was not until French and American engineers, being somewhat more free from grandmotherly legislation in this direction, turned their attention to applying mechanical motion to street traction that the matter became a fixed idea in my mind that the time would come when this country would have opportunities of handling motor-cars with freedom; hence, during the last five years, either personally or through my agents and correspondents, I have visited all the motor-engine works in Europe and America, where the power employed was either gas, oil, or electricity."

"And, as a result, what do you think is the most suitable type of motor for general highway work?"

"I scarcely know how to reply to your inquiry as to what I think the best motor for road traction purposes. There seems to be so many varying sets of conditions that one should feel nervous in expressing an opinion You must remember that I am merely an observer and not an inventor, but I may say I am impressed with the belief that a crude oil motor is an absolute impossibility, and that for several reasons, the principal one of which would be that perfect combustion cannot take place. Crude petroleum has for its constituent parts hydrocarbons of varying specific gravity and limits of boiling point, and when the conditions operating for the perfect combustion of any one of its several parts are put into operation, it follows that others must remain more or less outside the range of the combustion which operates successfully on one."

"As to the fully advertised claim *re* 'Master Patents,' so prominently brought before the notice of the public recently—are you not afraid of moving in the face of threats such as those made by Mr. Lawson?"

"I am somewhat reluctant to reply to this question. I do not believe that Mr. Lawson or any of his friends acting for the several Companies in which he is interested have possession of

L

any 'Master Patents,' using that word in its correct sense—and if it is a fact that they have, I should not value the possession of them very much. I wish to examine the question from the very much broader standpoint of efficiency and economy. Curiously enough, the essential point towards the production of a successful motor-car has been altogether ignored by Mr. Lawson in all of his different prospectuses and all his different statements, but I consider that his great parade of claims for 'Master Patents' is merely the traditional 'red-herring' used to prevent people from inquiring too closely as to the more important points of the motors. Just think for a moment what effect would be produced on the minds of any Board of Directors of any Railway Company, if any Engineer were to tell them he held the Master Patent for Locomotives. They would merely smile, and continue to make their engines, or have them made, on lines which embodied the idea of economy of fuel; and these points, efficiency and economy, have been hidden away for very obvious reasons by Mr. Lawson and his friends when speaking of motor-cars. It would be a very easy matter for me to design a motor-car for travelling to the moon, and I might call it a 'Master Patent,' but I believe 'Old Mother Goose' went '20 times as high as the moon' on a broomstick, at least so I read in the nursery, years and years ago, and such baby stories as being the possessor of the Master Patents for motor-cars should be used for nursery purposes, and not for commercial enterprises such as this—babies might or might not believe, but the average commercial man cannot. No, Sir, a Master Patent motor-car or motor-engine of any sort is to-day impossible, although the details associated with such cars and engines may be patented with advantage—however, I believe that Mr. Lawson uses this question of Master Patents merely for 'red-herring' purposes, and I am satisfied that he and every one of his advisers or sympathisers are very well aware of the fact that the Duryea Motor has passed the stage when it is necessary to bolster it up with ridiculous nursery stories of the broomstick style. As sole owner of the Duryea Motor-Car European patents I claim that it is the most economical engine—it is of course known that it is the most reliable—and because of that knowledge I offered to run a Duryea Car against any other commercial four-wheeled car of equal horse-power belonging to any other owner, for stakes of £5,000 each side. The Duryea Motor has passed the experimental stage, and is established as a certainty, and the engineers associated with it are now devoting their attention to efficiency and economy rather than any other phase of the question—that is, their efforts are in the direction of reducing the amount of fuel necessary for doing a certain amount of work, and this in the end must be the measure of efficiency."

"But surely electricity will be an important factor in our future operations?"

"No, I do not believe much in electric motors for street traction purposes, principally because of the huge weight necessary for primary or secondary batteries. I have often been amused to notice the efforts of the owners of such batteries endeavouring to offer their wares to the public by calling very distinct and prominent attention to their weak points. You will see such expressions as 'Weight reduced by 40 per cent.,' 'Space reduced by 45 per cent.,' 'Plates enclosed in refractory envelope,' 'Free from risk of short circuit,' 'No loss of capacity with age,' 'Discharge rate for up-grade work almost unlimited.' Now these are really and truly the weak points in each cell, and when one or other inventor makes such claims as these, he points to the fact that they are merely comparative expressions. When the very best cell available cannot give rapid discharge without seriously spoiling the plate—when short circuiting is a constant and ever present danger, and when they become too old for use in a very short time—it is not, in my opinion, a thing possible that we, in the present generation at least, shall see commercially successful vehicles running by electric current. Please again remember that I speak as an observer and not as an inventor. But if at any moment it be found possible to produce a motor worked by electricity, without the weak points above referred to, I am prepared to buy it, and pay a very large price indeed for it."

"What will the future of the industry be, and will existing vehicles crystallise into shape, or are we likely to see some absolutely novel departures?"

"Speaking generally about the motor-carriage business, I am disposed to think that there is no motor-carriage existing to-day which in 10 years' time would be fathered by any prominent carriage builder. I am more disposed to look at this question from a commercial standpoint, and I feel satisfied that the motor-cars of the future will be the work—not of one man—but of several working in conjunction, and as far as I am able to see, the most prominent difficulty occurs by reason of the prejudices and jealousies of rival patentees—each one wanting to consider his own particular invention more prominent than any other. This is more particularly so in reference to English and French inventors; American engineers are willing to combine and 'do a deal,' pooling their ideas as it were, and making the best effect of a number of different plans, and I am quite satisfied that to secure such men as Mr. Hiram Maxim and Mr. Charles Duryea, with their store of possibilities, their trained mechanics, their educated engineers and assistants, who are fully familiar with every particular connected with high-class motors, is to have hold of everything which is worth having in this department of mechanics."

"Have you any opinions as to the British Motor Syndicate's attempt to get £3,000,000 for their patents?"

"I think it would be out of place for me to make any very free comment as to my opinion of the policy followed by Mr. Lawson recently. Generally speaking, one can be very wise after an event, and now that we know Mr. Lawson has failed so signally, nearly every one is disposed to say, 'I told you so.' I am quite sure that Mr. Lawson could not do better than he has done with the motors which he had at his disposal; you see he had no high-class oil or steam motor to commence with, he had only 'Master Patents,' and he was therefore compelled to expend a large quantity of 'gas' to 'puff' the car along. This, of course, accounts for many of the wild statements made by that gentleman, but although this is my opinion I cannot think it was either courteous or wise for the holders of rival projects to flood the papers with their own particular objections and theories at a time when Mr. Lawson was going to the public with his scheme. I am a great believer in the doctrine of fair play, and wish every man to have a full innings without let or hindrance—criticise him afterwards as much as you choose, but not at the moment when no good effect can be produced. I think every commercial man interested in motor-car business will recognise the difficulties which Mr. Lawson had to contend with, and whilst sympathetically smiling at many or all of his wild-cat ideas, yet I think he should get credit for anything which he has done well. He has most certainly amused the European and American engineers immensely, he has proved conclusively that the comic element is a mistake in company promoting, he has added to the picturesque appearance of your Lord Mayor's Show Day by appearing in a fantastic costume more usually associated with the Whitechapel holiday element at Margate during the summer season, he has driven a 'Pilot Car' (one of the Master Patents, I suppose) to Brighton on Motor Car Liberty Day (14th November last), and has succeeded in being 'all at sea' and in a village blacksmith's shop at the same time (a truly marvellous feat), and he has fully supported one of the traditions of this great city by providing a dinner at the Hôtel Métropole, Brighton, in celebration of that day's events, but (how sad it is to use 'but') he was evidently still 'at sea,' or suffering from the effects thereof, when he failed to recognise the presence of ladies in commencing his after-dinner speech on that occasion. With this reservation I think Mr. Harry J. Lawson has done well, and deserves to be thought better of than is the case, and I, for one, will always be glad to see his 'Yachting Costume,' his 'Pilot Car,' and his 'Master Patents,' in evidence, as long as they add to the pleasure and amusement of engineers generally, and to the profit of Mr. Lawson particularly." [At this point our representative thought it well to leave, as his Editor has resolved to consign the British Motor Syndicate prospectus, as far as possible, to the region which holds those things which should never have been.]

TRADE NOVELTIES.

An Electric Bath-Chair.

MR. JOHN WARD, invalid chair manufacturer, of 246 and 247, Tottenham Court Road, London, has made a speciality of a motor bath-chair suitable for sick persons, or those who for any reason are unable to take prolonged walking exercise. It will be seen from the illustration which we give that it is a handsome and commodious vehicle, and is constructed in accordance with J. V. Sherrin's patent, the motor being one of the Britannia type. We had an opportunity before the procession to Brighton on the 14th November last—in which, by the way, one of these chairs took part—of testing the ease with which they travel, and the small amount of trouble involved in their management. To those who cannot take outdoor exercise without mechanical assistance these chairs will be very welcome.

The "Damon" Tyre.

AT the recent National Cycle Exhibition held at the Crystal Palace we had an opportunity of examining and trying the new "Damon" tyre, which has been specially designed for automotor work. It is manufactured by L. Broughton Wood, of Stoke-on-Trent, and we illustrate it herewith. From the engraving it will be seen that many of the disadvantages of the ordinary pneumatic tyre are avoided by the extra strength which is provided. The actual construction can be readily seen from the detailed description which is attached to our illustration. The tyre is formed with two concentric rings with rubber inserted, the latter being secured and held together by screwed bolts or nuts. It is remarkable for the ease with which it may be manipulated, while users secure economy and strength. Makers of motor vehicles should communicate either directly with the patentee or with the London agents, at 10, Dashwood House, E.C.

SNOW IN THE STREETS.

IN our last issue we briefly reported the fact that the House of Lords had, in the course of an important decision, decided that tramway companies have no right to use salt for the purpose of clearing their lines of snow. The action was between the Aberdeen Town Council and the local tramway company. Being so far north, the question has of course become keen; snow has fallen, and in the face of the interdict the service of cars has been interfered with. Immediately after the decision, and with the advent of the white flakes of winter, the secretary of the Aberdeen District Tramways Company wrote a letter to the Council stating that the directors were of opinion that an arrangement should be come to between the Council and the Company as early as possible for having the tramway lines and streets cleared during snowstorms in such a manner as to obviate interruption to tramway traffic, and suggested that a conference should be held on the subject. The Council's committee accordingly received and conferred with a deputation from the directors, consisting of Messrs. Cook, Collie, Allan, and Couper along with the secretary and manager. The directors suggested that the Town Council should in times of frost or snow undertake the duty of clearing the tramway lines as well as the streets, making use of salt so far as necessary for the purpose, the Company, on the other hand, affording the assistance of their staff and plant, and possibly also making a contribution towards the cost. Under such an arrangement the responsibility of using salt would be thrown upon the Town Council, who—the directors contended—were, as a road authority, in a different position from the Tramways Company. The deputation having withdrawn, the committee resolved to recommend that a reply be returned to the Tramways Company to the effect that, while the Town Council are prepared to clear the streets for ordinary traffic as expeditiously as possible, they do not see their way to undertake the responsibility of clearing the lines or keeping them clear for the passage of tramway cars. So a deadlock continues. The parties have had the inestimable advantage of a legal decision by the highest tribunal in this country—but they are, if anything, farther off than ever from solving the problem involved in the demolition of the snow.

BRADFORD TECHNICAL COLLEGE.

AT the annual conversazione held on 18th and 19th ult., an extensive and interesting collection of photographs, drawings, and models of motor-carriages was shown by the head of the engineering department, Mr. G. F. Charnock, Assoc. M.I.C.E., who has devoted considerable attention to the subject. The total number of exhibits was something like 350, and included examples lent by the Daimler Motor Company (Limited), Mr. E. J. Pennington, Mr. W. C. Bersey, the Anglo-French Motor-Carriage Company (Limited), Messrs. Roots and Venables, the Editor of THE AUTOMOTOR AND HORSELESS VEHICLE JOURNAL, and others. A four horse-power Pennington oil engine for a motor-carriage was loaned by the makers, T. Coulthard and Co., of Preston, and attracted considerable notice by reason of its lightness and the small space occupied. The exhibition proved so successful that it was decided to throw it open to the public on the following Monday after the conversazione.

NOTICES.

Contributions and articles likely to prove of interest to our readers will receive due attention, but in all cases the name and address of the writer must be given, not necessarily for publication.

All matter intended for publication should reach us not later than the 10th of each month. Stamped envelope must be sent if the manuscript is required to be returned.

All Advertisements should be sent to the Advertising Department, F. KING AND CO., LIMITED, 62, *St. Martin's Lane, London, W.C., where Advertising Rates may be had on application.*

The Annual Subscription is 7s., including prepaid postage to any part of the world.

Cheques and Post Office Orders should be made payable to F. KING AND CO., LIMITED, *and crossed London and County Bank; otherwise no responsibility will be accepted.*

THE AUTOMOTOR AND HORSELESS VEHICLE JOURNAL *can be obtained through* MESSRS. W. H. SMITH AND SON, *and at* WILLING AND CO.'s *bookstalls.*

When any difficulty is experienced in procuring the Journal from local newsvendors, intending subscribers can obtain each issue direct from the Publishing Office, by filling up and forwarding, with remittance, the Subscription Form accompanying the Paper.

The Automotor and Horseless Vehicle Journal.

A RECORD AND REVIEW OF APPLIED AUTOMATIC LOCOMOTION.

JANUARY 18TH, 1897.

ANSWERS TO CORRESPONDENTS.

B. R. (Huddersfield).—Having secured a return of your money you are to be congratulated, but you have evidently no further *locus standi* in the matter.

J. THOMPSON (Maida Vale).—The stroke is six inches; the revolutions approximately 650; and the initial pressure 36 lbs. We cannot give an average diagram.

EGLANTINE (Broadway). They are perfectly reliable; but why not advertise your requirements!

ONE IN DOUBT (Cheshire). The number of volts cannot possibly exceed two; we have only had an opportunity of examining an experimental cell. We found that the internal resistance was very great.

BENZINE (Kington-on-Thames).—You cannot, without modification, use the heavier hydrocarbons. If you did you would be speedily stopped by a solid cake of carbon deposits.

J. WILLIAMSON (Manchester).—We cannot advise you to advance money for experimental purposes unless you are made a party to the application for provisional protection. An assignment of a share of a patent cannot be registered until the final has been sealed.

W. M. MCGREGOR (Elswick).—The arrangement is bad; there is not sufficient clearance in the combustion chamber. For your purpose a water jacket is essential; do not be led away by statements based on the results of brief and inconclusive trials.

CONSTANT SUBSCRIBER (Leicester).—Is it not rather too soon to adopt this *nom de plume?* Any way we regret that we cannot possibly comply with your modest request.

SERPOLLET (Bedford).—There was nothing exceptional about the accident. It was the result of an ordinary street collision, which happens every day to horse-drawn vehicles without any comment.

INVESTOR (South Shields).—You can purchase the shares at about £1 2s 6d. We do not know what you can sell them for.

NELL GWYNNE (Autwerp).—The carriage is driven by a modified form of the well-known Daimler motor.

AMATEUR (Godalming).—You must run the risk, which, in your case, is very great, as it looks like an infringement. The Dunlop Company oppose all new applications, in order to test the matter in the Courts.

J. JEFFRESON (York).—Your suggestion shall be carried out in our next issue; and in the meantime we thank you for it.

EMBLEMATIC (Doncaster).—At your request we have carefully tested the cells sent to us. It is perfectly correct that, in comparison with others, the weight of the "grid" has been reduced as stated, while the area has been increased, but all this has been obtained by a total neglect of all considerations as to stability. In a few minutes on a jolting road the plate would collapse and a short circuit would, of course, be the inevitable result.

ROTARY (Shepherd's Bush).—As an idea your suggestion is, of course, admirable, although old; but how can you possibly obtain compression?

F. HAYTER (Devon).—We can only regret that our advice by letter is not satisfactory. The best plan you can adopt is to try the experiment, and you will then find that by "totally setting aside the Otto cycle" you will only succeed in filling your cylinder with unconsumed carbon.

JAMES SCOTT (Liverpool).—There is not the slightest risk of explosion; while from the section of the tube you will see that there is but little chance of its being burned away. The bugbear of explosion arising from cold water coming into contact with hot surfaces has been demolished by the elaborate experiments undertaken by the Boiler Insurance Companies.

INDIGNANT (Aberdeen).—Let well alone; experience can only teach the public and ourselves where the happy mean can be obtained.

FRUGAL (Finsbury).—Wait; none of the makers who will eventually supply the market have yet issued a comprehensive price-list. In the meantime everything is a matter of negotiation and of opportunity.

INVENTOR (Hastings).—Thanks for drawing. We cannot accept your statements, although, of course, we do not doubt them. If you will give us an opportunity of testing your motor we shall be pleased to illustrate and describe it—but in our own way.

IMPATIENT (Coventry).—Put on the curb a bit. Do you imagine that within two months of the trial of the "Rocket" the kingdom was covered with a network of railways? Motor-carriages are not evolved instantaneously—they take time to build. "Make haste slowly," is in our case the best motto.

EXPERIMENTER (Thirsk).—If you wish to try oils of various density you had better fit an air valve capable of delicate adjustment to your vaporiser, and you can then secure by "trial and error" the proper admixture which will completely consume the various products. That is the only method we can recommend.

J. PERKINS (Swansea).—The secretary of the Club will, doubtless, give you all the information. Write to him at 40, Holborn Viaduct, London, E.C. We do not possess a copy of the rules.

W. LEBRUN (Jersey).—Our publishers will lend you a set for your purposes, if you forward them a stamped and addressed envelope.

A. M. B.—But why do you write your signature in such a way? We have looked up your letter, and submitted it to our printer, who has grown grey in the task of deciphering such riddles. He suggests that your name is Bowman, while we make it Bridghouse. As a compromise we have cut off the signature to your letter and pasted it on the wrapper. We trust it may reach you.

TYRO (Westminster).—Mere drawings will be of no use. The object of our contemporary is to obtain practical results.

SIMPLEX (Norwood).—"Molesworth's Pocket Book," published by Spon, will give you the information you desire.

R. V. (Dublin).—Thanks for your information, but we have no desire to reopen the matter. We expressed our opinions very fully in the last issue, and have no desire to "whip a dead horse." We would rather see those concerned using their undoubted ability in the direction of some project calculated to serve our common ends.

SPORTSMAN (Kempton).—We believe the Derby scheme has been dropped; at any rate, we fervently hope that it has.

T. MAY (Cardiff).—We wrote you that you could not do better than apply to the representative at Wembley Park.

GRADIENTS (Westmoreland).—We have not the necessary space to spare here to answer you in full; if, however, you will refer to our advertisement columns you will see that we publish a pocket-book which will give you all the data you require.

R. F. HERON (Hampstead).—We do not know anyone who will teach at all at the present time; write again some time hence and perhaps we may then be able to advise you.

THOS. GREENE (Mageney, Co. Kildare).—We wrote you as the subject matter of your letter was urgent, and you will now see from our columns that the money is being returned in cases where sufficient effort is made to secure it.

BRITANNIA COMPANY (Colchester).—We presume the list we sent you was adequate for your purpose, as we have not heard further from you on the subject.

J. MACKENZIE (Grange Road, Middlesborough).—We believe the Credenda Tube Company can supply you with what you want.

J. W. EAST (Louth).—We will publish an illustration with full particulars in our next issue.

J. A. BEAL (Cardiff).—Speaking generally, one which covered the materials and construction for a certain period, subject to fair wear and tear and a minimum speed at a given load when working at full power.

*** THE BRITISH MOTOR SYNDICATE (LIMITED).—To the very many correspondents who have written to congratulate us on the position taken up in our columns with reference to this Company we can merely express our thanks for their cordial approval and appreciation. We are very pleased to know that, owing to the efforts of the Press generally, the public have not been largely entangled in this dubious enterprise; and that, as a matter of fact, the promoters have practically been allowed to enjoy their monopoly of the "master patents" which they claim to possess. If ever they realise the mammoth profits which were shadowed forth in the prospectus, we shall be the first to congratulate them on their good fortune; and in that case they will bless the journalistic infidels who refused to believe the glowing statements which were set forth. The Syndicate have the patents; the shareholders have, on their own showing, the necessary confidence and capital to carry out their views; and it is for them in the course of the future to prove, by the payment of cash dividends, how wrong and blind we all were in not accepting the generous offer which they made to all and every one of us to share their good fortune on the terms of subscribing a mere three millions sterling of capital.

WHAT WILL THE NEW YEAR TEACH US?

1896—eventful as it was in history-making epochs and surprises of varied kinds—may, when the story of the century eventually comes to be written, be known as the year which was famous for a revival of the strangled industries connected with motor traffic on the highways. Even, however, if this does not ultimately prove to be its chief claim upon the attention of the historian of the future, it is at least certain that this all-important subject will be amongst its leading characteristics. This country, immersed in the task of spreading a network of unrivalled railway systems throughout the land, which have helped to place its commerce and enterprise in the forefront of the world's industry, has, under the repression of an absurdly construed law, utterly neglected the possibilities of cheap and rapid communication on the highways. In the task of displacing the horse for the heavy work of the land and in the rapid transit of passengers through long distances Great Britain has played the very foremost part; but in riveting our attention to the great problems involved in long-distance travelling, the scarcely less important factors concerned in the every-day traffic of our streets have been allowed to fall into a condition of absolute neglect. We have, through sheer apathy and want of organisation, allowed animal power to perform the work which, as a great mechanical and engineering race, we might easily enough have achieved by simpler and more economical means.

In the meantime our Continental and Transatlantic neighbours, unfettered by judicial restrictions and with a keen desire to secure cheap and ready transport, made stealthy but rapid progress in the perfection of a method of locomotion, the very alphabet of which had to be learned from the efforts of the English pioneers. The start which they then obtained might have been even more firmly established than it has been but for the wariness of a few of our countrymen who, at considerable trouble to themselves, and at no little expense, raised the danger signal and at last awakened our public men and the Legislative Assemblies to the realities of the situation. There is no need now to again trace the story which has been told in our recent issues, as to the means by which Sir David Salomons and those associated with him organised the agitation which culminated in the passage of the Light Locomotives Act, and the regulations which have been made in pursuance of its provisions. Suffice it that in spite of some drawbacks which time will modify, we have now a workable measure which, with patience and care on the part of those interested, should prove a sufficient charter to ensure the ultimate success of a great industry which, in the modern sense at least, may be fittingly described as new.

The advent of the enabling Act, which came into force on the 14th of November, has been celebrated by jubilation; the motors have been either eulogistically described or contemptuously abused, according to the tastes of the writers, while we have had at least one gigantic Company *fiasco*. The time has now come for real hard work and for looking the varied problems with which we have to deal squarely in the face. We have enjoyed a splendidly initiated Emancipation Day *fête* in the shape of a trip to Brighton; we have swallowed the bitter pill which its promoters subsequently administered to us by way of a corrective; and have listened to the croakers who spell defeat and disaster out of the fact that English manufacturers have not been able to crowd our streets at a moment's notice with motor-carriages constructed to meet the requirements of regulations, when the ink with which they were written is scarcely dry. Of course it would be open to English users to buy Continental patterns and makes for their use—but quite apart from their unsuitability for our requirements, what would our friends who are so fond of shouting in derision "Made in Germany," "Manufactured abroad," have to say if such a custom became by any means universal?

What, then, is the outlook for 1897? To answer this question dispassionately, and with any pretence to accuracy, involves a careful inquiry into the processes which are going on beneath the apparently motionless stream of British motor-carriage work. With a fairly complete knowledge of what is being done by engineers and inventors interested in this matter, we can confidently assert that the prospect is in every respect a favourable one. The number of leading firms who are endeavouring to add motor-carriage building to their other special features may be counted by the score, and in nearly every case the desire seems to be—we are pleased to note—to depart as far as possible from the types which have been formulated by our Continental and American friends. Months must elapse before practical trial on the highways can begin to eliminate the forms which are unsuitable for our roads and streets, and when these have gone out of sight—and perhaps mind—the natural principle of evolution will at length bring forth the vehicle which by its suitability shall prove by its fitness to be the one which shall survive all others. The story of the bicycle, although on a much more imposing scale, will, doubtless, be retold; first, the period of exaggeration, ridicule, and bluff through which we are now passing; then the stage of doubt, semi-oblivion, and earnest, but quiet, experiment which can only bring success; next will inevitably come the triumph of assured success which will only astonish those who forget the trite axiom that history has a knack of repeating itself.

ROAD TRACTION IN POPULOUS DISTRICTS.

THE admirable paper which was read by Mr. J. F. Thompson before the last meeting of the Liverpool branch of the Self-Propelled Traffic Association—and which is fully reported in another column—may be read with interest and profit by all concerned. Without going into the questions raised by the speaker, we may note the attention which is being rapidly given in the crowded districts which surround Manchester and Liverpool to the favourable prospects which are held out by motor vehicles as a means of solving the huge problem of bringing the producer into the cheapest communication with the buyer. Manchester has shown by the prompt, if reckless, manner in which it has poured millions of sovereigns into the construction of its none too successful Ship Canal, how keen the city is to obtain prominence, and if Liverpool can, by any reasonable scheme of motor transit for goods on roads, see a reasonable prospect of success, want of money, ingenuity, or enterprise will not stand in the way of its being carried out. The local branch is doing excellent service to the community by enabling these proposals to be thrashed out by practical men, and the whole country must benefit by the discussions which are taking place. We trust that London and other important centres will soon follow the example thus set. What is wanted more than anything else at the present juncture of affairs is a frank interchange of opinions between those entitled to speak with authority. The result cannot fail to be of benefit to all. Mere *ex cathedrâ* statements by those whose utterances are tainted with a suspicion of interested motives are of little value; but in the arena of free debate the truth has a habit of invariably getting uppermost at last and of remaining there. All that is wanted is a small amount of organisation, and the engineers and carriage builders of the metropolis will soon make their voices heard with at least as much effect as their colleagues residing in the chief provincial centres.

PENNY PARCEL DELIVERY BY MOTOR VEHICLES.

WE are told that what has been done for letters by Rowland Hill is to be achieved in London for parcels by a new enterprise called the London Penny Parcel Delivery and Automatic Advertising Company, which proposes to place on the streets of the metropolis 1,000 Tricycle Carriers of novel construction, and to open, in every district, offices for the receipt of parcels. Within a five-mile radius of Charing Cross parcels not exceeding 3 lbs. in weight will be delivered for one penny - an innovation that ought to prove a perfect god-send to the weary City man, who is expected to lug home parcels in the evening, and for ladies who have to burden themselves with ungainly packages in the course of their shopping. For parcels between 3 lbs. and 6 lbs. it is proposed to charge $1\frac{1}{2}d.$, and for those between 6 lbs. and 9 lbs. $2d.$—the latter weight being the maximum fixed for the moment, just as operations are at first to be confined to London. For any distance beyond the five-mile radius, but within the metropolitan area, an additional penny per parcel will be charged, but it is hoped that the public patronage will be so great that the Company will soon be able to carry for a penny a parcel up to 10 lbs. for any distance in London. A main source of the Company's revenue is expected to be found in the novel form of its advertisements. Each Tricycle Carrier will bear a box to hold the parcels, and on the glass sides of this box will be displayed a prominent advertisement, which will automatically change at regular intervals. These perambulating advertisements ought certainly to attract attention by their novelty, and we understand that already contracts have been given by a good many of the leading advertisers.

REVIEWS OF BOOKS.

"Steam Locomotion on Common Roads." By W. FLETCHER. (London: Messrs. E. and F. N. Spon.) Price 5s.

THE author of this ably compiled work has been a prolific writer on the subject of motor-carriages for the last 20 years. The innumerable papers which he has contributed to the technical journals have doubtless done much to help on the movement which led to the passage of the amending Act of last session. In this volume—which is admirably illustrated throughout—Mr. Fletcher treats exhaustively of the rise and progress of mechanical road vehicles until the days came when, by the working of the law, none but engines of the heavy traction type could be used on the highways. All the engines turned out in the early days of the century are fully described, while the details shown will be of service to the designers of to-day. Full justice is done to individual inventors and manufacturers, while the list of names is very accurate, and can be consulted with full confidence. We are pleased to hear that a second volume is in preparation with the object of bringing the matter up to date. The task could not be entrusted to better hands, and when this appears, the two volumes will prove to be perhaps the most comprehensive record on the subject to be found in our technical literature. In the meantime, all interested in the matter may be safely advised to invest in the book, the historical value of which it is difficult to over-estimate.

"Tramway Motors; Lessons from America." Reprinted from the *Glasgow Herald*. (Glasgow: George Outram and Company.) Price 1s.

THIS unpretentious pamphlet contains far more valuable matter than can be found in some costly and much-vaunted volumes on the same subject. It owes its origin to the enterprise of the proprietors of the *Glasgow Herald*, who, towards the end of last year, sent out one of their staff to America with instructions to visit the principal cities in the States and report as to the method of haulage adopted for the tramways in each place visited, with the view, if possible, of enabling the citizens of Glasgow to determine which of the rival schemes laid before them would best suit their local requirements. The letters—some twenty in all—appeared in the paper during the months of October and November, 1896, and have now been deservedly reprinted. The articles are carefully written, and are brimful of statistics and facts which will be found indispensable to all who wish to accurately study a matter which is every day growing to be of greater importance to the municipal authorities of this country. The writer evidently leans to the overhead electrical system—but, as the publishers are careful to point out in their preface, "the articles were written from the point of view of the present position in Glasgow," and local requirements must always prove powerful factors in coming to a decision as to the best system to be adopted. Without attempting to express any opinion as to conclusions arrived at by the writer, the solid facts and figures which the book contains renders it of the utmost value to all concerned.

THE Secretary of the Self-Propelled Traffic Association—Mr. Andrew W. Barr—has just issued a very neat pocket-book for the use of the members, containing a reprint of the Locomotives on Highways Act, 1896, and the various rules which have been made in accordance with its provisions.

MR. WALTER HORNCASTLE states, in his circular for January, that motor-car companies are responsible for a total capitalisation of something like £6,000,000 during the past year.

IN reference to our statement in December issue that Mr. McKim had purchased Messrs. Roots and Venables' motor patents we now understand that a sale was not concluded, the negotiations being broken off at the last moment. We regret the inadvertent admission of the paragraph.

THE "FACILE" PETROLEUM OIL-ENGINE.

THE Britannia Company, of Colchester, have for some time past given special attention to the development of the petroleum oil-engine, which they have succeeded in bringing into practical working shape. The "Facile" engine (Gibbons' patent) is the outcome of their labours, and a photograph of this was published in our second issue. Figs. 1 to 6, which we now give, show the details of this system. In the "Facile" engine one valve similar to a large safety-valve, with a piston body instead of wings, is employed as both main air-valve and exhaust-valve. The air, in passing into the cylinder, helps to keep this valve cool. The engine is of the internal vaporiser type, the vaporiser also forming the ignition tube, and being enclosed in a casing attached to an extension of the cylinder cover, which has cast in it a passage leading to the casing. This brings the combustion space from the back of the cylinder round to the side. The air supply passes round this casing on its way to the cylinder, through the double-purpose valve. The oil is injected into the bulbous end of the vaporiser by a rod working in an oil-box, and receiving a longer or shorter stroke controlled by the governor. The governor acts on a cam, which leaves a trip finger more or less time in contact with the rod it pushes. Referring to our engravings, *a* is the framing of the engine, and *b* is the power cylinder, which is provided with a water-jacket, *c*, in the usual manner; *d* is the combustion-chamber, which is connected to the cylinder, *b*, by a short neck or passage, *e*, and which is of much smaller diameter than the cylinder, and placed parallel thereto, as shown in Fig. 2; *f* is the jacket surrounding the combustion chamber, *g* the valve-box, and *h* the valve working therein, and serving both as an air-inlet valve and an exhaust valve, the space, *i*, above the valve communicating by the passage, i^1, seen at the bottom of the vaporiser, u^1, in Fig. 2, directly with the interior of the combustion chamber, *d*, whilst the space beneath the valve is in communication through the ports, *j*, *j*, and the pipe, *k*, with the jacket, *f*, and by the ports, *l*, *l*, with the atmosphere, according to the position of the valve, *h*; *m*, *m*, are holes in the jacket, *f*, for admitting air for the formation of the explosive charges. The valve, *h*—which, as shown in Fig. 3, is a mitre valve—is provided on its under side with a hollow cylindrical extension, which fits within the valve-box, *g*, and is provided with a series of circumferential apertures or openings, *n*, n^1, n^2, n^3, n^4, communicating with the ports, *j*, *j*, *l*, *l*.

During the compression and combustion stroke of the piston, the valve, *i*, is in the position shown in Fig. 4. When the exhaust stroke of the piston commences, the cam, p^2, lifts the valve, *h*, from its seat, and places the apertures, n^3, n^4, opposite to the ports, *l*, *l*, so that the gases from the cylinder, *b*, can pass under the valve, *h*, into its cylindrical extension, and thence escape through the apertures, n^3, n^4, and the ports, *l*, *l*, to the atmosphere. During the time that the ports, *l*, *l*, are open, the air inlet ports, *j*, *j*, are closed by the rings, *o*, o^1. On the completion of the exhaust stroke the lift, p^3, of the cam raises the valve still further, the ports, *l*, *l*, are closed, the apertures, n^1, n^2, brought opposite the ports, *j*, *j*, and on the outgoing stroke of the piston air is drawn through the holes, *m*, *m*, into the jacket, *f*, and thence through the pipe, *k*, and the ports, *j*, *j*, into the valve box, whence it passes into the cylinder, *b*, through the aperture, i^1. In Figs. 2 and 4 *u* is the vaporising chamber and igniter, which is arranged partly within the combustion chamber, *d*, and partly outside it, the part outside being provided with internal ribs, u^1, u^1, and being heated for starting the engine by the flame of a lamp. After the engine has been running for a short time the part of the chamber, *u*, within the combustion chamber, *d*, will, it is said, be sufficiently heated to serve as the igniter.

A shield is placed around the portion of the vaporising chamber and igniter, *u*, within the combustion chamber, *d*, but with an intervening annular space, for the purpose of preventing the air entering the combustion chamber from impinging against the walls of the chamber, *u*, and cooling it. The shield,

v, is placed at a slight distance from the chamber, u, in order to afford a space into which the gases can penetrate.

In Figs 4 and 6, w, w^1 are the barrel and plunger of the pump for injecting the oil into the vaporising chamber, u. This pump is constructed as shown in Fig. 4. In the end of the plunger is formed a passage, x, which terminates in a cross passage, x^1, shown clearly in Fig. 6. Around the barrel, w, of the pump is a chamber, y, and around a portion of the plunger of the pump is a space, y^1, which communicates with the chamber, y, through a passage, y^1, the space being kept constantly filled with oil under a slight pressure. When the plunger is full out, the cross passage, x^1, is in the space y^1, so that the oil can flow from the latter into the passage, x, and fill the space above the plunger. Immediately the upward movement of the plunger commences, the passage, x^1, is moved into the part of the pump barrel which the plunger fits, so that the return of oil through the passage, x^1, is prevented—the result being that the oil in front of the plunger is injected into the vaporiser, u. The engine is well mounted on a strong wrought-iron frame and four wheels, and is fitted with a water-cooler.

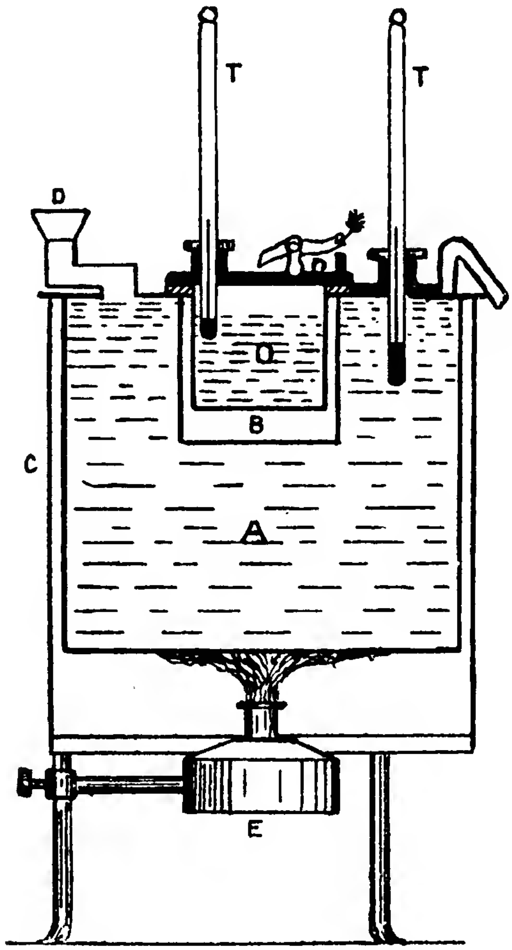
BY MOTOR-BUS AT MIDNIGHT.

EARLY on Sunday morning, the 20th ult., the Strand, the Embankment, and the adjoining thoroughfares were the scene of what may be correctly termed the first completely successful trial of one of the new electric omnibuses which are to be shortly placed on the streets of the metropolis by the London Electric Omnibus Company. The vehicle, which is constructed on Mr. Radcliffe Ward's system of electrical traction, left the Horse Guards' Avenue shortly after midnight. Travelling through Whitehall at the rate of between seven and eight miles an hour, it glided smoothly down Victoria Street on to the Embankment, where it attained a speed of eight and a half miles an hour. After running the whole length of the Embankment and up Whitehall into the Strand, a test of the capacities of the omnibus in climbing was made. The steep incline running up towards St. Martin's Lane past Trafalgar Square was mounted with ease. Throughout the whole run the motion caused was slight, and no throbbing or jolting was felt. As might have been expected, the bus was greeted in a not too kindly way by the cab-drivers about the streets.

ABEL'S FLASH-TEST APPARATUS.

UNDER the Petroleum Acts it is provided that oils sold for the purposes of illumination shall not have a flashing point of less than 73° F., which shall be determined by a special apparatus invented by Sir Frederic Abel for the purpose. A section of this bath and lamp is shown in the accompanying illustration, in which C is a copper bath, containing water A. This forms the water bath, within which there is an air chamber B, which carries a gun-metal oil cup D. This cup rests upon an ebonite ring, and over the air chamber B, and has a tight-fitting lid on which is fixed a gas-burner. The oil cup carries a thermometer T, and above the cover is fixed a slide, which is caused to uncover three holes. This gas-jet swivels on a lever, and, moving with the slide, carries a small flame, while the movement is so combined that, as the lever tilts, the flame is passed through one of the openings in the slide and reaches the top of the oil in the cup. The right hand thermometer T is intended to take the temperature, while the spirit lamp E supplies the necessary heat.

A pendulum 24 inches in length is employed in order to time the operations involved in the test of the flash. At the commencement of the experiment the temperature of the water in the bath is brought to exactly 130° F., while the oil is cooled to 60° F., and then poured carefully into the oil cup D. The lid is then put on, the rise of temperature being noted on the thermometer in the oil cup. When a temperature of 66° F. is reached, the testing is started by setting the pendulum in motion, and its operation is as follows:—The first three oscillations draws the slide slowly open, while the fourth closes it rapidly. At the same time the test flame is gently tilted through a hole in the slide to the space above the oil. This is repeated once for every increase of a temperature of 1° F., until the vapour of the oil ignites within the oil cup, giving a pale blue flash. The temperature of the oil at which this occurs is called the flashing point; *i.e.*, the flashing point is that temperature at which the oil gives off a sufficient vapour to be ignited by a



flame. As we have stated above, the lowest point legally allowed for petroleum intended for burning in lamps in this country is 73° F., or 22·8° C.

AT a meeting of the Belfast Corporation in committee recently, the Tramway Company's renewed offer to introduce electric traction on getting a seven years' extension of the present lease (of which ten are yet to run), was again considered, and the Corporation decided not to grant any extension of lease, but the Company would be allowed to introduce electricity and double their lines without any additional payment for the unexpired term.

CONTINENTAL NOTES.

Motor and Cycle Exhibition in Paris.

As briefly recorded in our last issue, the fourth "Salon du Cycle," or rather International Exhibition of Cycles and Motor-Carriages, opened on the 13th ult., at the Palais de l'Industrie in the Champs Elysées. It may be said, perhaps, that new features, new inventions, and new applications of mechanical conception were somewhat conspicuous by their absence this time, and there is truth in the comment of critical observers that the principal characteristic of the exhibition was the development and perfection of ideas already adopted. The show, however, was a good one of its kind, and certainly deserved the enormous interest which was taken in it by the ever-increasing crowd of devotees of the wheel.

With regard to the bicycle portion of the exhibition, it was noticeable that the prices of machines remain about the same as last, despite the announcement that there was to be a fall in them, brought about by competition. There appears to be a growing demand for bicyles of larger frames and higher development; the seat, it is remarked by the initiated in such matters, is placed more forward than in previous years, whilst the gear case, to protect the chain from mud and dust, is getting more and more popular. As for the motor-carriages, they presented a magnificent show at the Palais de l'Industrie—their number and variety would have been deemed really incredible.

Aluminium bicycles seem to be gaining a little in public favour, although opinions differ very much touching their advantages and usefulness. But they look bright and pretty, which with many persons is a consideration.

By far, however, the most striking part of this year's exhibition concerns automobilism. Among the automobiles on view that turned out by M. Léon Bollée was as much admired as any. These machines, which we have already illustrated, are two-seated and single-seated. That exhibited by M. Bollée under the name of "Voiturette" is pronounced by certain expert judges to embody the best idea at the present day in the horseless carriage line.

Those who followed the Paris-Marseilles race recollect very well how bravely these little machines held their way through all the stormy weather which had to be faced during that memorable race. The machine, light though it is, is no "fancy" one. In fact, its lightness is precisely, it is remarked, its power, and allows of a person going about town making calls at the rate of five miles an hour if desired, or taking a spin in the country at a brisk racing speed. M. Bollée's "Voiturette" has three wheels, and though but a trifle higher than an ordinary tricycle, two persons can be quite comfortably seated on it. It weighs about 300 lbs., and is best described as a cross between an automobile carriage and a motocycle. The back wheel alone is worked by the motor, the other two in front having the steering gear attached. The inventor holds that by this arrangement much stability is ensured for his machine on turning, stability being further guaranteed on the fact that the centre of gravity is very low.

Automobiles, such as the Dion et Boutin, were well to the fore, and there was a large display at the Palais de l'Industrie of automobile vehicles as delivery vans and carts, which are more and more used and approved by tradesmen and the commercial world.

In connection with horseless carriages, mention may be made of a new electric *coupé*, invented by M. Darracq. This *coupé*, hung upon *huit ressorts*, resembles from every point of view the fashionable *coupés* turned out by the best Parisian makers. There is a seat at the back for the engineer, so that those seated inside the carriage have an entirely free view. The motor is supplied with current from a conveniently situated battery of accumulators. The steering is managed by the front wheels, moved by a wheel at the engineer's seat. In the same manner the brake is applied. The *huit ressorts* and the inflated india-rubber tyres make the *coupé* run as smoothly as possible.

This vehicle, in the opinion of the inventor, is especially suitable for use in the crowded Paris streets. It is affirmed that this electric *coupé* can be steered with the greatest facility, and presents the advantage that on going down hill the movement of the wheels recharges the accumulators, the motor becoming a dynamo and acting as a recipient of power instead of a distributor.

With regard to the question of economy, it is claimed that the electric *coupé* for use in Paris realises a saving of 40 per cent. when compared with the use of a *coupé* drawn by a horse. This electric carriage was not at the Cycle Exhibition, but was inspected at the workshops of the inventor by a number of well-known amateurs of automobile carriages.

M. Dalifol showed a new vehicle propelled by a horizontal motor, as is the case with all the motor cycles and light vehicles, with the single exception of the Dion tricycles, and the gas mixture is exploded by electricity, a practice which is being employed to an increasingly large extent in the new motor vehicles. In fact, manufacturers and users can no longer ignore the fact that with the liability of the petroleum spirit to overflow from the reservoir or the carburator the use of the firing tube is attended with a certain danger, as is illustrated by the burning of at least three or four vehicles during the past three years, and of the total destruction of a goods delivery van from this cause in the streets of Paris a few weeks ago. With the improvements being made in the electric firing of the gas mixture, makers claim that the possibility of premature explosions has been overcome, and if this be true there is no reason why the firing tubes should continue to be employed. Moreover, electricity is almost a necessity in up-to-date vehicles, in which the engine can be started from the driver's seat, so that there will be no necessity for the machinery to run while the carriage is at a standstill. This is one of the principal improvements that will have to be made in all the new self-propelled carriages, and there is every promise that before long the work of starting the motor by turning a handle will be a thing of the past. But for this, electrical firing is indispensable.

A carriage possessing these advantages was shown for the first time by MM. Kellner et ses Fils, 125, Avenue Malakoff, and if the vehicle is all that is claimed by the makers, it is perfect of its kind. It is constructed for three persons, and is propelled by a two-cylinder horizontal motor of $3\frac{1}{2}$ horse-power. The gearing is accomplished by the aid of leather belting and wood pulleys. The forepart of the vehicle carries the water reservoir and the electric battery, and behind the cushions of the seat is the reservoir for the petroleum spirit. The driver pushes forward a starting lever which admits the gas mixture into the cylinders, the electrical communication is established, and it is claimed that the carriage starts without further trouble. The only thing to be regretted is that no opportunity is afforded of seeing the vehicle at work. A carriage that can be started with so much facility, and only requires the motor to work when running, must represent relative perfection in the construction of self-propelled vehicles if, as is claimed, there is an entire absence of vibration, and noise, and smell. Practical experience, however, can alone show whether these claims are justified.

The system of friction gearing employed by M. H. Tenting is not new, but it continues to hold its own among all the new methods of power transmission being brought out, as is proved by the fact that it has been adopted to a more or less extent by two or three other firms. The motor used is a two-cylinder one, placed nearly horizontally in the same plane and working on a common crank. The crank axle carries a large friction wheel, upon the periphery of which run two small friction cones held in position by springs so that they may be drawn away from the wheel or pressed upon it to graduate the friction. Between these cones is a loose friction wheel carrying the pinion for gearing on to the driving wheels. The loose wheel may be drawn backwards and forwards between the centre of the cones and their circumference to regulate the speed of running, or it may be drawn clear altogether to put the machinery out of gear. The pinion is geared on to the driving wheels by a system of cogs. The petroleum spirit is pumped into the cylinders where it is vaporised and exploded. By this means it is claimed that considerable economy is effected.

A new system of carriage propulsion was shown by M. Emile Mors, in which the motor is placed vertically, the two cylinders being inclined at angles of about 45°, and the crank shaft is geared on to the intermediate axle by leather belting. The special feature of this system is the electrical firing, which is

FIG. 1.

accomplished by means of a small dynamo driven by a friction wheel running on the fly-wheel.

Steam was represented in the carriage of MM. N. Nègre et Ruffin, and though the engine may be efficient enough to propel the vehicle it is doubtful whether the system is all that is required by buyers. A multitubular boiler is carried in the forepart of the carriage, and is heated by petroleum. The engine is called a rotary, from the fact that the four cylinders are placed at angles of 45°, and work on one crank. It is fitted just behind the boiler in front of the driver, and the whole mechanism is too much exposed and too prominent to give a satisfactory appearance to the vehicle. It was shown at work, and, in fact, was the only mechanism in the exhibition that did run, and the exhaust steam being visible was not calculated to convey a favourable impression to visitors. It is evident that steam is yet far from taking the place which it ought to occupy in the propulsion of road vehicles.

FIG. 2.

In the carriages of M. P. Cusset, of Levallois-Perret, the power of the single cylinder horizontal motor is increased by the employment of a compressing cylinder, in which a valve to admit the gas mixture is opened by the explosion in the motor cylinder, so that this latter is always full at the moment of the explosion. It is a very quick-running motor, and the gas mixture is exploded at each revolution.

The only electrical carriage in the show is that of M. Darracq, and propelled by a dynamo on the rear axle and fed by Fulmen accumulators, weighing about 400 kilos., that are stowed away in the front and rear of the vehicle. It is claimed that once charged these accumulators will drive the carriage 120 kiloms. The cost of these electrical carriages is, however, excessive.

One of the chief novelties was the petroleum fore-carriage constructed by M. Prétot, 42, Avenue Philippe-Auguste, and intended to be fitted to any type of carriage. It consists of a sort of bogie frame carrying all the mechanism comprising a two-cylinder horizontal motor of five horse-power, which works on an intermediate axle placed in front of the fore wheels, to which it is geared by a chain. It is claimed that by this means the mechanism has more of the hauling than propelling action, and that consequently the power is utilised with much better effect. The attachment to the carriage is extremely simple, consisting, as it does, merely of bolting the bogie to the fore axle and cutting two holes in the front part of the vehicle, one for the levers, and the other for the spindle which serves for steering.

The Société des Automobiles Peugeot, three of whose exhibits are illustrated on this page, for instance, showed a carriage propelled by their new horizontal motor, in which the gearing

FIG. 3.

is effected partly by friction cones and partly by leather belting, but it was impossible at the show to get any particulars about the details of the mechanism. One feature, however, worth notice is the use of an intermediate shaft carrying the driving chain, instead of coupling the crank shaft directly to the driving wheels themselves, as is the case with all the other chain-geared motor vehicles. The appearance of the carriage is thus much improved, and the gear is not so liable to be clogged with mud thrown up by the wheels. In this, as in nearly all the new motor-cars, a reversing gear is employed. To sum up the show, it may be said that much more attention has been given than hitherto to the body of the self-propelled carriages, especially with regard to the finish of the vehicles, though it would appear that their construction is still far from being sufficiently robust to withstand the strain that is put upon them by the motors; the motors employed are mostly of the horizontal type, geared with leather belting; electrical firing is coming moro and more into vogue; little or nothing has been done to prevent any overflow of petroleum spirit from the carburator or the reservoir; the burnt gases are usually sent into a chamber to expand before escaping into the air, but beyond this nothing practical seems to have been done in the way of suppressing the noise and vibration of the vehicles, at least to the extent represented by the makers themselves.

Notice of Forthcoming Meeting.

Tuesday, January 19th.—At the Royal Institution, Colquitt Street, Liverpool, "Mechanical Haulage on Common Roads," by W. Worby Beaumont, M.I.C.E., M.I.M.E.

Proposed Exhibition of Motor Vehicles in Liverpool.

At a Council meeting of the Self-Propelled Traffic Association (Liverpool Branch) the question of holding a parade or exhibition of motor vehicles was discussed at length. The general opinion seemed to be that there was no need to arrange for a display of light carriages since numerous other opportunities would arise, but it is within the bounds of possibility that a display may be organised for May 1st. Ultimately the following gentlemen were elected to form a sub-committee for the purpose of drawing up the regulations and conditions to govern a prize scheme and competition for motor-wagons suitable for heavy goods traffic:—Messrs. A. Bromley Holmes, M.I.C.E., Alfred Holt, M.I.C.E., Alfred L. Jones, J.P., A. G. Lyster, M.I.C.E., and Henry H. West, M.I.C.E., with Mr. E. Shrapnell Smith as honorary secretary.

"THE MOTOR-WAGON SCIENTIFICALLY CONSIDERED."

At the fourth ordinary meeting of the Liverpool Branch of the Self-Propelled Traffic Association, held at the Royal Institution, Liverpool, on the 5th inst., under the presidency of Mr. A. L. Jones, a lecture was delivered by Mr. G. F. Thompson, consulting engineer, Liverpool, the subject being:—"The Motor-Wagon Scientifically Considered." Amongst those present were Messrs. Alfred Holt, Maunsell C. Bannister, John A. Brodie, Everard R. Calthrop, A. Bromley Holmes, A. G. Lyster, Arthur Musker, G. F. Ransome, Henry H. West, John Wilson, Lawrence Jones, Chas. Burrell (of Thetford), and E. Shrapnell Smith.

The Chairman, in introducing the lecturer, said that he hoped they would that night see some practical use in the Association. (Hear, hear.) Most commercial men in Liverpool knew the extreme hardships Liverpool shipowners and shippers had to put up with from the railway companies. (Applause.) They had appealed to the railway companies time after time for some consideration, but they had never been able to get the slightest concession. They had heard a good deal about motor-cars, and that night they were to hear a paper from Mr. Thompson about what might be considered a good and useful convenient motor-wagon. What they wanted was a good and cheap means of carrying cargo from Liverpool to Manchester, or to any place within 20 or 30 miles from Manchester. He did not know what Mr. Thompson had to say, but he did know that it was possible for them to take cargo from Liverpool at one-third of the charge now made by the railway companies. In adopting any new system such as was now being brought forward they had this advantage, that they would not have that double or treble handling of cargo which was so damaging to fragile packages. Even if the railway companies carried cargo free, it would be better for the owners to send their goods by motor-wagons, because they would carry the cargo from the ship's side to the consumer. There was no difficulty in a car leaving Liverpool at night and getting to Manchester in the morning, and this was where a motor-car traction-engine would have a great advantage over the railway companies, besides which, this traffic would have a great tendency to increase the value of land within a certain distance on either side. All this would tend to put them in a better position to meet the continued and increasing competition of foreign countries, such as Germany. The Dock Board had shown every desire to maintain Liverpool as one of the first ports of the kingdom. (Hear, hear.) The Board had met them very fairly, and they had not much to complain of at present, but the railway companies absolutely would not move, so that if Liverpool was to go ahead, as he had no doubt it would—for he had no doubt that Liverpool would hold her own as a great port—but if the city was to go ahead Liverpool men must work in the interests of the port with a determination to bring about a better state of things (hear, hear) than existed at the present time. For his own part he was quite willing to give time or money to bring about that state of things. Motor-cars would use the highways, and, therefore, no land need be bought, and there would be no rails to lay or bridges to make. He was not quite sure that Liverpool was right—in fact he was inclined to think that Liverpool was wrong—in not taking in hand Mr. Alfred Holt's plateway scheme when it was put forward. (Applause.) There was no doubt that had Liverpool taken it up Manchester would have been saved a good deal of money (laughter), and Liverpool would have benefited greatly. But they were there to take things as they were, and under the present circumstances to do what they could for the best interests of the port. He had great pleasure in calling upon Mr. Thompson, who said:—

Mr. Chairman and Gentlemen,—The history of road locomotion, owing to its wealth of incident, forms, perhaps, one of the most interesting pages in the annals of industrial progress, and, from its first inception, mechanical locomotion appears to have had a peculiar fascination for ingenious minds, all sorts and conditions of men having endeavoured, more or less successfully, to make it a *fait accompli*. It will have been noted by all who have studied the history of the subject, that the annals record more failures than successes, which fact may be said to be the natural consequence of treading upon practically unknown ground, or of dealing with unsolved mechanical problems; but there is, I think, a further and more conclusive reason for so many failures in the past, and which a closer scrutiny of the history discloses, and it is that comparatively few of the inventors or designers in the past were engineers or men having any scientific or mechanical training, but were, on the contrary, as regards applied mechanics, merely enthusiastic amateurs, following vocations remote from engineering. All were, doubtless, skilled in their own professions or trades, but were unlikely to be equally proficient in the science of engineering. I do not, of course, suggest that there were no real successes in past years, as in point of fact there were many, and it will be found that with few exceptions the vehicles were the productions of engineers, and were designed upon more or less scientific principles, and that little or no experimenting was required to complete their success. In reviewing the past history of road locomotion, we are, of course, dealing with a period when the "rule o' thumb" was to a large extent the standard measure, and the value of theory and scientific principle was not appreciated to the extent that it is at the present time. The reason, therefore, as to why the endeavours of so many enthusiastic experimenters were frequently attended with failure is not far to seek, as they were all more or less guilty of one fault of omission which was, in almost every case, the cause of failure, that was, they approached their subject without due consideration of the scientific principles involved in the problem of mechanical locomotion; and, as the untrained mind is apt to err in almost every case where physical laws or scientific principles are concerned, many of those worthy men, in spite of their energy and persistence, met with repeated failures, but when occasionally something practical was evolved from the chaos of experiment, it was not so much due to consideration of the underlying principles, as to the mere avoidance of the errors which had contributed to previous failure.

It has been truly said, that we sometimes benefit more by our failures than by our successes. A peculiarity of the unscientific mind is, that it either ignores, or fails to appreciate, the unalterable character of the passive and active forces of nature, and frequently seeks, by elaborately devised contrivances, either to circumvent natural laws, or to defy physical forces. The unscientific mind usually sees in complication and elaboration, imaginary improvement in mechanism, and the solution of problems, which, on the other hand, the scientific mind knows to be impossible. The history of road locomotion teaches us that little of real practical value is evolved by blind experiment in the field of mechanism, but that, on the other hand, by building up a structure upon a sound scientific basis, success may be practically insured before the field of experiment is entered upon. Guided by this principle, let us study the problem of road locomotion upon a scientific basis, and to do so the fundamental principles to be observed in the design of mechanical apparatus generally must be considered; as to those, let us hear what one of the greatest mechanicians who ever lived said, more than a hundred years ago—I refer to James Watt, whom I will take the liberty of terming the "Shakespeare of Engineering," inasmuch as he formulated principles, evolved truths, and established axioms, which live to-day, as do the wise sayings of the "Bard of Avon." Perhaps the greatest axiom established by Watt was that "the supreme excellence in mechanism is simplicity," the scientific truth of this has been established by the test of experience, and its import is perhaps more fully appreciated to-day than at the time it was uttered. We might perhaps amplify what we may term "Watt's Law," by adding "and simplicity in mechanism is the secret of success." Any complication of apparatus or the employment of superfluous material merely entails expenditure of motive power to no useful purpose, but, on the other hand, creates undue friction, and energy is further wasted in the setting up and retarding useless momentum.

Correctness or soundness of principle is of first importance as a factor in successful engineering, but there is another point almost equally vital, and that is perfection of detail; doubtless many more failures could be traced to defective detail than to fault of principle.

The first principles, therefore, to be observed in the design of mechanical apparatus generally, and self-propelling vehicles in particular, are:—

1. Soundness of principle.
2. Simplicity of design.
3. Correct proportioning of material to power.
4. Perfection of detail.

And these may truly be said to be the elements of success. Before considering the design and construction of the vehicle it is necessary that we should investigate the elements of road locomotion, and the first matter, therefore, to which our attention must be directed is the consideration of the physical conditions involved in the rolling contact of wheels with various surfaces, and this is, after the question of propulsive power, the most important factor in the problem of successful mechanical traction. The conditions of surface presenting the greater difficulties to be overcome in mechanical or other traction are:—

1. Unevenness.
2. Yielding, or soft.
3. Inclined.

Taking these conditions in order we will first consider unevenness, this being, in more or less degree, the condition of all road surfaces. Unevenness, however small, comparatively, necessitates a continual lifting of the vehicle, whether drawn or self-propelling, and which lifting is not in any way assisted by the descent of the wheels into the hollows of the surface, except when travelling at a high rate of speed, then the slight momentum due to the descent of the wheel does in some measure assist its ascent up the following rise, but this is only the case when the unevenness consists of rounded hollows and mounds. When the unevenness is due to stones projecting above a fairly level surface, each one becomes a species of stop and, according to its size, acts with greater or less degree as a check to the progress of the wheel, and the effect of that check varies according to the diameter of the wheel and the point in its periphery which strikes the obstruction. The diagrams A and B illustrate this point. (Diagrams drawn upon a blackboard were here referred to.) In the case of A, the wheel is 30 inches diameter, and the obstruction equal in height to one-tenth the diameter of the wheel, or an angle of inclination of 18°, whereas in the case of B, with a wheel 45 inches diameter, or 50 per cent. larger than A, the height of the obstruction becomes now only one-fifteenth of the diameter, and the angle of inclination is reduced to 15°. Further, in the case of A, the effective leverage of tractive pull is only 80 per cent., whereas in the case of B it has increased to 86·7 per cent. This reasoning practically proves the case in favour of comparatively large wheels. If the obstruction becomes crushed or forced down into the road surface by the weight coming upon it, then the amount of lift of the wheel is proportionately reduced, but it does not follow that any power is saved, as power has been expended in depressing or crushing the obstruction.

Upon hard and fairly smooth surfaces, the tractive force necessary is always proportionate to the weight of the vehicle and its load, other factors such as friction and method of propulsion being equal. But by increasing the diameter of the wheels, the tractive force required is diminished, the rule being that the force is reduced as the diameter of the wheel is increased. It is said that within certain limits the tractive force required to draw or propel a vehicle of a given weight does not vary as the number of wheels, and theoretically it would appear reasonable, assuming that proportion of bearing surfaces and treads of tyres were correct. Traction upon soft or yielding surfaces increases as the width of the tread. On hard surfaces increase of width of tread makes little or no appreciable difference in the resistance, except perhaps by covering a larger number of irregularities to actually reduce the tractive force, unless the weight of the wheel has been increased by the widening of the tread, then the advantage of the greater width of tread is lost in the increased inertia and friction. When the surface is yielding and the wheels depress it, it becomes equivalent to ascending a continuous incline, and the resistance of such incline will vary according to the nature of the surface, and the depth to which the wheels sink into it. The power absorbed in the compression of a soft yielding surface or what is equivalent thereto, ascending an incline equal to the depth of the depression, is illustrated by diagrams C and D. C represents a wheel rolling upon an unyielding surface and requires a pull of only 25 lbs. to move it. D shows a wheel of similar diameter upon a yielding surface, and the depth of depression is equal to an angle of say 10°. To move this wheel now requires a pull of 136·1 lbs. In the calculation the extra friction due to increased pressure upon the axle bearing and the contact of the wheel rim with the sides of the rut formed by the depression of the road surface are not estimated, but it would be safe to add at least another two per cent. or 20 lbs., thus increasing the pull necessary to 156·1 lbs. But there is yet another factor which must not be omitted in estimating the tractive pull, that is, the loss of effective leverage, which is as the depth of depression to the radius of the wheel, owing to the fact that the line of pull is parallel with the normal surface and not with the angle of inclination.

Power Required for Self-propulsion as Compared with Traction.

It is a fact, now generally recognised, that in the case of self-propelling vehicles to do work equal to the average horse by mechanical means, requires from two to three mechanical horse-power, and the question is often raised as to the theoretical explanation of this apparent paradox. The reason is not far to seek. It is not because a horse under ordinary circumstances exerts a force greater than the mechanical unit, as, on the contrary, it is the fact that under normal conditions the animal exerts a force of only about 65 to 70 per cent. of the mechanical horse-power, and this fact would appear to emphasise the anomaly. But although the animal, in the ordinary way of working, only exerts a force of, say, two-thirds the mechanical unit, he can, on occasion, for periods of short duration, exert a force of as much as 10 mechanical horse-power, and which reserve power he brings into action when starting a vehicle or ascending a gradient; therefore a motor to do the same work as a horse must be of, say, three mechanical horse-power, if not more. But there is actually more power required to move a given load when the vehicle is self-propelling than when drawn by horse or other means, and the reason is, that in the one case the power is applied to the mass and the wheels are merely the rolling media supporting the weight, and the best possible mechanical effect is thereby attained; whereas, in the other case, when power is applied to the wheels in the form of turning effort, intermediate mechanism between power and load is brought into action, with a consequent loss of effect represented by the extra amount of friction set up. The wheels have now become levers, acting as between the ground and mass to be moved, and the force is now practically applied at the fulcrum or at a point between the periphery and the centre of rotation, and according as that point is brought nearer the centre of rotation, so must the force there applied increase to develop a certain power at the periphery, and the friction at the axle increases in like ratio. This resistance becomes more pronounced upon gradients and increases as the angle of inclination.

A natural deduction from the foregoing theory would be that to obtain the best effect all the wheels of a self-propelling vehicle should be driven; this would be theoretically correct, as there would then be no power expended in merely pushing forward idle wheels, but practically this is objectionable, inasmuch as any driving mechanism upon the steering wheels would interfere with their free movement and, further, would necessitate complication besides. There would be considerable difficulty in devising such compensating gear as would insure both leading and rear wheels doing equal work; we will, therefore, dismiss the point as being an unnecessary complication. We will now consider the question as to whether the leading or rear wheels should be the propelling wheels, and I may say that opinion is somewhat divided on this point, some makers having adopted the front-driving system, but the majority have decided in favour of the rear wheels being the drivers, which is undoubtedly the most practical method and, further, is theoretically the most correct system, as I think will readily be seen from the diagram shown. The first figure represents a front-driven vehicle ascending a gradient of 10 per cent. inclination, and it will be observed that the gravitation of the mass of the load tends to relieve the leading or driving wheels of about 10 per cent. of the weight borne when on the level and, at the same time, to increase the weight upon the rear, which in this case are the steering wheels; the objections to this arrangement are self-evident, and I do not think I need enlarge thereon. A rear-driven vehicle is represented upon a similar gradient, and it will be seen that in this case the gravitation of the mass tends to increase the weight on the driving wheels and, at the same time, to reduce the pressure upon the leading or steering wheels; this arrangement is both theoretically and practically correct for the following reasons:—First, the additional weight upon the driving wheels increases their adhesion but does not at same time increase the work to be done, as the actual weight of the mass, whether on level or on incline, always remains constant. Secondly, by relieving the leading wheels of a portion of the weight carried, they are thereby more free to rise and travel over the irregularities of the road surface which, when met with on an incline, tend to increase the resistance of that incline. There is also another point, and that is the leading wheels can, when comparatively lightly loaded, be the more readily and easily swivelled for steering purposes.

The next point to be considered is the construction of the vehicle and its weight in relation to the load carried. I might say that in railway practice in this country the weight of the vehicle in comparison with the load designed to carry generally exceeds the weights in vogue in the United States, where rolling stock for both passenger and goods traffic has certainly been brought to a higher degree of perfection than in any other country of the world. In this country the "tare" or dead weight of railway wagons averages 60 per cent. of the full load, whereas in America, where very large bogie-cars are employed for freight purposes, the weight of the vehicle seldom exceeds 40 per cent. of the load carried. This is much more rational when we consider the possibilities of scientific construction. Taking a modern bicycle as an example, we have in it a vehicle designed to carry from 100 to 200 lbs. and seldom weighing more than 20 per cent. of the load designed to carry. From actual tests made it was found that a bicycle frame of sound ordinary construction would sustain a weight equal to 10 men before showing signs of failure, thus proving that no vehicle, if scientifically designed and carefully constructed, need be more than 25 per cent. to 30 per cent. of the weight designed to carry, and, at that, to have a factor of safety of about 10. Of all systems of construction of framing for road or railway vehicles, the tubular is at once the most scientific, being the strongest for a given weight of material employed. The tube or cylinder being theoretically the form in which material can most resist not only compressive but also torsional and bending stresses. Where tensile strain is concerned, it is practically immaterial what the form may be, provided the sectional area is sufficient. The tubular system of construction for the framing of freight-cars has been employed for some time past in the States and has been adopted, to a small extent, in this country, but owing to the inherent conservatism of railway companies and wagon builders I am afraid it will be yet a considerable time before the system is more generally adopted in England.

With regard to vehicles for traffic on roads, the lighter the construction consistent with adequate strength the better, for two reasons:—(1) The lighter the vehicle the smaller will be the dead load; (2) A light framework possesses more elasticity or flexibility and its moment of inertia is less than one of rigid and heavy construction, and it is, therefore, less liable to injury from vibration due to unevenness of road surface.

Framing and Wheels.

This reasoning clearly emphasises the desirability of reasonably light and somewhat flexible framing for all vehicles intended for road traffic, as such are more subject to vibration and torsional strains than are vehicles running upon prepared tracks, and the design of such vehicles when self-propelling should be even more carefully considered than the construction of a locomotive for railway purposes, for the reason that the conditions under which it must work are more exacting, and its range of adaptability must be greater than that necessary in an engine intended to run on a prepared track. Reverting to the question of vibration, its effect can, of course, be practically nullified by interposing elastic media between the road surface and framing in one or another of two forms. First, in the form of springs, and, secondly, in the form of elastic treads to the wheels; but a still better effect is obtained by a judicious combination of the two forms. First, springs are better calculated to dissipate the effects of severe shocks than are elastic treads to the wheels, but, on the other hand, the elastic tyre possesses an attribute of which no other expedient is an equivalent, and that is in its keeping the inflexible rim of the wheel off the smaller inequalities of the surface, which are really the cause of jar or vibration, when the tyre is of metal, or any hard, non-elastic material. Regarding springs, it has been ascertained, by actual experiment, that with properly proportioned springs, the tractive force when travelling at moderate speeds over rough surfaces is thereby reduced to about half what it would be were no springs employed. As to the construction of wheels, there is only one perfect wheel suitable for light, or moderately heavy road vehicles, and that is the one built upon a truly scientific principle, the suspension system, which means, in other words, that the spokes are in tension instead of being in compression as in common wheels, and the knave or boss hangs as it were within the rim, instead of thrusting outwardly in all directions. This is the only system upon which a perfectly sound yet light wheel can be constructed, and when the spokes are arranged tangentially and interlaced it becomes a perfect driving wheel, inasmuch as the turning effort applied to the centre is communicated to the periphery by a practically direct pull, instead of by a bending strain upon the spokes as is the case in ordinary wheels having radial spokes in compression.

A wheel on the suspension system with pneumatic tyre is the scientific as well as the mechanical ideal, and, I might add, the commercial ideal, as I believe, made in a comprehensive and systematic manner as they are at the large manufactories in Coventry; wheels on this system can be produced at a cheaper rate than could wheels of equal strength on any other system. Many devices have been brought forward as equivalent of the pneumatic tyre for affording an elastic connection between the centre of the wheel and the part in contact with the road surface, but although successful as far as they go, they do not meet the case. Elasticity in a wheel is practically useless unless it be at the tread, as it is at that point where the shock is received, and if it be not at once absorbed by some elastic medium, it is, as a consequence, communicated to the whole of the rim and any other parts which are rigidly connected thereto, so that elasticity in the vicinity of the boss of the wheel in no way saves the rim from injurious shock, and is at best but a bad substitute for springs employed in the usual manner. Further, elasticity within a wheel in no way increases its adhesive or tractive power, and, considering the complication it entails in the construction of a wheel, it is, as a mechanical expedient, worse than useless. The great advantage and value of elasticity at the tread of a wheel is that it serves the double purpose, of first absorbing all jar due to rolling contact with an uneven surface, and, secondly, it intensifies the adhesion of the wheel to the road surface. Respecting wheels having plain unyielding treads, it has been found in practice that such wheels offer greater resistance to traction than when they have diagonal or transverse ribs or plates upon their peripheries; this is accounted for by the fact that many of the loose stones, &c., met with on road surfaces find their way into the spaces between the ribs, and consequently no power is expended in either forcing them into the surface or crushing them, as would be the case were the wheel rims plain.

STEERING.

The best method of steering self-propelling vehicles is undoubtedly that known as "Ackerman's system," which consists in swivelling the leading wheels independently instead of together, as is the case when a fore-carriage is employed. In Ackerman's system the leading axle is a fixture, and the wheels are mounted upon short pivots jointed to the ends of the fixed axle. These pivots have short levers attached to them at angles slightly out of square to which the steering handle is connected by suitable rods and levers. This system of steering possesses three distinct features of advantage. First, the body of the vehicle is supported at the sides, instead of at the centre—as is the case with a swivelling carriage—thus insuring greater stability. Secondly, the wheels being mounted on the ends of short levers instead of long levers, their movement is much easier, and they are further not affected to the same extent by unevenness of surface or obstructions, as when held at the ends of a long swivelling axle. The third advantage is that owing to the levers upon the wheel pivots being set out of square and their consequent movement through arcs of circles not coincident, there is a resulting variation of relative angle of the two wheels, and which, if the levers are set at the proper degree of inclination, insures each wheel being set approximately square to the radii of the circles of their paths. This is an important point, as if the wheels be parallel to one another there is a screwing or twisting of the wheel traversing the minor or inner curve.

THE ROD OF PROPULSION.

The most important element in successful road locomotion is adequate propulsive power, and from the data given it will be an easy matter to determine what power may be necessary to propel a given weight under various conditions; the next point, therefore, to consider is the system of propulsion. For freight purposes over long distances, there are, in my opinion, only two systems admissible, they are steam and oil, or explosion motor. Practical opinion is strongly in favour of steam, but I am inclined to the belief that in oil it has a very formidable rival, therefore, let us for a moment glance at the relative merits and drawbacks of steam and oil.

One great advantage which steam possesses is that it is generally understood, it is easily generated, and the materials necessary thereto can be obtained almost everywhere. But to enable this class of power to be held in reserve energy must be stored either in the form of pressure or of heat, and in any case the container must be necessarily strong and heavy. The latter form of storage is the more desirable as the element of danger created by the storage of pressure is not present in the storage of heat under proper conditions. A steam-engine can be readily started, stopped, and reversed, and its range of power and variation of speed are practically unlimited, and when duplex cylinders are employed, perfect balance may be insured. Regarding the oil or explosion-engine, its principal attribute is that only the motor and fuel are necessary for the development of power, there is no medium or third element required as in the case of steam or electricity. The heat-producing material is in a highly concentrated and portable form, is an article easily procurable, cheap and safe, when its flash point is above 80° F. The principal objections to the oil-engine are that it is not a self-starter and it has practically no flexibility in the matter of speed or power, and must be kept running even while the vehicle is stopped so as to be ready for re-starting. Further, its action is somewhat jerky, owing to the thrust-effort being only at intervals and always in the one direction; this is perhaps the most serious objection to the explosion-engine, but when it is considered that pulsation or vibration in a motor is only the evidence of unbalanced thrust-effort or the momentum of matter in motion, I think ingenuity should be able to cope with this element and so remove a stigma from an otherwise admirable apparatus.

Referring now to the more commercial aspect of the matter, the best and most economical working conditions would appear to be fulfilled by employing one motor freight-wagon drawing a simple freight-wagon. The weight limit fixed by the Local Government Board in this case being:—Motor and follower-wagon together, unladen, four tons, and speed limit, six miles per hour. To take full advantage of the weight limit the motor-wagon, together with engine and fuel, might weigh, say, 2¼ tons, and the follower-wagon, say, 1¾ tons. The motor-wagon might then be designed to carry from five to six tons and the follower a similar load; only one-half of the load would then be self-propelling, the other half would be drawn, and, therefore, moved under more economical conditions. The horse-power required for such vehicles and loads on the level would be about 17 mechanical units, but the motor should have a margin of power for starting the load and ascending gradients of, say, 50 per cent., that is, 8½ horse-power, which added to 17 makes the total power of the motor for such work, say, 25 effective horse-power. I say effective as meaning over and above the power necessary to overcome inertia and friction of engine and machinery. Every motor-wagon should have two men in charge, an engine-driver and stoker, and be the motor of very small power the same attendants would be necessary, whereas the same two men could manage equally well a motor-wagon drawing even 10 wagons after it, and little, if any, more work would be entailed than if it had no follower.

The only remaining matter of importance is the question of cost of working, and as that is as yet a matter of speculation and estimation rather than fact, I would prefer not to commit myself to any definite statement, but I am of opinion that upon fairly good roads, having no gradients above 10 per cent. inclination, with either steam or oil it might be readily possible to convey goods at a cost of 1⅛*d.* per ton per mile, and in arriving at this amount I have taken into consideration cost of fuel and engine sundries; wages for two attendants; interest on capital outlay; repairs, depreciation; insurance of motor and load, and rent of shedding for accommodation of motors when not in use. But I have not included cost of loading and unloading, and, further, I have based my calculations upon the assumption that the wagons be fully loaded; allowing for the light load contingency it might be advisable to increase our figures to 1¼*d.* or 1⅜*d.* per ton per mile.

In conclusion, I would say that the natural tendency of human inclination is to select the best, and the ultimate success of the mechanically-propelled vehicle is a question of the "survival of the fittest," and this is the underlying principle of all real progress, and he whose endeavours are directed towards the attainment of perfection, whether it be in mechanism or other useful art, will surely reap his reward in due season: but no endeavour in the direction of the attainment of supreme excellence in mechanism can be really profitable unless our efforts are guided by the light of science. (Loud applause.)

The Chairman, in commenting upon the lecturer's remarks, said he was gratified to find that Mr. Thompson's calculation as to cost of running exactly agreed with his own estimate, and with a guarantee as to cost actually given him by an eminent firm of traction-engine builders, and he thought that if goods could be carried, say, from Liverpool to Manchester, or similar distances, at the cost estimated, there was a good field for an economical motor-wagon.

A discussion followed, in which several gentlemen connected with shipping and engineering interests took part. After the lecturer replied to the several points raised during the discussion, the proceedings terminated with the usual votes of thanks.

THE BLOT ACCUMULATOR.

In common with all interested in the adoption of secondary batteries for use in traction work, we have long taken an interest in the system of Mr. G. R. Blot—as we have been acquainted for some time with the marvellously good results which Mr. Preece had obtained in the course of a series of elaborate experiments, carried out with the assistance of the Post Office experts. In addition to that testimony we had, too, the favourable opinions of some scores of Continental and English electricians, as well as the outcome of our own knowledge of the accumulator. We were therefore much pleased at the successful gathering which took place on Tuesday last at the Hotel Cecil, London, when, under the presidency of the Hon. R. R. Dobell, Mr. H. Tyrer Cheswright gave a lecture, illustrated with models and diagrams, on the principles and construction of the battery. The speaker said:—

The "Blot" Accumulator is of the "Planté," or pure lead type, containing no pasted oxide whatever; its construction is based upon the suspension of alternately corrugated and embossed ribbons wound round a "shuttle," such ribbons and shuttles varying in thickness in accordance with the electrical capacity and rate of charge and discharge required, and being fixed free to expand in an unoxidisable form.

Of these accumulators we have several samples before us—most of which are illustrated in this article—with which we propose to show very briefly the special features and advantages of the "Blot" system, by demonstrating to you the rapidity with which these accumulators can be practically charged for traction purposes, also for motor-car work, a subject which is now engrossing the attention of the entire world; and, secondly, by explaining to you the exceedingly simple and mechanical construction of the plates, the manner of their erection in cells, &c.

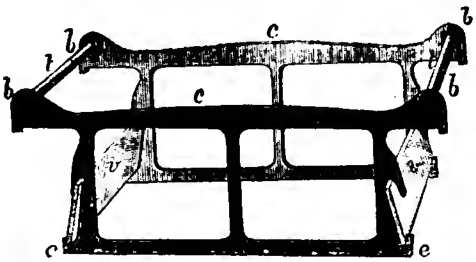
Whilst the "traction cell" is being charged in the short space of 15 minutes, if you will allow me I will call your special attention to the advantages referred to with regard to this system, which may be summed up as follows:—(1) Maximum electrical surface obtainable; (2) high rate of capacity and efficiency; (3) rapid charge and discharge; (4) immunity from buckling; (5) absolute and efficient conductivity between active material and the frame; (6) durability; (7) low cost of production.

With regard to the maximum electrical surface which is the largest obtainable, I think you will easily understand that this is arrived at by the fact of using alternately corrugated and embossed ribbons. This ingenious arrangement gives a great active surface with a small amount of lead (·333 m^2 per kg. of plate) as well as great porosity, due to the layers of ribbon being kept apart by the corrugation.

High rates of capacity and efficiency are attained and assured by the large and exceptional surface of active material exposed to the electrical action.

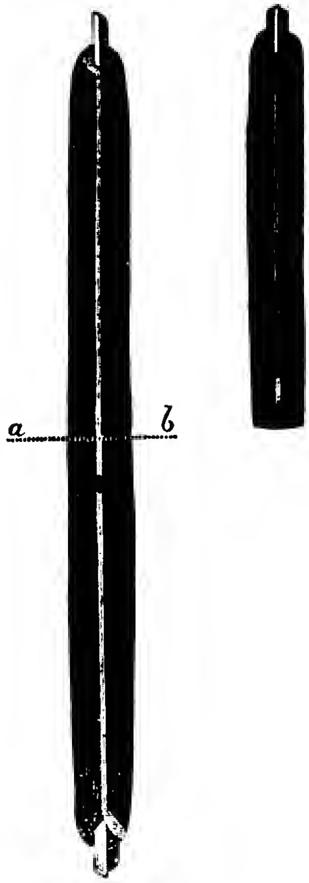
It is well known amongst electricians that the time required for charging and discharging an accumulator is in absolute proportion to its surface for a given weight, hence it has been the object of manufacturers to make the plates as *thin* as possible, but in the case of all oxide accumulators that have pasted plates it has been materially impossible to go beyond a certain point, as they otherwise disintegrated or fell to pieces, which limits for all practical purposes the rate of charge and discharge (as also their electrical capacity) to a very low regime. With the very largely increased surface of the "Blot" Accumulator this essential difficulty is entirely overcome, and in proof of which I would refer any gentleman to the curves on the wall, demonstrating both the electrical capacity and efficiency at high rates of charge and discharge; the charge varying from, say, one quarter of an hour, and discharge up to ten hours, which latter for ordinary stationary purposes is the usual rate. I would here mention that these accumulators have undergone, during the past two years, most severe and exhaustive tests by very competent authorities in France, Belgium, and this country. The extracts of some of the important reports will accompany the prospectus, which will shortly be issued to the public.

Swelling of the active material in accumulator plates has always been one of the greatest, if not the greatest, difficulty that has had to be contended with. With oxide plates it is produced by the difference of dilatation, the swelling of the active material and its consequent disintegration, the disintegrated parts, moreover, establishing but too often what is known as a "short circuit" (accidental contact between the two poles). I may mention that the oxide accumulators, notwithstanding these inherent defects, may be said hitherto to have taken precedence over the pure lead or Planté type, such as we are dealing with to-day, for the only reason that a pure lead plate has, up to now, never attained an equal electrical capacity, though known to be far more robust. With Mr. Blot's system we have even a much higher capacity than with any industrial oxide accumulator known, at the same time combining all the solid qualities and advantages peculiar to the Planté system (pure lead). Before leaving this question



1. Frame support for mounting plates in cell.

2. Complete plate; 4 shuttles.



6. Whole and half shuttle.

3. Complete plate; 8 shuttles.

7. Showing embossed and corrugated ribbon with loose ends.

4. Shuttles placed horizontally.

5. Shuttles placed vertically.

8. Complete cell in glass.

of buckling or swelling, I would like to explain how this inherent drawback is entirely obviated with the "Blot" plate. As already explained, the active material is composed of alternately corrugated and embossed ribbons, these ribbons being left entirely free at the base of the plate, allowing sufficient room for their extension and expansion vertically and horizontally. This is the only system where necessary expansion has been practically provided for, and this important point will be easily appreciated by all electricians, and particularly by those who have already had experience and paid for it.

The conductivity between frame and active material is a point which is of great importance. It is of no use being able to put a large quantity of electricity into an accumulator unless you can get it out again in a sufficient proportion. It will therefore be seen that the conducting surface of an accumulator plate must of necessity be proportionate to the electrical capacity of the active material. This is assured in the "Blot" Accumulator by the "shuttle" which forms the core of each coil of ribbon, such shuttle varying in thickness and consequent conductivity in accordance with the surface, size, and thickness of the ribbons themselves. The core of this shuttle is soldered electrically to the frame, thus connecting the active material with both, and ensuring a proper electrical contact of all the lead ribbons.

The rigorous tests which this accumulator have undergone have proved, beyond a doubt, their extraordinary durability, even at high rates of charge and discharge. Positive plates which have been in constant use during two years, and for which the current has been taken at the rate of 2½ ampères per pound, show no signs of deterioration. We have such a plate on the table before us, guaranteed to have been in use two years, and if we scratch the surface it will be seen that the surface only is attacked, the lead underneath having remained absolutely in its metallic state. With elements of such construction, moreover, it is possible, after a number of years' use, to reverse the polarity and use the plates to the last.

In conclusion, it may be stated that Mr. Preece, in his report, says:—"We have obtained 12·7 ampère hours per kilogram of plates. It acts under heavy rates, discharges in a superior manner, and it seems to be admirably adapted for traction purposes, as well as for electric lighting. The ampère-hour efficiency is 88 per cent., and the Watt-hour efficiency 76 per cent. at the normal rate of discharge." Mr. T. Parker, of Wolverhampton, a recognised authority, declares that the storage capacity of the "Blot" is the highest for its weight. It can be charged without injury in a very short time, and the energy is available at a great rate of discharge without damage. He adds:—"I have examined cells that had been in use for two and a half years; there was no buckling; the cell had given no trouble or loss by internal short-circuiting. There is positive prospect that their small depreciation, when working, will produce a new era in the use of accumulators."

The engravings which illustrate this article fully show the details of the construction of the battery and its finished appearance.

Liverpool Police and Automotors.

IN a report to the Watch Committee on motor-cars and light street locomotives, the Assistant Head Constable of Liverpool suggests that eight miles an hour should be fixed as the maximum speed, that there should be no restrictions on their use in streets along the docks, but that they should not be allowed to cross the city except during such hours of the night as the Committee might fix. With regard to the scheme which is on foot to establish a line of locomotives for traction on the road between Liverpool and Manchester, to which we referred in our last issue, the Assistant Head Constable understands that the present intention is to use three wagons with each locomotive; this traffic, therefore, would not be subject to the Act of last year, which only allows one wagon, but would be subject to the Acts 24 and 25, 28 and 29, and 41 and 42 Vict., under which the local authority has power to make regulations as to route and hours.

DOINGS OF PUBLIC COMPANIES.

Return of British Motor Syndicate Subscriptions.

WE understand that it is an unquestionable fact that some of the subscriptions to the British Motor Syndicate issue are being returned. Inquiries addressed to brokers show that in cases where sufficient pressure has been put upon the promoters, subscribers of £3 each for the shares have been able to obtain the return of their money.

SOME of the members of this Syndicate visited Coventry on Thursday last, and inspected some of the works there under the guidance of Mr. H. J. Lawson. Some speeches were made at a luncheon and informal meeting which took place later, but nothing of much importance with reference to the recent issue transpired. Many prophecies were made as to the profits to be gained in the future; threats were hurled at those concerned in rival patents; but no reference was made to dissatisfied applicants for allotments, and to the efforts which are being made to secure a return of the capital subscribed.

OUR contemporary, the *Pall Mall Gazette*—which took a prominent part in exposing the worthlessness of the master patents which were offered to the public—recently had the following note on the subject:—"We have little patience with those who were foolish enough to subscribe to the British Motor Syndicate issue; but still, the less trouble they have in getting their money back the more shall we be pleased. 'In a recent issue of your paper,' writes one of them to-day from the North, 'you stated that the Syndicate was, under pressure, returning the money to some of the allottees, and as I am an unfortunate victim, I should esteem it a great kindness if you would give me information as to how I might recover the money already paid to the Syndicate's bankers.' Such letters as these, of course, suggest the need of organisation. Communications we have received show that while some have obtained the return of their money, others are moving for it through their individual solicitors. Might we suggest that it would save much time, trouble, and expense if the subscribers acted collectively instead of individually? Perhaps one of the firms of solicitors or one of the shareholders who are acting would be willing to step forward with name and address, that a nucleus for joint action might be formed." We have also received innumerable letters on the same subject, and of much the same tenour; our advice has been of similar purport to that given by the *Pall Mall*, and we are very pleased to note that a combination of clients and solicitors has taken place.

New Issues.

STEEL WELDLESS FITTINGS FOR MOTOR-CARS, CYCLES, &c.

The Standard Weldless Tube and Cycle Components (Ltd.) (Chillingworth's Patents), is an important undertaking which has just been formed with a capital of £160,000, divided into £1 ordinary shares, for the purpose of purchasing the Standard Tube Company, of Birmingham, including all the freehold works, land, machinery, tools, &c., as well as additional machinery necessary to increase the output of weldless steel tubing up to 5,000,000 feet per annum, and to acquire Chillingworth's Patents, the adoption of which, it is claimed, will create a revolution in the manufacture of fittings for motor-cars, cycles, engines, &c. These fittings are stronger and lighter than those put together with the ordinary fittings now used. By Chillingworth's process sockets of all sizes and shapes can be forced outwards by pressure from the inside of tubing in a manner previously impracticable, thereby effecting a great saving in price, time, labour, and material, whilst in the production of weldless motor-car and cycle steel fittings the saving is even greater, whilst the fittings are absolutely reliable. Already a very large sale of these tubes has been effected in Germany, &c., and the Board of Directors, which is a very strong one, certainly appear to be fully justified in their anticipations of profits set forth in the prospectus which is now placed before the public. A practical demonstration was given on Wednesday last of these remarkable patents, and we notice that Mr. A. G. S. Manning (late engineer to the East and West India Dock Company), and Mr. F. R. B. Liebenrood, after inspecting the Chillingworth process, have agreed to join the Board on behalf of the vendors. A deserved feature is made of the fact that there are no preference, deferred, or founders' shares, and consequently the value and profit derived from the purchase and taking over of the property will accrue entirely to the ordinary shareholders from the first. Emphatically favourable reports upon the patents are given by Mr. Fletcher Moulton, Q.C., Mr. T. M. Goodeve, and Messrs. Brewer and Son, and any profits arising from the re-sale of the foreign patents, subsidiary companies, licenses to work, &c., will go to swell the profits for the ordinary shareholders. The directors propose setting aside £30,000 for working capital, and the services of Mr. Lewis, the present manager of the Standard Tube Works, have been secured for a period of five years. The offices of the Company are 7, Philpot Lane, E.C. Specimens of the fittings manufactured by this process can be seen at the Works, Wharf Street, Aston, Birmingham; 2, Cherry Street, Birmingham; 7, Philpot Lane, E.C.; and at 76, Queen Victoria Street, London, E.C. Subscriptions (2s. 6*d.* per share on application) will be received by Parr's Bank, Limited, 77, Lombard Street, E.C., and the Birmingham District and Counties Banking Company (Limited), Colmore Row, Birmingham, and their respective branches, where prospectuses can also be obtained.

New Companies Registered.

[Under this heading we intend in future giving a full list of any new Companies registered which take power to make, deal, or become interested in any manner in automotor vehicles. Where detailed particulars are not given under this heading we shall be pleased to reply to inquiries through the "Answers to Correspondents" column. All communications should be addressed to the Editor. The only stipulation which we make is that where the inquiry involves a search of the records at Somerset House—as in the case of information on the subject of the holdings of shareholders—a postal order must be enclosed to cover the Government stamp of one shilling which is charged before a search is allowed to be made.]

	Capital. £
Cycle Electric Lamp Co. (Limited), Manchester	30,000
Cycle Steel and Screw Co. (Limited), Birmingham	5,000
"D B" Spoke Co. (Limited), Warwick	5,000
E. and H. Hora (Limited)	25,000
Electrical Traffic Syndicate (Limited)	1,000
Garrison Cycle Co. (Limited), Heywood	10,000
Girling Cycle and Motor Car Co. (Limited), Brighton	20,000
Globe Venture Syndicate (Limited)	100,000
Goy and Co. (Withers and Chandler) (Limited)	35,000
Great Yarmouth and District Tramways (Limited)	1,000
Harris's Patent Record Gear (Limited)	120,000
Hobart, Bird, and Co. (Limited), Coventry	25,000
Joslins (Limited), Colchester	50,000
Marks' Hub Syndicate (Limited)	2,000
Millet's Patent Motor-Wheel Co. (Limited)	100,000
New Motive Power Syndicate (Limited)	15,000
New Traffic Syndicate (Limited)	12,000
Northway Cycle Co. (Limited)	5,000
Pedersen's Cycle Frame (Limited)	250,000

CORRESPONDENCE.

*** *We do not hold ourselves responsible for opinions expressed by our Correspondents.*

*** *The name and address of the writer (not necessarily for publication)* MUST *in all cases accompany letters intended for insertion, or containing queries.*

"AUTOMOTOR" AS A TITLE.

To the Editor of THE AUTOMOTOR AND HORSELESS VEHICLE JOURNAL.

DEAR SIR,—It is with much pleasure I see we now have a journal devoted entirely to horseless vehicular traffic, and one which I sincerely hope will make a point of disseminating information in regard to the subject in a totally unbiassed manner.

Please forgive me for taking exception to the title you have chosen. In the first place, it sounds very much like the name of an existing paper if the syllable be read backwards; and secondly, the word "Automotor," to my mind, conveys nothing in connection with either vehicles or locomotion, seeing that a stationary steam-engine, for example, might be accurately classed as an "automotor." I would, therefore, suggest that, before it is too late, you should strike out this unnecessary word from your pronoun, and let it be simply THE HORSELESS VEHICLE JOURNAL.—Faithfully yours, ALFD. R. SENNETT.

Putney, *Dec. 10th.*

PNEUMATIC TYRES.

To the Editor of THE AUTOMOTOR AND HORSELESS VEHICLE JOURNAL.

DEAR SIR,—When reading your journal for December I was much interested in an article *re* "Pneumatic Tyres," and the practical remarks therein stated by Professor H. S. Hele-Shaw. His views seem to be on the same line of thought as mine. A theory which I have for the easy running of the pneumatic tyre is that, when the wheel with its load is being driven or drawn on the ground, the tyre is depressed at the point of contact with the ground (slightly forward of the centre of the wheel), which causes the air to rush round the wheel until it comes to the point of contact at the other side of the wheel or tyre, and the air being under compression, it has a tendency to give the wheel a lift: thus the weight is helping the wheel forward; for you will see from the above description that the centre of the axle has a tendency to be forward of the centre of the periphery.

This principle is demonstrated in a spring wheel, which you will see on a prospectus that I enclose. You will see from this that when the wheel is pushed or drawn the springs give way, letting the axle take a forward position as to the periphery of the wheel: thus the weight is again helping the machine forward. These wheels run with remarkable ease, going over obstacles with great facility. It is through noticing the above facts that I have taken out a patent for an improved wheel, which I consider will supersede two previous ones. I form a hubless wheel, and by suitable arrangements I secure a smaller wheel within the hubless wheel. By this arrangement I come to the rolling principle which the Professor speaks of. When the wheel meets an obstruction it simply rolls over it without being jerked over. By my principle you will see that I get a forward centre when the wheel is driven forward which helps the machine along, and a backward centre when the power is reversed, thus acting as a brake. This wheel is applicable to any kind of vehicle, and can have any kind of tyre on either of the wheels. The wheel really goes over a brick with as easy a motion as a boat over a wave, and really easier than a pneumatic tyre. That is what all riders say who have ridden it.—I am, &c.,

W. P. W. Weatherill.

33, Beech Street, Manchester.

MOTOR VEHICLES FOR SEVENOAKS.

To the Editor of The Automotor and Horseless Vehicle Journal.

Sir,—That charmingly-situated, health-giving town on an eminence, with its (roughly speaking) 23 miles of exceptionally well-kept roads has very poor communication, so far as locomotion upon them is concerned, for its 8,300 inhabitants, let alone for visitors by rail to the pleasant town, or for those who come to see one of the finest old residences in England. I knew Sevenoaks when the population was much less, but was served a great deal better, the London, Chatham, and Dover Railway Company connecting their station and the town with a two-horse omnibus. We also had a good service of trains connecting the two railway stations for the charge of 1*d*. per passenger. The line is still there, but the train service has been allowed to cease, and in its place we have the Company's 'bus, which only makes four journeys each way for the charge of 6*d*., which is far too high for the middle class. No doubt the great cost attendant upon keeping horses deterred anyone from placing omnibuses on our roads, but now the new Act, which came into operation at the end of 1896, finds the means to overcome that difficulty. I trust we shall soon see some enterprising gentleman form a "Sevenoaks Motor Syndicate," and commence by placing two "electrical" cars on the two principal roads, both to start early in the morning from the Royal Oak Hotel. "A" car to proceed down the London Road to the South Eastern Railway Station, thence to the London, Chatham, and Dover Station, and up St. John's Hill through High Street to the Royal Oak Hotel. "B" car should proceed through the High Street down St. John's Hill to the London, Chatham, and Dover Railway, thence to the South Eastern Railway, and back to the Royal Oak Hotel by the London Road. I would suggest that the journeys be made continuous throughout the day, thus affording good communication to the inhabitants as well as to railway passengers. Those who take this matter up, if it is well managed, popular fares being charged, and quarterly or yearly tickets issued at moderate rates, will not only reap a good profit from their undertaking, but will confer a boon upon visitors and the inhabitants generally, and will also materially enhance the welfare of the town of Sevenoaks.

Albert Bath.

MASTER PATENTS.

To the Editor of The Automotor and Horseless Vehicle Journal.

Sir,—In a letter on the subject of the patents owned by the British Motor Syndicate published in one of your contemporaries recently, Mr. Walter Rowbotham writes:—"Now, it is possible to vaporise them" (heavy hydrocarbons) "by a body in the cylinder heated by means of electricity, and thus the danger of fire or of flame blowing out is obviated, and the engine is ready for starting in a few seconds. I ask you if you do not consider this a master patent, and if you do not think there is as much distinction between this method of vaporising and that of using an outside flame, as between the Otto and the other makes of gas-engine?"

Mr. Rowbotham does not state to what particular patent he refers, but it is certain that the British Motor Syndicate owns no master patent for the method of vaporising hydrocarbons which he describes. The method of vaporising heavy hydrocarbons by means of an electric heating resistance, so that the resulting vapour may be ignited and burned, was published in several technical journals about 10 or 11 years ago (I have not my references by me as I write, and so cannot give exact dates), and was patented about 11 or 12 years ago. It does not follow, however, because the Syndicate referred to does not own a master patent for this method, that it does not own valuable subsidiary patents. That may, or may not, be the case.

J. G. Lorrain.

LIGHT *v.* HEAVY OILS AS EXPLOSIVES.

To the Editor of The Automotor and Horseless Vehicle Journal.

Sir,—I have noticed in several papers paragraphs about motor-cars firing themselves. I should like to point out that this arises from the fact that the said cars derive their motive power from the use of the light hydrocarbons, such as benzine, petrol, or naphtha, which vaporise at a very low temperature and ignite on the appearance of a light. If a heavy hydrocarbon were used this would not take place, as that grade oil needs considerable heat to effect its vaporisation, and is nothing like so inflammable as the lighter one. But for this very reason, and also on account of the smell and smoke given off from the heavy grade, these dangerous hydrocarbons are preferred.

Now, by the letters lately appearing in so many papers, people are led to believe that, the Otto cycle patent having expired, there are no patents of value to be obtained for motor-car engines, thus implying that the said engines are practically perfect. If this is so, why do not makers produce their cars free from the need of water, free from vibration, free from smell, and, last but not least, free from the danger of firing? That they have not done so is clearly evidenced by the occurrences of a few days ago, which, I expect, will be pretty frequent while people use these dangerous light oils.

I should like to inform you that the heavy grade oils can be used, and there are patented methods of vaporising them without using any outside heat, the vaporisation being effected in the interior of the cylinder without the aid of flame. There are also patents for anti-vibration, for practically avoiding smell and vapour, when a heavy grade oil is used, and for dispensing with water for cooling purposes, though, as you state in your issue of the 16th inst., these are not in the possession of the British Motor Syndicate.

A motor-car built on the lines I have indicated would be comfortable and quite safe, and so would rapidly become popular.—Yours faithfully, Walter Rowbotham.

27, Vittoria Street, Birmingham, *Dec. 31st.*

SELF-PROPELLING TRAFFIC.

To the Editor of The Automotor and Horseless Vehicle Journal.

Dear Sir,—I have watched with the deepest interest the turn matters have taken in regard to this important subject, which, if properly handled, may be made at no remote date to constitute an industry of great magnitude and of national importance. Those who have not especially studied it appear to be under the erroneous impression—possibly from the fact of the newest form of motor-vehicle having been introduced from the Continent—that the subject is new to our country. This, however, is far from being the fact, for at one time we led in this branch, and indeed at the commencement of this century we in England were quite as far advanced, at least in regard to the heavier type of self-propelling vehicle, as are our Continental friends to-day.

In 1831 steam stage-coaches were running regularly, punctually, and satisfactorily between the towns of Cheltenham and Gloucester, giving great satisfaction to passengers, and conveying them at a cheaper rate than the horse-drawn stage-coaches of the time. In 1846 steam stage-coaches were running every hour between St. George's Square, Glasgow, and Paisley; these being so well patronised that they were almost always overcrowded, and had to be supplemented by a kind of trailing dog-cart, conveying six persons in addition to the 20 passengers—sometimes, it is averred, overcrowded up to 40—carried on the coach. Further developments in both cases were put a stop to by the antagonistic and short-sighted policy pursued by the road trustees, who caused ridges of stones 18 inches in depth to be placed across the roads for the purpose of impeding the progress of the mechanically-propelled coaches to such an extent indeed as to render the roads impassable to horse-drawn traffic, the latter being compelled to make a detour during the prevalence of this unpatriotic and un-English mode of opposition. Sufficient time, however, had been given to unequivocally demonstrate the unqualified success of the innovation, with the result that owners of landed estates, farmers, and others interested in horse-flesh began to take alarm at the probable effect developments in that mode of terrestrial travel and transport might have upon their individual interests, and they in turn began to offer the greatest possible opposition in their power. This opposition unhappily was rendered but too effectual through their obtaining the passing of most iniquitous highway bills, by which mechanically-propelled vehicles were taxed so highly in their running on turnpike roads as to render their earnings unremunerative; such tolls, indeed, amounting in some instances to as many pounds for steam-carriages as shillings were charged for horse-drawn vehicles.

The effect of all this was to nip in the bud, so far as rural highways were concerned, the industry which we to-day are re-inaugurating. In towns the onerous restrictions weighed less heavily, and in 1832 we had in London a line of steam omnibuses plying regularly and satisfactorily between Paddington and the Bank, whereby it was proved that—even with the comparatively primitive steam-engine then available—an expenditure of but 14 lbs. of coke per mile was all that was necessary to propel an omnibus containing some 20 passengers, and weighing some 2½ to 3 tons, notwithstanding the fact that Pentonville Hill had to be negotiated on each journey.

About this time occurred the historical event known as the "railway mania," this having the effect of completely diverting public attention from this mode of locomotion to that by means of locomotives on smooth rails. Sufficient, however, has been done to demonstrate great economical and other advantages to be inherent to horseless road locomotion. Nothing more of public importance could be done during the existence of the legislative restrictions, and it is indeed remarkable to trace what an immense amount of work and individual experimenting has been done in our own country since that time by engineers and inventors, who knew that their efforts could not result in any public benefit unless the then existing laws were altered.

Horseless road locomotion was therefore exiled from our shores and, driven from their native land, more than one of our English-built self-propelling carriages—half a century since—sought asylum in foreign lands. One emigrated to the "States," another made peregrinations in Brussels, whilst another disported itself upon the boulevards of Paris, the patent for which, indeed, was purchased by a French Company for no less a sum than £16,000, quite a refreshing fact to contemplate in these days of the wholesale purchase of foreign patents.

Happily, to-day our highways are once again thrown open to self-propelling traffic, but, unfortunately, during the "close time" an entirely new profession has sprung up—that of the Company promoter—and in this case it has suited the pockets and convenience of these gentlemen to induce the public to believe that not only were the vehicles themselves exiled from our country, but with them went all the engineering talent, ability, perseverance, energy, and invention of which it would appear we have been foolish enough to assume our own country may have reason to be proud. Now we are invited by heads of this novel profession to pay very large sums of money for patents (*sic*) relating to what they are pleased to call "motor-cars"—vehicles which do not in any way appeal to English tastes or play their *rôle* in anything like a satisfactory manner, being, indeed, entirely devoid of that degree of luxury which has come to be identified with the productions of the British carriage manufacturer.

Upon the Continent—due in a large measure to the establishment of a large and influential "Automobile Club"—the subject of horseless road locomotion has been viewed more or less from the point of view of sport, and the attention of the French engineer and carriage-builder has been directed almost exclusively to the production of light self-propelling road vehicles, possessing the sole merit of being able to travel at a high rate of speed, such, as—very properly—is not permitted in our own country.

In Great Britain, unfortunately, we have been very slow to appreciate the advantages of good roads and proper travelling equipages. Long after the art of coach building had in other countries attained to a considerable degree of perfection, we were still travelling by saddle, transporting by pack-mule, and wading shoulder-deep in almost impassable highways. Both roads and vehicles have been steadily improved since the day when Walter Rippon constructed the first coach in this country—the one built for Queen "Bess"—until to-day we possess a system of highways extending to no less than 140,000 miles, excellently constructed and efficiently maintained, as well as equipages of all kinds, which reflect the greatest credit upon the coach-builder, and a breed of horses of which our country may be justly proud. In the face of this, and the fact that we are a horse-loving race, I think no good case has been made out for their substitution by the so-called "motor-car," or light self-propelling horseless carriage; therefore our Continental friends, confining themselves as they have to this class of traffic, have not advanced matters for us in the least degree, except in the notable instance of the Serpollet inexplosible steam generator and its application to mechanically-propelled road vehicles, in connection with which M. Serpollet's energy and ability in surmounting a difficulty once inherent to the employment of steam, and his recent very successful adaptation of liquid fuel, is worthy of the highest commendation.

There is, however, a side to the horseless road-locomotion movement which should be fraught with the greatest advantage to our country, and that is the mechanical road-transport of goods and the public conveyance of passengers. Occupying the first position in this relation undoubtedly is the adaptation of mechanical road transport to the exigencies of modern agriculture, then to passenger transport by means of omnibuses—with the horse-drawn prototype of which our streets have now become so inconveniently over-crowded—and lastly, but of vast importance, the delivery of all kinds of goods, not only by forwarding agents, but by all classes of our tradesmen. For such work, with the exception of the very lightest type of trade delivery cart, there can be no shadow of doubt that the most suitable motive power we possess to-day is steam, and after that, for urban service, electricity. In regard to these, the engineers of this country certainly require no extraneous assistance, either from the Continent or elsewhere, and my great wish in craving space in your columns is to draw public attention to this fact. With regard to petroleum motors, undoubtedly there is a vast field in store for these in connection with the lighter types of vehicle so soon as they shall have sufficiently developed as to become apposite for fulfilling the conditions required of them in this relation, and in regard to which English engineers, now that there are excellent prospects of an ample return for their labours, are now making steady progress.

We have in our own country engineering works of vast extent, most perfect organisation, and successful working, as the high class of the products turned out serve to show. We have also carriage-builders of eminence who can hold their own against foreign competitors. All that is wanted is the friendly co-operation and the taking of energetic measures on the part of English engineers and coach-builders, to bring about the much-desired change in our modes of road locomotion of the heavier or mercantile type. In my position as Hon. Executive Commissioner of the International Carriage Exhibition recently held at the Crystal Palace, I had the great advantage of conversations with each type of manufacturer, and I saw the paramount necessity for this co-operation, and I further ventured to suggest a scheme by which it could be fulfilled, and which has been received in a very gratifying manner by those interested. It is that neither carriage-builders nor engineers should construct self-propelling vehicles outright, for neither are fitted for such work, but that the vehicles should be designed in such a manner that the portions properly appertaining to each class of manufacturer should be kept distinct. This is quite a simple matter if the vehicles be designed on common-sense principles, namely, if the body be kept quite distinct from the under-frame, as in the construction of railway coaches. This being done there is nothing to prevent our engineers from making their under-frames complete with their motors in large quantities, turned out to gauge and template, with the maximum of economy, whilst, on the other hand, our carriage-builders would have nothing new to trouble themselves with, but would be kept busy in utilising their great experience in the construction of bodies, comprising elegance, comfort, and high quality of workmanship and finish. In this relation it is really amusing to contrast even the latest Continental production with the earliest of our own. Take for example the steam stage-coaches, referred to as having run between Glasgow and Paisley, and which were designed by the eminent engineer, Scott Russell, who built the "Great Eastern" steamship. These carriages were most elaborately fitted up and decorated, carried 20 passengers, had the body quite distinct from the under-frames, and were slung on elastic and highly efficient C springs. In the modern Continental petroleum-carriage, which has been brought to us with such a vociferous flourish of trumpets by the Company promoter, all these common-sense arrangements have been forgotten with the result that it is the most uncomfortable of vehicles, its vibration is almost intolerable, its noise most aggravating, and its odoriferous exhalations most offensive; for these great advantages (*sic*) the British public are paying vast sums of money.

Allow me to make the following suggestion, which, if acted upon, I feel confident would have a most beneficial effect, not only in expediting the introduction of a more efficient and more economical mode of common road locomotion, but also upon the engineering, carriage manufacturing, and cognate industries of our country, namely, that an "Association," for the purpose of assisting in the development and exploitation of self-propelling vehicles of British design and workmanship, should be formed; the work of such Association to consist principally in the getting out of designs in fulfilment of the undoubtedly existing requirements of the Agriculturist, the Carrier, the Tradesman, the Cabman, the Omnibus proprietor, &c., &c.

Manufacturing engineers, coach-builders, and allied trades would, of course, participate in such an association, the machinery and mechanical arrangements of such vehicles being constructed by existing British engineering firms, whilst the bodies and general coach-building would be carried out in the manufactories of British coach-builders, or, as the President of the British Institute of Carriage Manufacturers recently and wittily put it—the coach-builders would furnish elegant bodies, and the engineers motor souls. The Association should be possessed of a suitable staff and show-rooms for the permanent exhibition of British-built vehicles, as a set-off against what would soon be seen to be the second-rate productions of foreign design, and manufacturers would be spared the great expense and labour of getting out and pushing their own designs, whilst undue competition would be avoided.

It is scarcely necessary to point out—for this has already been done by experts in the columns of many newspapers—that the claim set up by a certain Company, or Companies, as to the holding of *master* patents, cannot for one moment be maintained. It is not necessary to hold a master patent or, indeed, any kind of patent, for the purpose of building self-propelling vehicles of all kinds; but during development undoubtedly such novel devices and expedients would be evolved as would constitute subject matter for Her Majesty's patent, and thus a Company commencing to-day, without the payment of a single penny for patents, would find itself in a year or so in quite as strong a position in this regard as those having paid many thousands of pounds for patents, which, as an eminent authority has pointed out, are practically valueless.

Permit me to say that I have discussed this scheme with the leading members of both the carriage-building and engineering trades, and, further, that I am in a position to state that the operation of such a concern could be carried on under the supervision and advice of the most eminent authorities representative of both industries, and strangely enough it could begin its operations with a bundle of orders from its very inception. Were such an arrangement carried out, I am convinced it would be to the great advantage of the engineering and carriage-building industries of this country, whilst the consumer would be most materially benefited, for how could Companies, whose shareholders have spent, or wasted, vast sums of money in the purchase of patents, possibly compete with existing firms already in a high degree of organisation, and who would not have to set apart any percentage whatever for money thus sunken?

With apologies for the length of my letter.

Faithfully yours,

Alfred R. Sennett, A.M.I.C.E.,
M.I.M.E., M.I.E.E.

Institution of Civil Engineers,
Westminster, S.W. *Dec. 8th*, 1896.

A RUN IN A PEUGEOT CARRIAGE.

To the Editor of The Automotor and Horseless Vehicle Journal.

Sir,—It may interest you to know that I made a satisfactory journey in my Peugeot carriage just before Christmas, from London to my home, four miles beyond Monmouth.

Perhaps a rough description of the vehicle, a photograph of which appeared in your December issue, would not be out of place. It was built by "La Société Anonyme des Automobiles Peugeot," of Paris, and is of the phaeton type, to seat four, all facing forward; it is fitted with a detachable canopy, which has leather blinds to unroll at the sides when necessary, and a glass window in front; the wheels are built on cycle lines, with steel tensional spokes, solid rubber tyres, and ball bearings The motor is an inverted Daimler, developing 3¾ horse-power. The carriage is geared for four speeds forward and one backwards. The fuel is of course the usual rectified petroleum or petrol, and is stored in a main tank containing sufficient for a run of 90 or 100 miles; from this tank it is fed automatically into a Phénix float-feed carburettor, where the petrol is vaporised and mixed with air, ready to do its work behind the pistons when ignited by the usual platinum ignition tubes. The cooling water is circulated by means of a rotary pump. The steering is actuated by a handle-bar, and is so arranged that each wheel turns on its own pivot, and the angle of turning of each is differential. The back wheels are of course also able to run each at its own speed by means of compensating gear.

To return to the journey alluded to above, we (friend, self, and luggage) left London (Knightsbridge) at 6.45 a.m., on Tuesday, 22nd ult., in darkness and fog, owing to which we had to proceed rather slowly for some distance, but after we got out in the country we found the ground hard with frost for 20 miles or so which was favourable. The route taken was as follows:—Hounslow, Staines, Egham, Virginia Water, Reading, Newbury, Hungerford, Swindon.

Owing to taking wrong routes and losing our way we did not arrive at Purton, five miles beyond Swindon (that night's destination), till 8.30 p.m. The distance from London to Purton by the correct route is about 81 miles, but we must have covered considerably over that distance.

The next day we were delayed by the non-arrival of our petrol supply, and, after waiting until 2.30 p.m., had to leave with a supply of common benzoline. Passing through Cirencester, we descended Birdlip Hill (Cotswold) in grand style. It is very steep and treacherous, nearly two miles in length, with several sharp curves, renowned for fatal accidents. Stopping that night at Gloucester, we proceeded the next afternoon leisurely on to Ross, but we repented our late start, as it became very dark and rained heavily, and we got some miles out of our way through being wrongly directed.

Owing to these facts, and difficulties in getting oil, we did not leave Ross until 9 p.m., and passed through Monmouth, arriving home (four miles beyond) about midnight.

Nothing of any importance occurred to the mechanism during the journey, with the exception of the pump ceasing to act two or three times near the end, due to mud. Some very steep hills were ascended with ease.

Had it not been for the long delay at Purton we should doubtless have had no difficulty in doing the journey comfortably in two days, as we had intended, although we had very bad roads and weather all the third day.

I have now done between 600 and 700 miles in this carriage, including the journey between London and Cambridge four times (two of which were done before November 14th).

I think this speaks well for the car.—Yours truly,

C. S. ROLLS, Mem. S.P.T.A.

South Lodge, Rutland Gate, S.W.

LONDON ELECTRICAL CAB COMPANY.

To the Editor of THE AUTOMOTOR AND HORSELESS VEHICLE JOURNAL.

SIR,—We shareholders have just received notice that 10*s.* per share (£1 shares) of the above Company is due on Monday next.

So far, we have not heard of any "trial trips" of these cabs! Can you explain why all the capital is called up before one cab is placed for hire on the streets? What has become of half our capital! Is it not sufficient to complete one cab?

Myself and other shareholders will be much obliged for any information or advice you can give us *re* this Company.—Yours faithfully,

SHAREHOLDER A.

January 14th.

NEW INVENTIONS.

Compiled for "THE AUTOMOTOR AND HORSELESS VEHICLE JOURNAL" by HERBERT HADDAN and Co., Registered Patent Agents, of 18, Buckingham Street, Strand, W.C., London.

Patents Applied For.

27,354. December 1st, 1896. E. W. BONSON. An improved electrical switch for power or traction purposes.

27,368. December 2nd, 1896. R. WADSWORTH. Motor or self-propelled road or street sweeping, scraping, sanding, and watering machines, watering vans, and carts.

27,373. December 2nd, 1896. A. J. WESTLAKE. Improvements in motor cycles and vehicles.

27,381. December 2nd, 1896. A. H. ALLEN. A new or improved motive power for horseless carriages.

27,423. December 2nd, 1896. W. W. CURTIES. A variable speed and reversing contrivance for motor-driven vehicles.

27,538. December 3rd, 1896. H. C. CAPEL and T. CLARKSON. Improvements in or relating to motor-carriages.

27,591. December 3rd, 1896. T. W. NAYLER. Improvements relating to gearing for motor-propelled vehicles.

27,603. December 4th, 1896. H. C. L. HOLDEN. Improvements in the construction of internal combustion engines in combination with cycles or carriages.

27,696. December 4th, 1896. F. L. MUIRHEAD, 124, Chancery Lane, London. Improvements relating to electrically-propelled vehicles.

27,714. December 5th, 1896. H. MELLER and C. A. BURGHARDT. Improvements in the method of driving motor-cars, motor-carriages, boats, and other vehicles.

27,793. December 5th, 1896. J. A. and W. D. DRAKE. Improvements in driving apparatus for motor-carriages and the like.

27,863. December 7th, 1896. W. W. CURTIES. Improvements in driving mechanism for steam-propelled vehicles.

27,915. December 7th, 1896. C. F. WOOD. Improvements in mechanically-propelled vehicles.

28,128. December 8th, 1896. G. IDEN. Improvements in the construction of mechanically-propelled vehicles.

28,160. December 8th, 1896. J. F. SLEAT, H. SKELTON, and C. HORSLEY. Improvements in and connected with driving-gear for velocipedes, motor-cars, and other vehicles.

28,192. December 9th, 1896. H. R. GILLING. Improvements in and relating to pneumatic springs for cycles, motor-cars, and other vehicles.

28,312. December 11th, 1896. J. HURROCK and D. J. McDONALD. Improvements in and relating to motor-cars.

28,331. December 11th, 1896. E. J. PENNINGTON. Improvements in starting devices for mechanically-propelled vehicles.

28,407. December 11th, 1896. H. H. GRIFFIN and G. GIBSON. Improvements in self-propelled vehicles.

28,474. December 12th, 1896. T. BOSHER and E. MOUNTFORD. Improvements in and relating to motor-carriages.

28,476. December 12th, 1896. J. and R. BURNS. Improvements in cycles, motor-cycles, motor-cars, and other vehicles.

28,519. December 14th, 1896. G. H. SCOTT and R. H. TAYLOR. A method and apparatus for automatically changing speeds of driving gears for bicycles, tricycles, motor-cars, &c.

28,850. December 15th, 1896. H. LANE. Improvements in the method of and apparatus for applying motive power to vehicles running on ordinary roads.

28,866. December 15th, 1896. J. GEISENHOF. Improvements in steering devices or under-frames for the fore-carriages of motor-cars.

28,867. December 15th, 1896. J. GEISENHOF. An improved motor-van.

28,985. December 17th, 1896. C. D. JENKINS. Improvements in and relating to motors for bicycles, tricycles, and other vehicles.

29,062. December 18th, 1896. J. FAVETS. Improvements in driving gear for cycles, motor-cars, and other road vehicles.

29,126. December 18th, 1896. V. POPP. Improvements in compressed air locomotive carriages.

29,210. December 19th, 1896. A. H. SMITH. Improvements in driving-gear for cycles, motor-cars, and the like.

29,378. December 22nd, 1896. A. G. ADAMSON and T. SCOTT. Improvements in autocars.

29,394. December 22nd, 1896. G. F. THOMPSON. Improvements in and connected with variable speed mechanism for self-propelling vehicles and other purposes.

29,486. December 22nd, 1896. A. J. BOULT. Improvements in or relating to road vehicles and motor mechanism for the same. (P. A. Darracq, France.)

29,528. December 23rd, 1896. A. MUSKER and C. MUSKER. Improvements in or connected with steam generators for auto-vehicles.

29,635. December 24th, 1896. J. R. K. LAW. Improvements in the driving gear of cycles, motor-cars, and other vehicles.

29,856. December 28th, 1896. W. J. H. JONES. Improvements in motor-propelled vehicles.

29,882. December 29th, 1896. C. PROVIS. Improvements in motor-cars, cycles, and other vehicles driven by electric, steam, oil, gas, or water power.

29,933. December 29th, 1896. The Hon. R. T. D. BROUGHAM and W. C. BERSEY. Improvements in controlling apparatus for electrically-propelled vehicles.

30,003. December 30th, 1896. W. WATT. Improvements in and relating to cycles, motor-cars, and other road vehicles.

THE AUTOMOTOR AND HORSELESS VEHICLE JOURNAL.

CONTENTS of No. 1.

CONTENTS of No. 2.

CONTENTS of No. 3.

Publishers—Messrs. F. KING & Co. (Limited), 62, *St. Martin's Lane, London, W.C.*

SITUATIONS WANTED.

ROLLING STOCK manufacturer's son, age 26, with engineering and commercial experience, desires agency for motor-cars in busy centre. Large connection. Address J. A. H., care of King & Co., Limited, 62, St. Martin's-lane, London, W.C.

ENGINEER, with sound practical experience of high-class engines, and thorough commercial training, having office in Manchester, is open to take up a good agency for motor-cars. Address Lancashire, care of King and Co., Limited, 62, St. Martin's-lane.

AS DRIVER or CONDUCTOR.—Captain of Great Wheel, Earl's Court; take charge of motors. Joseph Banks, 34, Beer-street, Wandsworth-bridge-road, Fulham.

AS CONDUCTOR.—Thoroughly experienced; good references. F. Blackwell, 35, Percy-road, Shepherd's-bush.

AS DRIVER.—Roger system or Daimler; experienced. A. J. E., 57, Iverson-road, West Hampstead, N.W.

VOL. I. NO. 5. FEBRUARY 17TH, 1897. PRICE SIXPENCE.

CONTENTS.

BENZINE MOTOR-CYCLE.*

ONE is apt to feel that the railway locomotive is a magazine of power, an annihilator of distance, an embodiment of energy, and altogether a marvellous production which commands respect almost as if it were a thing possessed of life and intelligence. Recently a locomotive has been devised for the use of the individual, which is no less interesting than the railway locomotive. It combines the peculiarities of the bicycle and the locomotive, and forms a new species of machine known as the motor-cycle. The particular machine which we illustrate was made in Munich, Bavaria. It was used in Germany by Mr. Henry Hirsch, of the *Scientific American* corps, and was by him brought to this country. It has been run over the ample floors of this office, much to the interest and amusement of the *employés* and visitors who chanced to be present at the time.

We have made an elaborate set of illustrations on account of the novelty of the machine, as well as the interest attached to the motor, aside from its connection with the bicycle.

Fig. 1 is a side view, partly in section. Fig. 2 is an enlarged perspective view of a portion of one of the cylinders, showing the valve motion. Fig. 3 is a sectional view of the benzine reservoir. Fig. 4 is a view of the igniting apparatus, with parts broken away to show the internal construction. Fig. 5 is a detail view of one of the ignition tubes. Fig. 6 shows the valve controller.

The frame of the machine is formed of four parallel tubes, two upon either side, connected with the main journal boxes of the rear or drive wheel, and united at their forward ends with two pairs of oblique tubes connected by cross-bars at the top, and carrying the steering head, in which is received the shank of the front fork, as in an ordinary bicycle.

Between the two pairs of horizontal bars are secured two motor cylinders, formed in one casting, and provided with a water jacket. The cylinders contain pistons connected by piston rods with the crank on the main shaft. The bearings of the crank-pins, as well as the bearings of the main shaft, are rendered nearly frictionless by the use of balls, as in the bearings of an ordinary bicycle. The cylinders are single-acting, and the cranks, which are on opposite sides of the rear wheel, are parallel, and extend in the same direction. The engines work on the four-cycle principle, and are so timed as to give one effective impulse for each revolution of the drive wheel.

On the top of the cylinder, above the explosion chamber at the rear of the piston is a valve-chest, containing two pairs of poppet-valves, one pair to each cylinder. The valve-chest is furnished with two separate chambers, one for the supply of the explosive mixture, the other for the escape of the exhaust, and the valves are held to their seats by spiral springs surrounding their stems, as shown. The valves which admit the explosive mixture are provided with light springs, so that when the pistons move forward the valves open inward automatically; but the exhaust valves are furnished with heavier springs, which hold them to their seats at all times, except when they are depressed by the valve operating levers, A A'.

These levers are made to open their respective valves in alternation by the peculiar combination of levers shown more clearly in Fig. 2. Upon the side of the rear or drive wheel is secured a cam, B, upon which presses a roller, *a*, carried by the arm, *b*, jointed to the lower side bar. A rod connected with the arm, *b*, is jointed to one end of the lever, C, the opposite end of which carries the hook, D. To the hook, D, is pivoted a three-armed lever, E, which is held in frictional contact with the hook by a strong spiral spring.

* From the *Scientific American.*

M 2

Pivoted to the top of the cylinders are two arms, *c*, *c'*, which are pressed towards the centre of the cylinder by springs. The forward projecting arm of the lever, E, is capable of bearing against the free end of one or the other of the arms, *c*, *c'*. The shorter arms of the lever, E, are alternately brought into engagement with studs, *d*, *d'*, projecting from the top of the cylinders. The angled arms, A, A', are pivoted on a rod supported by ears projecting from the cylinders, and their downwardly projecting ends are engaged in alternation by the hook, D. This action of the exhaust mechanism controls the machine.

The ignition of the charge is effected by heating the nickel tubes projecting about 2½ inches from the rear ends of the cylinders into the ignition box. In this box is placed a heating vapour burner, receiving its vapour from the vertical tube at the side of the box, which contains a wick saturated with benzine supplied from the reservoir. The tubes extend into a fireclay chamber, in which are loosely placed three nickel spirals below the tubes, for distributing and retaining the heat. The heating through the action of the engine. The tube, *i*, projects into the reservoir, and is provided with a hollow spherical lower end in which is formed a transverse slot. In this tube is inserted a wire or gauze cone connected at the top to the regulating valve, H, which latter also communicates with an air-supply valve, *k*. The regulating valve, which is thin, is arranged to slide over the opening which communicates through the pipe, *l*, with the supply side of the valve casing. The proportion of benzine vapour and air conveyed to the engine depends upon the position of the valve, H, and this is regulated by the lever, *m*, pivoted to the handle bar and connected with the valve, H, by a rod. The lever, *m*, at its free end has a latch which is arranged to pass under a lug projecting from the handle bar when the valve is closed, and when the lever is released to open the valve, the regulating cone screwing on the end of the lever rests against a finger projecting from the handle bar, and serves to adjust the position of the valve by engagement with the finger as it is screwed along the threaded end of the lever.

Fig. 1.

burner, arranged in this way, effectively heats both nickel tubes, thus insuring prompt and regular explosions. The ignition tube is provided at its inner end with a flange which is clamped in place by a yoke, shown in Fig. 5. The lower oblique tube on one side of the machine conveys air to the burner, and the oblique tube on the other side serves as a chimney for carrying the products of combustion from the burner. These tubes terminate in a comparted hood, F.

The benzine is contained in the reservoir, G, supported by the oblique tubes at the front of the machine. This reservoir is connected directly by the small pipe, *e*, with the burner which heats the ignition tube. In the top of the reservoir, G, is inserted a screw-capped filling tube, *f*, the lower end of which is covered with wire gauze. To the top is attached a screw-capped nipple, *g*, through which extends a wire having on its lower end a cork float, by means of which the depth of the liquid in the reservoir is ascertained.

A conical air supply tube, *h*, projects into the reservoir, and is provided at the top with a hood through which air enters into the reservoir. This hood is furnished with a check-valve which keeps the tube closed except when a partial vacuum is formed

The exhaust escaping through the exhaust valve is taken to a hood, I, made in the form of a hollow quarter-cylinder, which is divided into two compartments by a perforated curved partition. The exhaust pipe enters into the smaller compartment, and the larger compartment is filled with asbestos cord. The convex surface of the hood, I, is perforated. The asbestos cord serves as a muffler, which deadens the noise of the exhaust.

Over the drive wheel is supported a curved water tank, which is connected with the water jacket surrounding the cylinders, and the circulation of water serves to prevent the overheating of the cylinders. Strong elastic bands are connected with the connecting rod and with an arm mounted on a rock-shaft at the top of the cylinder. These elastic bands may be put under tension to assist in starting by means of a screw at the top of the frame, which is operated by a crank and mitre gear. The oil for the lubrication of the cylinders is contained in the upper oblique tube of the frame, and is fed to the cylinders by a sight feed, o.

To start the motor-cycle, the reservoir, G, is partly filled with benzine or gasoline; the door at the back of the ignition box is opened, and the burner for heating the ignition tube is started by giving it a preliminary heating by means of an alcohol torch. As the door at the rear of the ignition box

Fig. 2.

F.G. 3.

is opened for this purpose, the air supply pipe is closed automatically by means of a connection with the rear door. When the tubes are red hot the valve, H, is opened, the rubber bands are put under tension and the machine is moved forward by the operator until an explosion occurs, when he mounts the machine and proceeds on his way. The proportion of the supply of air charged with petroleum vapour and pure air is regulated by the

Fig. 4.

valve, H. By manipulating the cone on the lever, m, the supply of explosive mixture, and, consequently, the speed of the machine, is regulated. When the machine is fairly under way, the tension of the rubber bands is released.

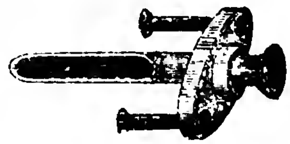

Fig. 5.

The action of the machine is as follows:—The forward motion of the piston draws in the explosive mixture through the valve, H, as already described. On its return, it compresses the explosive mixture in the explosion chamber behind the piston,

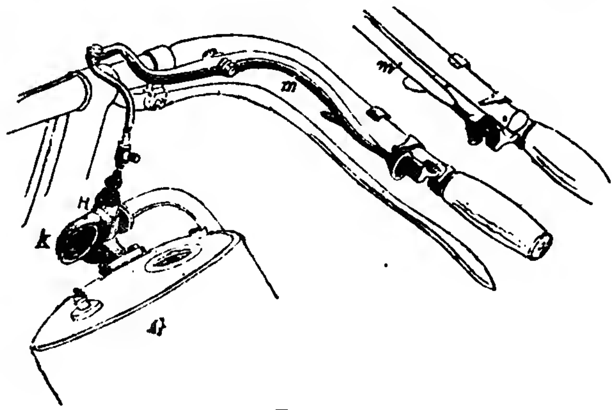

Fig. 6.

and a portion of the mixture is forced into the hot tube, where it is ignited, forcing the piston outwardly, giving the propelling impulse. The return stroke of the piston expels the products of combustion through the exhaust valve, which is opened by the cam, B, at the proper moment through the agency of the roller, *a*, and the hook, D, as already described, and the cylinders operate in alternation, thereby giving one effective impulse for each revolution of the drive wheel. To stop the machine, it is only necessary to close the valve, H, and apply the brake in the usual way.

The engine cylinders are $3\frac{9}{16}$ inches in diameter, with a stroke of $4\frac{3}{4}$ inches. The supply and exhaust valve apertures are $\frac{1}{2}$ inch diameter. The benzine reservoir is 13 inches long and $7\frac{1}{2}$ inches in diameter. The driving wheel is 22 inches in diameter, and the guiding wheel is 26 inches in diameter. The pneumatic tyres are made specially large and heavy to support the weight of the machine and rider. The tread of the machine is 4 feet; weight when in running order, 115 lbs. The reservoir contains a supply of benzine sufficient for a run of 12 hours. The machine is able to run at a speed of from three to 24 miles per hour.

MECHANICAL TRACTION OF ROAD CARRIAGES.

This, the fourth and last of the series of Arnold Lectures for the present session, was delivered by Mr. James W. Thomson to a large audience, in the Gymnasium of Gordon's College, Glasgow, on the 30th ult. Ex-Baillie Kemp, one of the Governors, presided. The subject was dealt with under three heads—steam, oil, and electric power. At the outset, a description was given of a steam van recently constructed by the Thornycroft Steam Carriage and Van Company, Chiswick, London, as illustrated by The Automotor and Horseless Vehicle Journal. The van weighs, with its boiler—which is of the vertical water-tube type—motor, and accessories, some 30 cwts., and has a carrying capacity of one ton. The Serpollet system of steam-car propulsion was then dealt with, and by means of a number of sectional diagrams the principle of the invention explained. The boiler is constructed of steel tubes of a concave form, which are very thick compared with their aperture, which is only a thin slit curved to follow the section of the tube. The slits vary in width from $\frac{1}{25}$ inch in the smaller sizes to $\frac{1}{8}$ inch in the larger tubes. The tubes are brought to a red heat, and a hand-pump is used to inject into them a small quantity of water, which is instantaneously turned into steam. On its passage through the upper tubes the steam becomes super-heated, and is delivered to the motor in this state, thus effecting economy in working. The motor now begins to work, and operates an automatic feed-pump, which delivers a constant supply of water to the boiler, no further attention being required by the driver. The speed of the engine, and therefore of the vehicle, is controlled by regulating the amount of water injected into the boiler, so that steam sufficient for the registered speed only is supplied. This is effected by means of a three-way valve placed between the feed-pump and the boiler. At full speed the valve is turned into a position allowing all the water from the pump into the boiler. When a lower rate of speed is required, part of the water from the pump is intercepted by the valve and returned to the feed supply tank; and when required to stop the car, the valve is adjusted so that all the water is intercepted and returned to the tank. No more steam being generated, the engine ceases to work, and the car comes to a standstill. A variety of views were shown of carriages and vans fitted with Serpollet generators. Attention was next given to oil-driven vehicles, the lecturer describing very fully the principle and construction of the Daimler motor, which, he stated, is that at present used by the bulk of the Continental motor-carriage builders. Oil engines, it was pointed out, differed only in detail, the principle being the gasification of petroleum, the vapour being mixed with air forms an explosive gas, which is ignited in the motor-cylinders, the force of the explosion driving forward the piston and operating the crank through the connecting rods. Sectional drawings and views of carriages, for pleasure and business purposes, fitted with oil motors, were projected on the screen, and the main features explained, as were also drawings and views of electrically-driven vehicles. In this connection the storage battery was explained, as being the main source of power in electric carriages. A very fine specimen of the coachbuilder's art was shown in a Victoria, just completed by Messrs. Thrupp and Maberly, London, for the Queen, from the designs of a Spanish electrical engineer. Information is meantime being withheld as to the nature of the elements of the primary dry battery, with which the carriage is fitted, the bare statement being made that the battery complete weighed only 2 cwts., and has a capacity and output to give a speed of 10 miles an hour for a period of 60 hours without requiring to be recharged. The recharging is also said to be easily and cheaply accomplished. If the statement furnished is realised a revolution in the use of electrically-driven carriages is bound to follow. The lecturer concluded by referring to the change of the conditions affecting motor-car traffic by the Act that came into force on November 14th last. The removal of restrictions should encourage a demand for self-propelled vehicles, and greater efforts on the part of carriage-builders and engineers to produce carriages of convenient and attractive design, and motors and driving-gear which can be manipulated and controlled with a minimum of skilled attention. An enthusiastic vote of thanks was accorded to Mr. Thomson.

AN AMERICAN VIEW OF THE FUTURE OF MOTOR-CARRIAGES.

As our cousins in the United States have had a considerably longer experience of the agricultural uses to which motor-wagons can be put, the following views, adopted by their experts, from a leading contemporary will doubtless be of interest:—

"There are two different ways of looking at motor-carriages—the business way and the pleasurable way. For the moment, at all events, it is the former that seems to have the greater future before it. Notwithstanding the immense extension of railways, there are still large tracts of country in which the sound of the passing engine is either not heard at all, or heard but very faintly. The slow-moving wagon is still the only means of carrying goods to market. Here, if there be anything in vendors' assurances, is a field for the new industry which can be worked with great profit. Every kind of agricultural produce will be heaped upon motor-wagons, and that large item in the cost of farming which is concerned with the management and care of horses will be suppressed. The motor-wagon, or the motor which is to draw the wagon, will be loaded as opportunity offers, and then will start for the distant town or station with no more outlay in labour than the wages of the man who sees that the power, whatever it is, is in working order, and that the machine itself is under proper guidance.

"But what is really wanted in many parts of the country is a co-operative motor—a motor which shall go about the villages and pick up a wagon here and a cart there, and so put large farmers and small farmers on a level in regard to the carriage of their goods. That this is impossible now we can quite see, but it may not be always impossible. It may not, that is, be beyond the power of science to devise a kind of vehicle, or a mode of coupling vehicles together, which shall make it safe to attach many to the same motor, even on an ordinary road. There will be abundant stimulus to the ingenuity of inventors in the large profits that might be made by anyone who can put an end to what is for the moment an insuperable difficulty."

Mr. W. Worby Beaumont has issued a notification that his civil and mechanical engineering practice, in favour of which he has resigned his editorial connection with *The Engineer*, will now receive his undivided attention at 222, Strand, London, W.C.

sowed brains and conscientious labour; they reap a golden harvest to-day. Their carriages, combining the best points of London and Parisian vehicles, and this combination improved not a little by the technical skill and artistic tastes of the brothers, are models of serviceableness and beauty. Orders come to the firm from all parts of the world; the "Heir apparent," Prince of Wales, added his patronage. Medals and diplomas, more than we have space to inventory, were awarded in various exhibitions. The extensive show-rooms at the corner of St. Vincent Street and Bothwell Circus, and the manufactory and principal show-rooms in North Street, where over a hundred workmen are employed, are well worthy of a visit.

Mr. Alexander Henderson is an honorary member of

of the principal cities?"

"It will be a long time before we see them largely used in our streets, at any rate as pleasure carriages. They may be more fully adopted for traction or commercial purposes, and the relieving of horses of their heavier burdens."

"Are the carriage-builders perfectly ready and willing to co-operate with engineers in evolving the carriage of the future?"

"I think the carriage-builders are perfectly willing to co-operate with the engineers in evolving the carriage of the future. We should all aim at improvement and development."

"Do you like the present Continental types, or do you expect to see an entirely novel departure made for this special purpose?"

M 4

"I think perhaps the present Continental types, that of the phaetons, have been selected for their adaptability for the motors in use there. The same types of carriages have not been in much favour in this country for many years. I would like to see a novel departure made for this special purpose, as it would foster and emulate original research; something light, graceful, and easy, the *tout ensemble* of which will be beautiful and artistic."

"Have you yet built or used a motor-carriage?"

"Our firm made the steam-carriage in 1872 for the late Mr. Charles Randolph, of Glasgow, the eminent engineer and shipbuilder, which was exhibited in the Crystal Palace at the last exhibition."

Thanking Mr. Henderson for his courtesy, our representative requested a photo of Mr. Randolph's carriage for reproduction, and the same appears below.

ELECTRIC TRAMWAYS COMMUNICATION.

The members of the Liverpool Engineering Society held a meeting at the Royal Institution in Colquitt Street on the 1st inst., Mr. S. B. Cottrell presiding, the principal business being the reading of a paper by Mr. T. M. Bigley, on the subject of "Electric Tramways to Connect Towns with Neighbouring Districts."

Mr. Bigley said that it would be worth while, he thought, to consider the subject of how to establish a more up-to date system of communication between towns and outlying districts which are at present connected only by the ordinary roads. There were many such districts throughout the country, not sufficiently busy, it might be, to attract or need a costly railway, and which could not be so conveniently served by the recently-styled light railway, which would be well suited by and afford a remunerative amount of traffic for an electric tramway laid along the high road. There was a pretty general belief that electricity was the "coming" motive power that would meet this want. In other countries it had already efficiently supplied it, and as there were very good roads in many of our country districts, should not a combination of these two facts suggest a practical means of bringing about the desired end? Mr. Bigley then, in an interesting manner, referred to the electric tramways already established in Great Britain, and to their adoption on the Continent and in North America. Special allusion was made to the electric tramway line at Hartlepool, recently inspected by the lecturer, who remarked that there ought to be in tramways of similar design and construction, extended, it might be, to at least a light goods as well as a passenger traffic, a solution of the question under consideration.

A discussion followed the reading of the paper, and Mr. Bigley was thanked for having contributed it.

OLYMPIA MOTOR-CAR EXHIBITION.

The International Cycling and Motor Exhibition Company are opening an exhibition at Olympia, Kensington, on Saturday next, February 20th, and the management, we understand, are making every effort to make this the largest and finest exhibition that has yet been carried out. This being their first start, we trust that all those interested in the future of the motor-car industry will come forward to help make the exhibition a fully representative one, so as to include all types of vehicles and motors, together with accessories up to date. This magnificent building is certainly one of the most suitable places in London which could be selected for an exhibition of this nature, as the enormous size should give ample scope for testing the vehicles in motion, and its central position and the great facility with which it can be reached from all parts should give it every opportunity of being a success from a commercial point of view. It is proposed to hold a series of grand bicycle races, and to have other entertainments, &c., to attract the people. The management is in the hands of Mr. Wallace Jones, and the Secretary is Mr. Cuthbert F. Griffin. To those who are interested practically in motor-cars, &c., who have not already secured spaces in the building, we would suggest that they should at once communicate with the management with a view to exhibiting vehicles, &c., as we are pleased to learn that the whole exhibition is in the hands of entirely independent gentlemen, whose great endeavour will be to place every type of vehicle and motor upon an equal footing, and give the best opportunities for testing the merits and examining into the details of the various claims of inventors, carriage-builders, &c.

Mr. Randolph's Steam Carriage.

THE ABERDEEN MOTOR-CAR DEPUTATION.

The Links and Parks Committee of the Aberdeen Town Council met on the 27th ult., under the presidency of Mr. Wilkie. The report of the motor-car deputation, whose doings in London were fully reported in our last issue, was accepted, and the deputation thanked for their diligence. It was agreed to take no action in the matter meantime.

The report is as follows :—In submitting their report your deputation have to state that it is not their intention to deal with every kind of motor vehicle in the market. They have confined their investigations mainly to the question of the practicability of applying self-propelling power to a heavy vehicle, such as would be required by the Links and Parks Committee as a conveyance to and from the beach. Your deputation have had opportunity of inquiring into the various possibilities for this purpose of oil, electricity, and steam, and of in some degree gauging their possibilities for the future, and they are pleased to be able to lay before the committee definite views as to which of these motive powers is best suited for the kind of vehicle referred to.

Oil Motors.

The Daimler Company, which deals in oil-motors, was first visited. This Company is at present devoting all its energies to the manufacture of small motor-cars, and has not yet experimented with anything larger than a vehicle to hold three or four persons. An offer was however made by this Company to supply an omnibus to hold 20 persons for the sum of £348, but hearing various opinions from the manager and his assistant, your deputation came to the conclusion that the oil-motor in its present state of development is practically useless for a heavy omnibus.

Electricity.

Your deputation next directed their attention to electricity as a locomotive power, and, along with Mr. Georgeson, of Mr. J. T. Clark's Coachbuilding Works, Aberdeen, visited Messrs. White, Jacoby, and Co., electrical and mechanical engineers, Blenheim Place, Camden Town. One of the chief objections to the electric motor-car is the great weight of the necessary accumulators. The firm of Messrs. White, Jacoby, and Co. are at present endeavouring to remove this difficulty, and are the inventors of the lightest accumulators now in the market; but your deputation were disappointed to find that an omnibus to hold 20 persons, even although fitted with this accumulator, would weigh over four tons. The expense of such an omnibus would also be very great. The battery would cost about £120, and the cells are expensive and require frequent renewing. In view of this, and the still greater objection that it takes one hour to charge the accumulators for a three hours' run, your deputation were forced to the further conclusion that electricity is also at present impracticable. These conclusions were confirmed by a visit to Messrs. Julius Harvey and Co., Queen Victoria Street, a firm which is connected with all the important motor-carriage builders in Britain and on the Continent. The representative of this firm maintained that steam is the only motive power which is capable of doing the work required by such a vehicle, and that there is no immediate prospect of either oil or electricity taking its place where much power is required.

Steam.

He referred your deputation to the Serpollet Company as being able to supply a vehicle to go on rails or road, which would exactly meet the requirements of the Links and Parks Committee. Your deputation were informed by Mr. Harding, of the Serpollet Company, that cars worked on this system could be seen at Willesden on tramway rails, and that a small road-car worked on the same principle was also in operation there. The Serpollet tramway-car as seen at Willesden was a large vehicle capable of holding 50 persons. The shape was the same as that of the ordinary horse tramway-car, and the motor, being situated beneath, was not visible. The principle of the Serpollet system has already been given in the public prints, and the following advantages are claimed for this form of car or omnibus :—(1) The instantaneous generation of vapour ; (2) the great elasticity of power, which can be raised in one moment from 1 horse-power to 20 horse-power ; (3) freedom from all danger of explosion ; (4) absolute control over both stopping and starting ; (5) absence of steam, smoke, noise, and vibration ; (6) the automatic cleansing of the boiler by the rush of vapour ; (7) great economy over horse traction. With regard to this last, the cost of running is computed at about half of that where horses are used.

This kind of car has been used with great success in Paris during the last two years on rails, but the Company claim that they are equally adaptable to road and street traffic, and affirm that they have received an order from the Paris Omnibus Company for 60 omnibuses to be worked on the same principle. The small street-car, although not so shapely a vehicle as the rail-car, worked admirably, and, from the exceedingly ingenious construction of the fore-axle, was very easily and quickly turned. The Serpollet car can be worked and controlled by an ordinary intelligent person, and, as has been stated, there is no smell, or vibration, or danger of explosion. It is equal to the electric car, even with a reduced weight of accumulators, and has an immense amount of reserve power for gradients and increase of speed.

This form of car is also very highly recommended by Sir David Salomons, one of the highest authorities on the present motor-car movement, and a practical engineer himself. This gentleman, speaking at Liverpool in the month of November, said :—

"My faith more than ever is pinned to steam after seeing the recent carriage of M. Serpollet in Paris. It runs up the steepest hill as on level ground. The ride from Paris to Versailles is very hilly, and with my carriage (which has an oil motor), I required an hour and twenty minutes to make the journey, but the little Serpollet carriage covered the distance in somewhat over half an hour, and on the long steep incline it rushed in front of every other vehicle, whether motor or horse drawn. There is not the slightest doubt but that the steam carriage, as solved by M. Serpollet, is the coming one. The boiler is small, non-explosive, and self-cleansing. The burner has nothing in it to get out of order, and the power given off is enormous compared with the size and weight of the vehicle. Sixteen English miles can be covered with this carriage easily per hour." Sir David Salomons further says :—"I have expressed myself very strongly that steam, and steam alone, will be the motive power of the future for self-propelled traffic. I feel confident that within a short time nine out of every ten motor vehicles will be constructed with steam motors."

After such an expression of opinion by so eminent and disinterested an authority as Sir David Salomons, and from what your deputation were able to see for themselves at Willesden and elsewhere, they have no hesitation in saying that the Serpollet car is the only thing in the market, or likely to be in the market for some time, which would suit the requirements of the Links and Parks Committee for the conveyance of passengers to and from the sea beach. Since your deputation returned, they have been in correspondence with Messrs. Julius Harvey and Co., with the view of obtaining from the Serpollet Company a price for supplying an omnibus. From the information received your deputation believe that a Serpollet omnibus, to hold from 20 to 30 persons, will cost from £600 to £700. The French makers, however, are so full of work they cannot supply England, and the English Company have not yet completed their own manufacturing arrangements. Under these circumstances, your deputation beg to recommend that the Council should defer giving any order until matters are further developed, as they believe that better terms will be got in a short time, when the Serpollet English factory is in operation.

THE STIRLING MOTOR-CARRIAGE.

This vehicle, which we illustrate herewith, has attracted great attention during the present month in Glasgow, where the public have been treated to a practical demonstration of its capabilities, and the amount of interest and enthusiasm aroused has been enormous. Messrs. J. and C. Stirling, of Glasgow, the builders, are to be congratulated on the unqualified success of the trial runs of their first car. The car left the carriage works for its first run on Saturday morning, the 6th instant, and a correspondent writes us as follows on the way it performed:—Proceeding along Cadzow Street, it was turned into Quarry Street to test its hill climbing qualities. This gradient was surmounted at the rate of six to eight miles an hour. The car then proceeded *viâ* Duke Street to Larkhall and Stonehouse. All the hills were taken at the same rate, including the long steep ascent out of Larkhall. On the return journey, in running fast downhill, the capabilities of the stopping and starting arrangements were fully tested, when it was found that the car at all times was under the absolute control of the driver. The brake gear is so perfect and complete that at any time the car can be brought to a standstill within a few yards. On Monday, over frozen roads, the car was driven *viâ* Bothwell and Uddingston to Glasgow, reaching the city under the hour, where it proceeded along Argyle Street, Union Street, Renfield Street, Sauchiehall Street, Bothwell Street, to the Central Station, Gordon Street, Buchanan Street, Jamaica Street, Eglinton Street, Cumberland Street, up Stockwell to Argyle Street, then back to Buchanan Street *viâ* Queen Street and St. Vincent Place, returning to Hamilton by Rutherglen and Cambuslang. Its behaviour in the thick of the traffic was perfect—stopping, starting, and reversing at the will of the driver. On Tuesday, several parties of local ladies and gentlemen interested in the new mode of locomotion were driven round the district, including a climb into Motherwell. All were delighted with the ease, comfort, and safety with which the car could be manipulated under all conditions. With regard to the cost of running the car, it may be stated that the fuel consumed is exactly in proportion to the work done, and the consumpt ceases the moment the car is stopped. The cost works out at about one halfpenny per mile, which on a run to Glasgow and back, carrying four to six persons, would cost something under threepence per head. For those who have not seen this carriage, we are able to furnish them with a brief description of it. The car is built to seat four persons on two seats, both looking forward, somewhat on the lines of a mail or Stanhope phaeton, the back seat being slightly raised in order that the view may not be obstructed by the persons occupying the seat in front. The body is varnished natural walnut, and the wheels and under carriage painted vermillion, with black lines. The car is driven by a two-cylinder Daimler oil motor, carried in a neat casing in front of the dash-board. It has now been demonstrated that the motor-car is a thoroughly practical vehicle, and it is only a matter of time when it will come into regular and general use. A very important point, and one which will interest all who contemplate acquiring motor-cars for trade purposes, is that the method on which Messrs. Stirlings' motor-cars are constructed admits of interchangeable bodies, so that the owner of a motor-van may in a few minutes convert it into a comfortable pleasure carriage.

We understand Messrs. Stirling are at present engaged on new designs for light, handy motor-cars to seat two persons, fitted with bicycle wheels and pneumatic tyres, for which there is certain to spring up a very great demand. At their recent exhibition a very neat design for parcel-delivery van was shown, and they hope shortly to have in hand a serviceable wagonette to carry eight persons. Messrs Stirling are to be congratulated on their enterprise and foresight in taking up a new industry which must ere long rival and surpass in importance the vast cycle trade. We believe the firm have recently been approached by several Glasgow capitalists with the view of acquiring their business and the benefits of certain advantageous working arrangements with the leading motor manufacturers in England which the firm have secured, in order to at once develop the business on a scale commensurate with its importance, and at the same time maintain the premier position in Scotland which the firm has already attained. Should the proposal be accepted, a very rapid development of the new industry is certain to take place, and employment found for a large number of hands.

NOTES OF THE MONTH.

THE abandonment of the North-Eastern Railway Company's scheme for a proposed railway between Cramlington and Blyth was a sore disappointment to the local public. But, failing to secure the needed assistance in that direction, a new scheme has been formulated by Mr. Mark Doney, of Shankhouse, the object of which is to secure improved communication between the town of Blyth and the outlying districts. The advent of the motor-car opens out a means by which the residents in the Cramlington and Shankhouse localities may more conveniently connect themselves with the world outside their own immediate district.

A CAPITAL exhibition of autocars was held last week at the Waverley Market, Edinburgh, when the vehicles exhibited—most of which have been illustrated in these columns—attracted a very large number of visitors.

WE are favoured with the compliments of the British Electric Traction Company, and a pamphlet on various methods of tramway working, having special reference to electric traction. We refer to it here because the overhead system of the distribution of electrical energy is fully described, and the system is given the testimonial of being superior to any other "for simplicity of operation, cheapness of construction, flexibility in adaption, and reliability in service." American and Continental companies have the credit of having carried the system through its experimental stages, and upon it is worked quite 95 per cent. of the world's electric tramway mileage. The percentage is doubtless correct; but the British public will be long before they adopt the hideous ugliness and great dangers to life which are involved in overhead electrical systems.

MILITARY men are discussing very seriously the possible uses in war of the motor-car. In a modern battle it might well seem to be as much out of place as Queen Boadicea's scythed chariots, but it might be made useful as a kind of movable hospital and for the conveyance of the wounded to the rear. Armour-plated and furnished with Maxims or other light and quick-firing guns, the car might conceivably be used to charge an enemy. Caran d'Ache several months ago made what he calls "Automobilism in War" a subject of one of his caricatures. He imagines an automatic clockwork soldier running on wheels, and serving the double purpose of a stalking-horse and carrier of soldiers' kits. The military motor-car would furnish equally good material for the caricaturist, but the idea of using it as a moving fort is not wholly absurd. Indeed, according to the *Army and Navy Gazette*, some prominent military officers are of opinion that the motor-car, when perfected, is destined to be to the army what the torpedo-boat is to the navy.

AN exhibition of motor-cars and cycles was, during last month, conducted in two of the showrooms of Messrs. J. and C. Stirling, coachbuilders, Hamilton, the proceeds being in aid of the funds of the Orphan Homes of Scotland.

MR. WORDIE, of the firm of Messrs. Wordie and Co., of Dundee, made merry one evening recently with his employés over the threatened advent of the motor, and stated that "several times he had told his Dundee employés, in a jocular way, that they would be able to do away with horses, that the carter would walk into the office and get his box of electric energy for 10, 15, or 20 miles, that he would then screw it on to his cart, turn a handle, and drive away. He did not think there was any probability of such a thing coming to pass in their day. But the motor-car had been developed, and would stay, although whether it would be a success was quite a different matter." The reform may not come in the way Mr. Wordie has sketched—but it is not safe for him to prophesy as to the ultimate result.

CONSIDERABLE speculation has been aroused by the registration of a limited company, entitled the "Maxim Motor Company (Limited)," with a total capital of £7. We are not aware whether the whole of this amount of capital is "called" or not, or whether any portion of it is held in reserve. Inasmuch, however, as the "Company" has been formed to adopt an agreement between Mr. H. Maxim and the "Company," and, as amongst its professed objects is stated to be the manufacture of "flying machines," many people have not unnaturally jumped at the conclusion that Mr. Hiram S. Maxim is associated with this somewhat curious enterprise. We are, however, able to state, on the authority of a letter which we have received from Mr. Hiram S. Maxim, that he has nothing whatever to do with the matter. The Mr. "H." Maxim referred to is Mr. Hudson Maxim, a very different person.

IT is, of course, a matter of common knowledge that Mr. Hiram S. Maxim has been for some time engaged at the Maxim-Nordenfelt guns and ammunition works in the designing and construction of several types of light motors; and the step which has been taken in registering the title of the Company referred to is obviously an unscrupulous attempt to gain possession of a name which it is judged would be an attractive one to the investing public. Mr. Maxim has, we understand, placed the matter in the hands of his solicitor, though we very much doubt that he will be able to obtain any legal redress for having been forestalled in such a manner.

THE Electricity Committee of the St. Pancras Vestry, considering the probable extensive demand for current to charge the accumulators for motor vehicles, hold that every facility should be granted to encourage this class of consumer, having regard to the fact that the charging would be carried out during the hours the central stations were running on a light load. Subject to special regulations as to the hours of charging, they have fixed the price for charging accumulators at 2*d*. per unit.

AT a public meeting in the Wednesbury Town Hall, on the 3rd inst, the Mayor presiding, a resolution was passed, on the motion of the Mayor, seconded by the ex-Mayor, sanctioning the decision of the Town Council to oppose in Parliament the Birmingham, Wolverhampton, and District Tramways Bill, 1897.

Mrs. Wood, the proprietress of some factory buildings near Mitcham Common, who died last week, had a great taste for inventing. One of her latest ideas was the invention of a motor-horse, which could be attached to any car. Mrs. Wood had had several models prepared, but the work was not completed before her death. We gave a description of this motor in our December issue.

As there has been some discussion recently as to municipalising the tramways, it is of interest to note what a vast enterprise tramways have become in the United Kingdom, which originally was very slow to take the movement up, and gave George Francis Train, the inventor of tramways, but a cool reception when he came from America to England to try and introduce the new system of street locomotion. A Parliamentary Return just issued shows that the authorised capital of all the tramway companies in the United Kingdom amounts to over £18,000,000, and of this nearly £14,000,000 of capital is for English and Welsh companies. The paid-up capital, however, is only £14,157,354 for the United Kingdom, and £11,160,108 for England and Wales. The total capital expended during the year was £11,742,204, as compared with £11,685,355 in the preceding year. The total for the United Kingdom was £15,195,993, against £14,956,343. The length of line open for public traffic in the United Kingdom was 1,009 miles, an increase of 27 miles on the preceding year.

Mr. Albert Scarfe, of High Street, Colchester, arranged last month a novel method of helping that deserving institution, the Essex and Colchester Hospital. He placed at the service of all comers a handsome brougham motor-car, on the condition that not less than sixpence was contributed to the hospital. The secretary of the institution (Mr. C. E. Bland) arranged that one of his assistants should be in attendance with a box to collect the money, and the result was a considerable sum was collected in aid of a worthy cause.

At the February meeting of the Warwickshire County Council that body had under discussion the question of enforcing the law regulating the use of light locomotives on highways. The Earl of Warwick said he had written Mr. Henry Chaplin asking if it was possible to make any alterations in the present regulations. The President of the Board of Agriculture had replied that it was not desirable to make any alterations so soon, but at the same time was good enough to say the matter should be taken into consideration. Although the police had regulations under which to work, it was almost impossible for them to arrest the driver of a car going at the rate of some 20 miles an hour. Mr. Vero urged that it would be most unwise for the Council to try and fetter the great motor-car industry. The Marquis of Hertford said the Committee thought it would be unwise to attempt any private legislation on their part at present. If they found the cars become dangerous it would then be time enough for the Committee to interfere, and ask the Council to take steps to make more stringent bye-laws. The recommendation of the Committee to enforce the law regulating the use of light locomotives on highways was adopted.

In another column we give a full report of the Aberdeen motor-car deputation's report to the Town Council; and a copy of this having been sent to Sir David Salomons, he has written the local authorities a letter, in which he gives some valuable information as to how a 'bus on the Serpollet system could be got up within a reasonable time and at a reasonable cost. He is very pronounced as to the superiority of the Serpollet motor over the other motors now in the market. Although wedded to electricity himself, he says he cannot recommend it in the meantime. Councillor Wilkie, who is the principal mover in the matter, is continuing his inquiries in regard to motor-cars, and he expects to be able shortly to lay before the Links and Parks Committee several proposals supported by high engineering authorities.

When we have tramcars running to the Pyramids we may look for football in the Holy Land. The concession of the Egyptian Government permitting the Cairo Tramway Company to lay a line of rails to the Pyramids seems to shake the dust of sanctity from the associations which have always surrounded these famous monuments of long departed ages. Imagine the shock which the antiquary, with a mind filled with the traditions of Egyptian Kings, must feel when he reads, "All the way to the Pyramids and back, 1*d*." Truly civilisation has much to answer for.

The eleventh ordinary general meeting of the Accrington Corporation Steam Tramways Company was held at the Victoria Restaurant, Accrington, on the 5th. The Chairman, in moving the adoption of the report, said he was glad to meet the shareholders under such favourable circumstances. The dividend had been honestly earned, and the Company was now in a sound condition. In the future they could look forward to a dividend of 6 per cent. on preference and ordinary shares. Mr. Riley seconded the motion, and the report was adopted. An interim dividend of 6 per cent. on preference and ordinary shares was declared, and a suggestion was made that the dividends of ordinary shareholders should be reduced from 8 per cent. to 6 per cent.

The report of the directors of the Blackburn Corporation Tramways Company (Limited), submitted to the shareholders at an extraordinary general meeting of the Company held on the 11th inst., states that the past half-year, as compared with the corresponding half-year ending December 31st, 1895, shows an increase in the gross revenue balance of £232 3*s*. 4*l*.; whilst, taking the whole year, 1896 shows a total increase over 1895 of £508 11*s*. 3*d*. The net balance of £2,026 10*s*. 6*d*. is sufficient to pay a dividend at the rate of 6 per cent. per annum to preference and 4 per cent. per annum to ordinary shareholders. According to the decision of the shareholders in December last, the directors have made an arrangement with the Corporation for electric traction on Preston Road and Witton sections, all the terms of which, with the exception of one or two matters of detail, have been settled, and the agreement is expected to be ready for completion at an early date.

Sir David Salomons, Bart., will read a paper before the Society of Arts on Wednesday, May 12th, on "Motor Traffic: Technical Considerations."

THE FLEUSS TUBELESS PNEUMATIC TYRE.

WE give herewith a couple of engravings showing the construction of this tyre, which has rapidly taken its place amongst the leading makes, and bids fair to outstrip most of them in popularity. It is succeeding on its merits, as it is very simple, easily repaired, and comfortable to ride. We have not yet had an opportunity of trying the tyre on an automotor vehicle, but hope to be able to do so shortly, when we will report our opinion. In the meantime we may state that the following claims made for the tyre for cycling purposes are completely sustained in practice:—

The tubeless tyre is precisely the same externally as any other tyre; it has all the advantages of speed attributable to the single tube without its disadvantages; it is easier to detach than any other on the market; it is the best of all puncture-resisting

INFLATED

tyres; the system of manufacture necessitates automatic sealing of small punctures from thorns, &c., while there is no additional weight or thickness added; it has no air tube to burst or get pinched between cover and rim, or to be chafed by cover, or spoke heads and nipples; it has extensible edges, therefore works more easily than any wired-on cover, or cover with inextensible edges; it holds air better than any other tyre which has an independent air tube; and it does not need a patch to repair a puncture, a blob of solution is all that is necessary, the pressure of air from inflation does the rest.

The makers of the tyre are the Tubeless Pneumatic Tyre and

DETACHED
FOR REPAIR

Capon Heaton (Limited), 31, Moor Street, Birmingham. We append a photograph of Mr. Henry A. Fleuss, the inventor of the tyre, who is a well-known patentee of ice-making and refrigerating machinery, the tyre business being only a profitable way of utilising his leisure hours.

A GOSPEL MOTOR-CAR.

WITH AN ASSISTANT-PREACHER ENGINEER!

A BAPTIST chapel in Woolwich is announced for sale, the advertisement describing it as "suitable for a cycle maker's establishment and show-rooms." Across the Atlantic the Baptists have taken time by the forelock and made arrangements whereby they can continue to propagate the Gospel even though their chapels have to be sold or let to cycle manufacturers. They have just built what is described as "the Horseless Gospel Wagon," and the originator is the Rev. E. E. Knapp, pastor of one of the New York Baptist chapels, who is well known in this country in connection with his advanced ideas of furthering the doctrines of Christianity. Mr. Knapp recognises that people will not go to chapel, so he has decided that the chapel should be taken to them. Hence the Horseless Gospel Wagon, which is propelled by a gasoline motor, and will travel at any speed up to 14 miles an hour. The frame of the vehicle is naturally rather large. The driver or engineer sits in front, whilst the minister speaks from his pulpit in the middle of the car. Around him are seats for his choir of 12 ladies and gentlemen. In the rear is fixed a powerful organ, which is played by Mrs. Knapp. Mr. Knapp is to be assisted in his work by the Rev. Dr. Henry Hudson, who will also act as assistant engineer. The horseless chapel will travel throughout New York, stopping outside saloons to enable the tipplers to hear something of the Word of God. During the winter months a tank of coffee will be kept, and this will be distributed, together with tracts and hymn-books, amongst the crowd around. The car has some resemblance to the gaudy wagons connected with travelling circuses, as it is decorated in such a way as to attract as much attention as possible.

THE WOLSELEY AUTO-CARRIAGE.

This carriage, which was exhibited at the National Show, is in the form of a dogcart, the seats being arranged for two people back to back. It has three wheels, the one steering wheel in front being similar to that of a bath chair. The framework throughout consists of tubes, rendering it very light, and yet strong.
the seat
panels, \
soaking
The e
cylinder
a tank u
into the

The Wolseley Auto-Carriage.

to fit the hardened steel bushes in the ends of the connecting-rods.

The differential speed gear is of a new and special design particulars of which we may be able to describe in a future issue, together with a section of the car. The forward and backward motions, and the application of the brake, are all worked with one lever, which can be fixed either side of the car.

The firing is effected by an electric spark from a small accumulator, which is carried in a box in the front footboard. The engine is made in a very substantial manner, and, being designed for hard use, has good long bearings, cast steel frame, &c., and an aluminium bed-plate. All the bearings are fitted with grease lubricators, which will last for a considerable time without replenishing. The exhaust discharges on to the ground, after assisting to cool the water in the tank. One good feature about the car is the handy way in which the seats, &c., are arranged to allow of ready examination of the motor and gearing.

CHEAP ELECTRICITY FOR AUTO-MOTORS.

About a year ago, when the electrical engineer to the Brighton Corporation proposed a certain reduced scale of charges for electricity supplied for lighting and motive purposes, the engineers of various electrical corporations in London wrote long
. Arthur
ndpoint,
l prices.
electric
only has
al profit
district
lectrical

engineers in the employment of private corporations declared that the proposals of Mr. Wright were financially impossible and must result in failure. In his report to the Brighton Corporation, Mr. Wright says:—"The financial success of the Brighton system of charging, coupled with the fact that some 29 other towns throughout the country have already decided to adopt it, is strong enough evidence of the commercial soundness of the principles on which it has been based. From last year's results we actually find that the only extra cost the Corporation are now put to in having to continue to supply electricity, after the plant, &c., has been got ready for the purpose, amounts to nearly five-eighths of a penny per unit. In other words, supposing each consumer last year paid the cost of getting ready the plant, &c., necessary for his wants, amounting to $\frac{1}{4}d.$ per lamp per day demanded, and was then charged for all the electricity consumed at the rate of $\frac{5}{8}d.$ per unit, the result of the year's working would have shown a net profit of close upon £1,000. As, however, our initial price of 7*d.*

for the first hour each day does not yet quite cover the cost of getting ready and running during that hour, there still remains a loss on the sale of the 7*d.* units, which has obviously been made up out of the profit arising from the sale of low price units. Now, if all the units after the first hour's daily use at 7*d.* were charged at a penny each, the entire expenditure would be covered by the revenue. As, however, something undoubtedly ought to be put aside every year to the contingency fund, I strongly recommend you for the present year to fix the charge for the low price units not at 1*d.* but 1½*d.* This will ensure our making an adequate net profit, while at the same time it will give a very considerable impetus to the use of electricity in private houses and for motors. This alteration in the tariff will greatly benefit the general body of ratepayers, who will, through their district fund, get the electricity consumed by the street lamps at something under 2*d.* per unit instead of at 3¼*d.* It will also have the effect of reducing the average price paid by private houses and shops from about 5*d.* to 4*d.* per unit. It should be borne in mind that a tariff of 1½*d.* after the first hour will make electricity, if it be used regularly, as economical for power purposes or for cooking as the average gas-engine or stove. Such a tariff will enable us to supply motor-car batteries and the sea-shore tramways at an encouraging price. There are probably some 60 or 70 gas-engines still running in Brighton, and the many hours these are in use each day make it just as well worth our while to encourage their substitution by electric motors as it does for us to cater for the daytime users of artificial light. I am convinced that the effect of this tariff, which I strongly advise you to adopt, will considerably reduce our expenses per unit in supplying electricity to the ratepayers in general, as it will still further diversify the classes of the consumers supplied, and thereby spread out over the day the useful duty done by the plant and mains."

The committee recommended that the initial charge of 7*d.* per unit for an average of one hour per lamp per day be continued, and that the charge for electricity over such average be reduced from 3*d.* to 1½*d.* per unit.

In London the charges for electricity vary from 5*d.* per unit in St. Pancras, where the municipality has control, to 8*d.* in the City, where the supply of current is in the hands of a private company. The Westminster Electrical Supply Corporation charge 6*d.* per unit, and the Metropolitan Company 7½*d.* A unit, it may be explained, is the quantity of electricity required to keep a 16 candle-power lamp incandescent for 16 hours. A representative of *The Daily Telegraph* has had a conversation with the secretary of one of the leading electrical companies, and drew his attention to the report of the engineer to the Brighton Corporation. The official, while very courteous, declared his inability to accept, on the strength of a newspaper report, so extraordinary a statement as that electricity could be supplied at the rate of 1½*d.* per Board of Trade unit. He pointed out that what is known as the Brighton proposals had been entirely refuted in a correspondence which took place in an electrical journal some months ago. The representative, in reply, pointed to the engineer's report, in which the success was made quite clear—so much so, that a further reduction was proposed for the current year. To this the rejoinder was that it would be impossible to pronounce an opinion on the facts in the report. To a query as to whether the high price of electricity in London was due to increased cost of production or the desire to pay a large dividend to shareholders, the reply was that neither of these factors entered seriously into the matter. The only thing, therefore, that was made clear is that the inhabitants of Brighton can have electric light for the price of gas, or about one-half what it costs the unhappy inhabitant of the metropolis, who is, of all persons in the United Kingdom, the most dependent on artificial illumination.

STRAKER'S MOTORS.

MR. SIDNEY STRAKER, of 139, Cannon Street, London, has introduced a variety of oil motors suitable for all descriptions of motor traffic. We illustrate two of these engines, Fig. 1 representing a double-cylinder motor of four horse-power; while Fig 2 shows a single-cylinder motor of ¾ horse-power. Much

FIG. 1.

care has been exercised in designing these engines, as the various parts are easily accessible, while the lubricating arrangements are very complete. The workmanship and material are all that can be desired, and we can safely recommend these motors to carriage-builders and others who may wish to experimentally convert an ordinary carriage into one to be propelled by machinery. The following are some particulars with reference

FIG. 2.

to the four horse-power double-cylinder engine:—It is speeded at 400 revolutions per minute, and if supplied for working light oils will require petroleum of 0·68 to 0·7 s.g., or if for heavy oils such as Royal Daylight, &c. The speed of the motor is variable to the extent of about 30 per cent., which is effected by actuating the cylinder adjustments supplied with it. The total approximate weight may be taken at 200 lbs., and the circulating water necessary for this motor will vary from 10 to 18 gallons.

N 4

CONTINENTAL NOTES.

(FROM OUR OWN CORRESPONDENT.)

Automotor Race from Marseilles to Nice.

NICE, *Feb. 1st*, 1897.

FOR some considerable time past great interest has been aroused on the Continent as to the probable result of the motor contest from Marseilles to Nice. This was organised by the Comité des Fêtes at Nice, in conjunction with the Automobile Club of France, valuable prizes being offered to nearly all finishing. The weather has proved the chief drawback to those who entered for the affair, the rain and snow, which have continuously fallen for weeks past, rendering the roads rotten, and in many places absolutely unsafe. It is true that the weather cleared a day or two before the actual start, but the wind which prevailed did but little towards drying up the roads, or to make travelling easier.

During the three days of the actual race scarcely any rain or snow fell, but the wind was bitter and piercingly cold, making riding a very unpleasant matter. The course, the total length of which is, roughly, about 145 miles in length, consists of roads which are none too good, and which are very uneven, some of the gradients being extremely steep.

Six o'clock on Friday morning, the 29th ult., had been fixed for the start, but in accordance with the wishes of many of the people of Marseilles, who wished to attend the function, the time of departure was delayed till seven. The extra hour, however, did not make much difference to the temperature, the air being so wintry and the wind so biting that none but the most enthusiastic turned out. Out of the entries the good muster of 28 motor-carriages and 9 motor-cycles faced the starter, and were despatched at intervals of one minute. The following is a list of those who left Marseilles :—

M. Baulthy, Paris (Panhard and Levassor).
M. Petrus, Nice (Peugeot).
M. Charron, Paris (Panhard and Levassor).
M. René de Knyff, Paris (Panhard and Levassor).
M. Egrevi, Paris.
M. A. Lemaître, Ay. (Panhard and Levassor).
M. Prévost, Paris (Panhard and Levassor).
Comte de Chasseloup-Laubat (Dion steam tractor).
M. M. Dupré, Tours.
M. E. Giraud, Paris.
M. Laumaillé, Nice (Peugeot).
M. Albert Peter, Nice (Peugeot).
M. Beauvais, Toulon (Peugeot).
M. Bruninghaus, Nuits.
M. Albert Gautier, Nice.
M. Millaux, Bollène (Peugeot).
Vicomte de Sallmard, Nice.
Bicycle Club of Lyons (Benz carriage).
M. Vauquelin, Cannes.
M. Henri Peugeot, Audincourt (Peugeot).
M. D. Courtois, Laon.
M. Comiot, Paris.
M. E. Michelin, Clermont-Ferrand.
M. Drassel, Paris (Vacher).
M. Cahen Marcel, Paris.
M. Sibilat, Rouen.
M. A. Michelin, Paris (Dion Steam).

The following were the motor cyclists who started :—

M. Lafitte, Marseilles.
M. E. Chesnay, Dijon.
M. Rivierre, Paris (Dion tricycle).
M. Cabassus, Marseilles (Dion tricycle).
MM. Chauchard and Nicodémi, Nice.
M. Monter, Paris.
M. Marcellin, Marseilles.
M. E. Roussier.
M. Bussac, Marseilles.

The arrangements made throughout the course were admirable, the police and the municipal authorities co-operating to keep a clear passage-way by issuing notices to the inhabitants to keep the children out of danger, while suspending the traffic at special points in order that the contending motor-cars might have every chance of securing an unimpeded passage. From the commencement of the first stage, interest was centred in the doings of M. Lemaître on the Panhard-Levassor, and the Comte de Chasseloup-Laubat, whose steam tractor fairly held its own on the level, while gaining a distinct advantage on any rising ground. The inhabitants of the various villages and towns turned out in full force, and gave the automotorists a very cordial welcome as they passed. Several accidents happened towards the end of the first day's run, obstructions in the road being the chief cause of the upsets which occurred. The Comte de Chasseloup-Laubat only stopped twice on this stage—once for coke and the second time for water; he being untroubled in all other respects. His nearest antagonist, M. Lemaître, was, however, bothered a great deal with punctured tyres.

The order of arrival at Fréjus was as follows :—

	H.	M.	S.
Comte Chasseloup-Laubat	4	47	14
Prévost	5	12	11
Lemaître	5	12	17
E. Giraud	5	38	11
De. Knyff	5	43	51
Levielté	6	2	11
Gauthier	6	6	24
Peugeot	6	9	15
Chesnay (motor-cycle)	6	17	14
Vicomte de Soulier (motor-cycle)...	6	19	18
Lafitte (motor-cycle)	6	20	0
Cabassus (motor-cycle)	6	29	7
Marcellin (motor-cycle)	6	41	7
Bruninghaus....	6	46	7
Rivierre (motor-cycle)	7	18	6
Chauchard & Nicodémi (motor-cycle)	7	42	15

In the second day's run the events of the preceding one were practically repeated—steam in the person of the Comte de Chasseloup-Laubat taking the lead and easily keeping it—his nearest attendant being again M. Lemaître. Mishaps were fairly plentiful, mainly happening to the motor-cycles, which somehow seemed to be in the way. It would be useless to give the times for this stage or the short one on Sunday from Nice to La Turbie, a distance of some 11½ miles only. Suffice it to state that Comte de Chasseloup-Laubat succeeded in covering the 42 miles between Fréjus and Nice in 1 h. 50 m. 44 s., M. Lemaître arriving some 13 minutes later. The first motor-cycle into Nice was that driven by M. Monter, which was the property of Baron Zulen de Wyevelt, the time taken on the road being 2 h. 12 m. 5 s. In the last short processional stage from Nice to La Turbie yesterday (Sunday), M. A. Michelin succeeded in getting in first with his steam tractor in 31 m. 50 s., the Comte de Chasseloup-Laubat arriving second in 37 m. 50 s., and M. Lemaître third in 52 m. 55 s.

The following is the official time for the three days' race over the full distance, as issued by the authority of the Automobile Club :—

Motor-Carriages.

		H.	M.	S.
1.	Chasseloup-Laubat	7	45	9
2.	Lemaître	8	17	27
3.	Prévost	8	26	58
4.	De Knyff	9	5	14
5.	E. Giraud	9	24	23
6.	A. Michelin	9	35	50
7.	Gauthier	9	47	12
8.	Henri Peugeot	9	48	42
9.	Leveillé	10	10	24
10.	Bruninghaus	10	15	19
11.	Egrevi	11	51	6
12.	Cahen Marcel	11	56	5
13.	Peter	11	58	58

		H.	M.	S.
14.	Beauvard	12	24	55
15.	Sibilat	12	50	59
16.	Courtois	12	51	40
17.	Petrus	13	20	29
18.	Millaud	13	29	56
19.	Dravet	14	20	3
20.	Laumaillé	14	29	7
21.	Bicycle Club Lyonnais	18	6	23
22.	Dupré-Neuvy	18	10	30
23.	De Sahlmard	19	29	29

Motor-Cycles.

		H.	M.	S.
1.	Chesnay	9	23	36
2.	Marcellin	9	40	53
3.	Vicomte de Soulié	9	46	18
4.	Monter	10	13	31
5.	Rivierre	10	29	57
6.	Cabassus	10	33	15
7.	Chauchard-Nicodémi	10	45	30

In this instance steam was unquestionably successful, and the result can only provoke another contest over a longer journey, in which the stages should be much longer, and more equally distributed over the number of days occupied than was the case in this instance. The time taken by the winner was very good under all the circumstances, the average speed per hour being 19 miles.

The French Automotor Competition of July.

The Automobile Club of France have officially issued the regulations for the competition, which, as previously announced in these columns, they have arranged for July of this year. The rules are as follows:—

Minimum weight of transport cars for travellers or merchandise, one ton.

Article 1.—A competition organised between autocars (automobiles, traction carriages, and road trains) for the following purposes:—

(1) Public transport of persons in the towns; communication between the railway stations and places not directly connected by railway.
(2) Services for the delivery and transport of goods.

Article 2.—The meeting or competition will take place on several routes branching from a town situated in the neighbourhood of Paris, the 1st of July, 1897, and following days.

Article 3.—The competition will have regard to cost—that is to say, will consider the load and the total expense of carrying it; it will take account of the different factors which influence the net cost, and of the connection between the weight carried and the weight of the rolling stock, as well as the comfort of the same.

Article 4.—The following will be admitted to the competition:—

(1) Vehicles which will carry (exclusive of conductors) at least ten passengers, with 30 kilogrammes of luggage.
(2) Vehicles for goods, carrying a minimum of a ton.
(3) Mixed vehicles, built in view of the transport simultaneously of travellers and merchandise, with a minimum of weight carried of 1,000 kilogrammes.

The Commission will make classes, according to the carriages engaged in the competition.

All the vehicles must have the certificate of class furnished by the Commission of the Automobile Club.

The competition is international.

Article 5.—The number of vehicles is not limited, but no constructor can send several vehicles of the same type and of similar dimensions.

Article 6.—For each vehicle entered an entrance fee of 200 francs must be paid up to June 1st, or twice this amount after that date.

The entrance list will be closed at midnight on June 25th.

Every application for entry must be accompanied with the entrance fee, which in all cases will be acknowledged.

Article 7.—Every competitor should send before June 15th a photograph of the vehicles he is entering, together with the selling price.

The competitors must send in good time to the *locales*, to be named by the committee of the Automobile Club, the necessaries required for the competition.

These articles will be afterwards delivered to the competitors under the authority of the Automobile Club.

All the vehicles should be able to run a distance of 15 kilometres at least without needing replenishing.

Article 8.—The trials will consist of a six days' service, constituting a total run of 300 kilometres.

Each vehicle will twice make the following series:—

First Series: Route A, 40 kilometres, with stoppages every 1 kilometre.

Second Series: Route B, 50 kilometres, with stoppages every 5 kilometres.

Third Series: Route C, 60 kilometres, with stoppages every 10 kilometres.

There will be stoppages appointed on ascents and declivities, on macadamised and paved roads.

The vehicles engaged will be divided into groups, so that each day in each of the three directions A, B, C, they will carry different loads.

All the vehicles will run with the load according to their capacity as stated by their owners.

Article 9. The Commissioners, chosen among the members of the Commission of the Club not competing, will accompany the vehicles. They will be charged with—

(1) Noting the amount of consumption of oil for fuel and lubricating, &c.
(2) Timing the courses at the stopping-places and by the way, according to the regulations which will be given them by the Commission.

The speed on the rising ground will be considered from the point of view of its effects on the stability of the vehicle. The Commission will decide the maximum of speed to impose on each vehicle following its conditions of entry, and the Commissioner will be charged with seeing them respected.

(3) Noting in each case the distance the vehicles run before completely stopping under the action of the brake.
(4) Noting their estimation of the vehicles in reckoning the facility of their control of going forwards or backwards, of their security and comfort, of the expense of keeping them up, of their capacity to redeem the capital charge on them, of the frequency, the importance, and the facility for doing repairs, and of the frequency of replenishing.

Article 10.—In the town which is the centre of the competition there will be a place where the "stabling" of the vehicles will be obligatory.

Repairs must be made in the presence of the Commissioners.

Article 11.—Medals and diplomas will be granted to the vehicles which are recognised as fulfilling the conditions requisite for one of the services in view of which the competition is organised.

There will be prepared by the Commission a report, giving a reproduction of the photograph of each vehicle and the details of the competition.

This report will be sent by the President of the Automobile Club of France to the Society of Civil Engineers of France, to the industrial Societies of different localities, and to the Maires of Communes. It will have, in short, all the publicity possible.

Article 12.—Competitors must conform to the ultimate decisions of the Commission, particularly in regard to the details of the regulation of the trials.

Article 13.—The civil and penal responsibilities which rest upon the competitors being so well understood, the Commission decline all responsibilities whatever in this regard.

o

NOTICES.

Contributions and articles likely to prove of interest to our readers will receive due attention, but in all cases the name and address of the writer must be given, not necessarily for publication.

All matter intended for publication should reach us not later than the 10th of each month. Stamped envelope must be sent if the manuscript is required to be returned.

All Advertisements should be sent to the Advertising Department, F. King and Co., Limited, 62, *St. Martin's Lane, London, W.C., where Advertising Rates may be had on application.*

The Annual Subscription is 7s., including prepaid postage to any part of the world.

Cheques and Post Office Orders should be made payable to F. King and Co., Limited, *and crossed London and County Bank; otherwise no responsibility will be accepted.*

The Automotor and Horseless Vehicle Journal *can be obtained through* Messrs. W. H. Smith and Son, *and at* Willing and Co.'s *bookstalls.*

When any difficulty is experienced in procuring the Journal from local newsvendors, intending subscribers can obtain each issue direct from the Publishing Office, by filling up and forwarding, with remittance, the Subscription Form accompanying the Paper.

The Automotor and Horseless Vehicle Journal.

A RECORD AND REVIEW OF APPLIED AUTOMATIC LOCOMOTION.

FEBRUARY 17TH, 1897.

ANSWERS TO CORRESPONDENTS.

Angus (Liverpool).—The best test would be for the makers to enter for *The Engineer* contest, when they could be certain of absolutely fair play; but, as we are advised, they have no intention of taking that course.

J. Hartland (Belfast).—The engines are 6 inches in diameter, with a stroke of 10 inches; the normal pressure being 60 lbs., the cut-off takes place at three-eighths of the stroke. Our experience is that they are somewhat noisy, but reliable.

Inventor (Holloway).—It is only part of a complicated game of bluff. Wait until some firm of standing is attacked; you will see a very different result.

G. MAURICE (Hartlepool).—Benzine which flashes at the temperature stated is prohibited by Statute.

STUDENT (Dublin).—Write to Whittaker's and Longman's for their catalogues; they both publish works which will be of service to you.

A.S., E.R., G.N., W.B., and E.S.—Illness and absence from town must be pleaded as the only excuse for want of attention; but you shall find in the next issue the items you inquire about.

MECHANIC (Coventry).—The differential speed gear shown in the engraving you send was probably known to the engineers of ancient Babylon; but that fact does not, of course, prevent anyone calling it a "master patent" in 1897.

IGNORAMUS (Greenhithe).—If you will submit a definite problem we will work it out for you, as you frankly state that you are ignorant of the first principles involved.

GEORGE MCINTYRE (Leeds).—We cannot identify the vehicle by the meagre description you send. Probably it belongs to the Motor Syndicate, who have purchased a number of Continental carriages.

ARCHDEACON OF TUAM.—We cannot in the present transitory stage of the industry advise the purchase of any particular carriage or motor for the purpose you mention. The next few months will see some radical changes, and the chances are very great that you would eventually repent buying any of the makes which are for the moment before the public.

W. BOURNE (Perth).—For some reason the Thirsk correspondent now declines to go further into the matter.

H. W. WEBB (Beckenham).—Several makers are experimenting upon compressed gas as a motive power for light carriages, but hitherto we have not met with a thoroughly satisfactory system. The charging will, of course, always be a difficult matter.

H.A.P. (Glasgow)—Thanks for your letter. The pocket-book is not all we should like, but to compare it with those which have been in existence for nearly 20 years is hardly fair. A work of that kind can only be a thing of gradual growth. We have many tables and data in hand already to improve the next. The firing arrangement of the invention you mention has been altered, and we will illustrate it in an early issue. The copy of the specification is not yet ready—we will advise you when it is published.

P. THOMPSON (Dublin).—In nearly every instance the steering is effected by means of the front wheels, but independent gear as we have illustrated is used.

MATTHEW DONALD (Manchester).—The wheel is the subject matter of a patent, and as you are already in communication with the makers they are the proper people to apply to.

PUBLICITY (Glasgow).—You had better apply to our publishers, Messrs. F. King & Co. (Limited), 62, St. Martin's Lane, London, W.C.; they will advise you on the questions involved as to the best method of obtaining the greatest publicity for your exhibition.

TYRES (Northampton).—The general opinion appears to be that for heavy traction work ordinary pneumatic tyres are useless.

JAMES (Hartlepool).—The thickness should certainly not be less than three-eighths of an inch. If you tried to make the walls thinner you could not get a sound casting.

J. DIXON (York).—It is rumoured that an amalgamation of some of the great builders has been actually accomplished, with a view to the subsequent addition of a motor branch.

A. YOUNG (Antwerp).—We cannot give you the information. Provisional protection only has been applied for, and therefore nothing has been published.

E. H. (Yarmouth).—There is nothing unusual in such a course. It is surely worth paying the extra money to have the opportunity of being off the bargain at any time you choose.

SPECULATOR (Devon).—There is no market, and consequently no reliable price for the shares.

!"CUANDO escribe, refiérese Al "THE AUTOMOTOR AND HORSELESS VEHICLE JOURNAL."

THE SHUFFLING TRICKERY OF THE BRITISH MOTOR SYNDICATE.

WHEN the promoters of the £3,000,000 *fiasco* based upon the ruins—we can scarcely call such a substructure a foundation—of the British Motor Syndicate issued their recent prospectus to the public we denounced the document as a dishonourable one. While adopting an extreme step of this kind we took the opportunity of expressing a hope that those concerned in that impudent attempt to fleece the public of money would, for the sake of the industry in which we are all concerned, mend their ways, and do their best, by manufacturing motors and carriages, to justify the position which they had assumed as leaders in the automotor world.

We greatly regret to find that every step taken by the Syndicate, and every glimpse that outsiders can obtain as to its methods of management, only tends to more conclusively prove that the policy of this Company is one of bluff and nothing more.

During the last month, many instances which would prove this contention have cropped up, but the bare mention of a few will suffice. On the front page of a contemporary, which we regret to mention is strongly suspected of being within the "sphere of influence" of the British Motor Syndicate, we find, under date the 23rd ult., the following notice printed in flaming red letters:—

BRITISH MOTOR SYNDICATE

v.

HON. C. S. ROLLS.

PATENTS UPHELD.

MR. JUSTICE NORTH GRANTS PERPETUAL INJUNCTION.

THE DEFENDANT PAYS.

"Licenses are granted to manufacture on advantageous terms, but proceedings will be instituted immediately, claiming an injunction and damages, against any person infringing any of these rights."

Now, in order to appreciate this manifesto at its true value, it is necessary to go back to the £3,000,000 prospectus, in which it was stated that the British Motor Syndicate held all the "master patents" for motor-carriages in this country. As a matter of fact, they do not possess a single one—and this fact has been pointed out by every independent technical journal in the kingdom — but awkward things, like facts, rarely trouble the conscience or the digestion of "Showmen" of the calibre of those who rule this Syndicate. In private conversation and in public speeches they had talked wildly of the injunctions which they meant to obtain to prove their position, and so something resembling snch a legal progress had to be obtained at any cost. Their appreciation of the valne of an injunction somewhat resembled Sam Weller's love of the magic word "alibi"—it had to be got—anyhow, at any price, and on any terms, and then the position wonld be saved, as the engineering world would at once bow to the all-powerful Syndicate.

The victim selected for the experiment was the Hon. C. S. Rolls, who is a member of the Motor-Car Clnb, and, in the eye of the law an infant. He is an enthusiast in antomotor carriages, and he has always been foremost in placing his vehicle at the disposal of those who were likely to help on the movement. In October of last year, when he desired to purchase a motor-carriage of the Pengeot type, he wrote to Mr. H. Lawson and the British Motor Syndicate (Limited) for information as to who represented M. Pengeot in this conntry, and from both qnarters he received a reply that they regretted their inability to give the desired information, not being agents for the firm in question. As a result, he bonght a carriage on the Continent, and brought it to England, when he was threatened by the Syndicate with an action if he did not pay them a royalty in respect of the motor nsed.

We have no desire to enter here into all the complicated legal questions which would arise even if the Syndicate's patent in this car happened to be a valid one, bnt we may mention that, on the facts as stated to us by the Hon. C. S. Rolls, wo have a strong legal opinion that in no case conld he have been made liable for a royalty or for damages. The gnardians of the defendant in this case, however, took a rational conrse. The Hon. C. S. Rolls is an amateur rider, he has bnt little at stake in this hobby, and they came to terms with the Syndicate, as the cheapest way ont of their difficnlty.

What were the terms? That the British Motor Syndicate should pay their own costs, and that in consideration of a nominal payment of £15 they would give Mr. Rolls a perpetual license to use this carriage. Where is the victory? Where is there any npholding of patents? As a matter of fact, not a word was said on that snbject. These patents are to-day as free from the stamp of legal approval as they were when they were first transferred to the Syndicate.

When snch efforts as these are made to hoodwink the public, and when we are told that the Articles of Association of the Syndicate contain snch extraordinary clauses as those which are reprinted in another colnmn, it is small matter for wonder that shareholders who have been dnped into applying for an allotment are combining to get their freedom from the snares by which they have been entangled. We read, too, that the Earl of Winchilsca has resigned his seat on the Board of Directors of the Great Horseless Carriage Company, and that Mr. E. T. Hooley is seeking to minimise his connection with Mr. Lawson. He states that he was asked to act as broker to the British Motor-Car Company, and he did so, receiving a fee therefor. He did not take any shares in the Company, nor had he anything to do with floating it. His only connection with the Company was in the capacity of broker. If those connected with the Syndicate cannot or will not mend their ways then the sooner the concern is dead and buried the better. The longer it goes on in its present way the less reputation will be left to all who are connected with the concern, and when the bnbble does burst the worse will it be for all who are now trying to pnff it ont to the fullest possible size.

MECHANICAL HAULAGE BETWEEN LIVERPOOL AND MANCHESTER.

That practical steps are now to be taken in the direction of promoting mechanical hanlage between Liverpool and Manchester is evident. A meeting was held last week of the Prize Scheme Snb-Committee of the Liverpool Branch of the Self-Propelled Traffic Association, at which Messrs. Alfred Holt, A. L. Jones, A. Bromley Holmes, and E. Shrapnell Smith (Hon. Sec.) attended. The proposal to offer a premium for the best self-contained motor-wagon was deferred. The Snb-Committee then considered the qnestion of advertising for tenders for the conveyance of goods between Liverpool and Manchester by mechanical hanlage, and a resolntion in favonr of this conrse was adopted. Tenderers are to base their offers on the assumption that the weight to be carried will not be less than a thousand tons per week, and the time occupied in transit must not exceed fifteen honrs. We trnst that a practical resnlt will be obtained, as the conditions are eminently business-like, and shonld attract the attention of some of our leading engineers.

MOTOR-CARS FOR DUST COLLECTING.

The Urban District Council of Chiswick is among the first of local authorities to adopt the steam motor-car for the purposes of the collection of dust and house refuse. Hitherto the Council has followed the course pursued by its predecessor, the Chiswick Local Board, and has let the dust collection to contractors. Under this system the cost has increased yearly, while the work has been very inefficiently performed, complaints being constantly received of the non-removal of dust. At a recent meeting the Council received tenders for dust collection for the year from April 1st next at £2,000 and £1,900 respectively, the latter sum being £460 in excess of the sum for the year ending on March 31st next. Before accepting either of these tenders the Council instructed the surveyor, Mr. Arthur Ramsden, to report as to the saving likely to be effected by the purchase for dust-collecting purposes of a steam motor tip-car, a design for which, prepared by Mr. John I. Thornycroft, had been submitted by the Steam Wagon and Carriage Company of Chiswick. This could be purchased for £350. The surveyor reported that if two of the motor-cars were purchased at the price stated, and the payment spread over three years, he estimated that there would be an immediate saving of £50 a year, and that at the end of three years the saving would be about £250 per annum. The Council has decided to purchase two of the motor-cars on the terms suggested, to be delivered on March 31st next.

DOINGS OF PUBLIC COMPANIES.

The British Motor Syndicate.

THE *Financial Times* has been busily investigating the prospectus which was issued by the above Syndicate, and states that the numerous requests for advice led them to re-examine the prospectus of this bombastic undertaking, and a point that seemed worthy of attention was the fact that the Memorandum of Association was conspicuous by its absence. Its place was taken by a number of mediocre illustrations, and the only satisfaction obtainable was in the statement that "the Memorandum and Articles of Association . . . . can be inspected at the office of the Syndicate." Unwillingness to encroach upon the time of the Syndicate's officials, whose energy, we fancy, must be fairly well exhausted by the demands for a return of subscriptions, led them to pursue their investigations at Somerset House, with results that they venture to describe as astounding in the extreme. It will be remembered that the Syndicate was originally formed with a capital of £150,000, in November, 1895. Nine months later this amount was increased to £1,000,000. The Articles of Association, dated 21st November, 1895, contain the following clauses:—

Transfer and Transmission.

18. Save as hereinafter provided, no share in the Syndicate shall be sold or transferred to a person who is not a member, provided that it shall be in the discretion of the directors to determine that any share or shares in the Syndicate may be sold or transferred to any person or persons who is not a member.

19. Save as hereinafter provided, any member of the Syndicate proposing to transfer any shares in the Syndicate (hereinafter called the retiring member) shall give notice in writing to the Syndicate that he desires to transfer the same. Such notice (hereinafter called the transfer notice) shall constitute the Syndicate his agent for the sale of the shares, at a price to be fixed by the directors, or if such price is disputed by the retiring member, at a price to be ascertained by arbitration pursuant to the Arbitration Act, 1889. In case the transfer notice shall include several shares, it shall operate as if it were a separate notice in respect of each share. The transfer notice shall not be revocable except with the sanction of the directors.

20. If the Syndicate shall, within two months after being served with the transfer notice, find a purchaser for the shares, and shall give notice thereof to the retiring member, he shall be bound, upon payment of the price fixed in accordance with the last preceding article, to transfer the shares to the purchaser.

21. If the retiring member, after having become bound as aforesaid, makes default in transferring the shares, the Syndicate may receive the purchase-money, and shall thereupon cause the name of the purchaser to be entered upon the register as the holder of the shares, and shall hold the purchase-money in trust for the retiring member.

22. The receipt of the Syndicate for the purchase-money shall be a good discharge to the purchaser, and after his name has been entered on the register in purported exercise of the aforesaid power, the validity of the proceedings shall not be questioned by any person.

23. If the Syndicate shall not, within two months after being served with the transfer notice, find a purchaser for the shares, and give notice in manner aforesaid, the retiring member shall be at liberty to sell or transfer the shares to such person, and at such price as he shall think fit. Provided that he shall first have given an option to the directors to find a purchaser at that price, and they shall not, within ten days after such option has been given, have found a purchaser accordingly.

24. The shares specified in any transfer notice shall, subject to the directors' discretion, mentioned in Art. 18 in the first instance, be offered to the members. Such offer shall be made by a written notice specifying the number of shares to which the member is entitled, and limiting a term within which the offer, if not accepted, will be deemed to be declined. After the expiration of that term, or the earlier receipt of an intimation from the member to whom such notice is given that he declines to accept the shares offered, the directors shall be at liberty to sell such shares to any person or persons as they shall think fit, at the price fixed in accordance with Art. —.

In face of these extraordinary articles we cordially endorse the following remarks made by our contemporary:—

"In the course of a fairly extensive experience of public companies and their ways we have never heard of such extraordinary provisions as those contained in the above articles. It would not be surprising to find a private syndicate erecting ingenious barriers to prevent the introduction of an unfriendly element upon the death or defection of one of its members, and we trust that when the matter has been brought before the notice of Mr. Harry J. Lawson, he will promptly assure us that the articles we have quoted were devised to meet such a contingency in the days when the Syndicate comprised merely a small circle, and when harmony and unanimity were essential to the building up of the huge scheme with which the world is to-day only too familiar. The members of the Stock Exchange who are now dealing in the shares; people who have realised, or desire to realise, their holdings even at the depreciated price now ruling; those who may possibly see some potential value in the shares, and who after purchasing run the risk of finding the transaction cancelled—all these sections of the community have a right to demand from Mr. Harry J. Lawson an immediate explanation.

"Either the arbitrary powers conferred upon the directors still hold good, or else they have been waived. In the former case, a monstrous disability is imposed with regard to the disposition of the holdings; in the latter case, the public should be assured that they are perfectly at liberty to buy or sell in the open market, in accordance with the universal practice. Assuming that the above articles still exercise binding force, the shareholders who have already commenced to repent, and who have sought to free themselves from the consequences of their foolishness, will repent the more, and will be stimulated to further efforts for the return of their money, while those who have bolstered themselves up with hopes that all may yet be well will begin to entertain serious misgivings concerning the future. At present there is practically no possibility of organised opposition to the management—excepting, of course, the legal proceedings that are understood to be pending. There is no statutory meeting of shareholders to afford an opportunity for protest, as this function must be presumed to have been held in the days of the Syndicate's obscurity. We believe that the great bulk of the shares are still held by Mr. Harry J. Lawson and his colleagues, and if this be so, the convening of an extraordinary meeting is probably impracticable. The annual meeting is not likely to be held yet awhile, so that the complaisant individuals who took part in the recent junketting at Coventry may not be able to renew for some months to come the acquaintanceship then formed. We regret that that opportunity for a serious consideration of the position was not taken advantage of either by Mr. Lawson or by those of his critics who possessed the necessary *locus standi*. Denunciation of 'printers' twaddle' is interesting, and, indeed, amusing, but a reply to honest criticism would have been more to the point."

London Electrical Cab Co. (Limited).

THE statutory general meeting of the shareholders of the London Electrical Cab Company (Limited) was held on the 29th ult., at Winchester House, Old Broad Street, Mr. H. H. Mulliner (the chairman of the Company) presiding.

The CHAIRMAN said: Our attention has been called to several very silly letters in the papers, wondering why a large number of cabs are not already on the streets of London. Well, it is perhaps hardly necessary to explain that until the Company was formed and the capital received it was quite impossible to order the cabs, and when they are ordered they require to be built, all of which takes some time. It would have been quite possible to have had one ready by now, and with this one we might have organised trial trips, &c., with newspaper reporters present, and have so created an impression that we were very busy people. Personally, I am very tired of hearing about trial trips with motor-carriages, and I think some of the public are in accord with me with these views. What would interest them and me much more would be to see a number of electrical cabs which would not only run a trial trip, but which would run commercially, and which would be capable of earning a dividend to the shareholders. (Applause.) As far as actually running an electrical carriage is concerned, there is no difficulty about that. Mr. Bersey, whose services we have, and the whole of whose patents we have acquired the use of, run electrical carriages several years ago, which were quite as good even then as any electrical omnibus or other electrical motor-carriages which have been seen or heard of recently. Since then, and previous to the formation of this Company, Mr. Bersey has wonderfully improved these carriages, and, as referred to in the prospectus, had already attained a great degree of perfection with them. Our responsibilities are, however, much more serious than building electrical carriages, which will simply run along to the astonishment and delight of the public. Our responsibility is to build electrical carriages not only which will run along to the satisfaction of the users, and fulfil all the requirements of the Act, but which will be suitable to stand the immense amount of wear entailed by daily public use in London, and, what is still more important, they must be so constructed and so arranged, both as regards the supply of electricity and the durability of their parts, that they will be capable of earning good dividends for the shareholders. And whilst on this subject, I should like to trouble you with our views on electricity as a motive power for vehicles in London, because our views vary very much from what is generally understood on this subject. I have no belief whatever in the idea that persons will be able to buy an electrical carriage and keep it themselves, and charge it with electricity from the ordinary electric light arrangements that they may have fitted up to their house or stables. It might happen in a few cases that persons could do this, but they would have to have considerable expensive electrical apparatus, and they would also have to have a competent electrician to deal with the necessary charging, &c. Further than this, as the cost of electricity depends upon the amount which is used, the supply would prove very expensive, and no makers of accumulators would probably be willing to guarantee the accumulators to individual persons, as there would be considerable doubt as to their being properly looked after. But I have the very greatest belief in electricity as the future motive power for street traffic in London, where, in cases like the London Electrical Cab Company, it can be organised on a thoroughly business-like basis, *i.e.*, where you can have one experienced man responsible for the charging of the accumulators, and where you can contract with the supply companies and the accumulator makers, and where you can have exactly the apparatus necessary for taking the accumulators on and off, &c. Then the drivers need have no knowledge at all of electricity, and have nothing to think of except conducting the vehicles, every precaution having been taken to ensure that these drivers should not be able in any way to interfere with and so possibly damage the electrical apparatus.

Now as to what we have actually done in these two months. Our first thought was, naturally, to design the cabs. I have here 30 drawings, showing how thoroughly this work has been done; but these drawings, now they are completed, do not nearly represent the work which has been put into them. I believe these drawings now represent a perfect and suitable vehicle; they are the result of the whole of Mr. Bersey's experience of eight years, together with Mr. Brougham's experience as a practical electrician, and any experience I may claim to possess as a practical coachbuilder. I wish to mention here the obligation we are under to the Great Horseless Carriage Company, who have lent us their draughtsmen, their engineers, and aided us in every way in their power. You will remember that on the prospectus a report from Mr. Manville was published, and we naturally considered that no vehicle should be commenced until Mr. Manville had passed it as being, in his opinion, perfect. I believe Mr. Manville to be the highest authority we have in all matters of electrical traction, and before he passed these drawings and specifications, which he has now done, he thoroughly went into every point with us, and suggested many valuable improvements. Perhaps the most valuable improvement to which I refer is the Johnson-Lundell Series Parallel Controller. This invention will produce the following results:—(1) It is the only invention which enables the electricity to be used in exactly the ratio that it is required—*i.e.*, there is no perpetual waste of electricity going on through resistance or other means, as is usual. This alone would save from 35 per cent. to 40 per cent. in the amount of electricity used. (2) It will considerably simplify the construction of the vehicle by saving several complicated changes of speed-gearings, &c., and by saving these and the necessary handles it will make the driving of the vehicle much easier. After considerable negotiations we have acquired the sole use of this invention for the purposes for which this Company is formed by payment of a royalty per vehicle, and after payment of this royalty the price of the vehicle will be reduced below the cost at which it could be constructed without it. We have, further, gained the hearty co-operation of the British Thomson-Houston Company, the largest and most experienced makers of electrical traction apparatus in the world.

Another step was to obtain suitable premises. In this direction we consider we have been fortunate. We have taken a lease of large premises in the most convenient spot in London for our trade, viz., Lambeth, near Westminster Bridge. Next, the question of the electrical apparatus for transforming the electricity and for taking off and removing the accumulators, &c. This has all had to be worked out in the same way and tendered for, and is now on order. One more matter, and perhaps the most important—that is the accumulators. Mr. Manville drew up a complete statement of the various requirements, and invited tenders and samples from every maker of repute. These samples are being tested at Faraday House in a perpetual state of vibration, or as near as possible the same conditions they will be subjected to in actual use. Meantime, for our first vehicles we had to order accumulators, and I am glad to say that we have been able to place this contract with the Electric Power Storage Company. I need hardly say that we insisted, and the Electric Power Storage Company agreed to guarantee these accumulators at 10 per cent., as stated on the prospectus. I should like to add that the more I have gone into this the more confident I am that electricity is the future motive power for street traffic in London, and I confidently believe that the original shareholders in the London Electrical Cab Company will have much to congratulats themselves upon in the future. There is one thing more we have to congratulate ourselves upon, viz., that instead of having to spend money in building works and putting down expensive machinery, &c., this Company is, up to now, practically incurring no expenses whatever.

Mr. Green. I should like to know how many shares have been allotted, and how much has been paid up?

Mr. Wiltshire. Will you kindly say how many cabs you propose to run?

Captain Frederick. Will the tariff to the public be the ordinary tariff of the London cabs, or similar to the present system now adopted in London; or will there be a special rate?

The Chairman. In reply to the questions which have been asked, I may say that the total amount subscribed by the public was something like £63,000, and the vendors were most reasonable with the Company in making the following conditions, which I think you will admit are very fair. The conditions were, first, that the proportion of working capital should remain exactly the same as stated in the prospectus, viz., the unusually large amount of two-thirds working capital, and one-third to the vendors. This leaves us with about £42,000 working capital, which is ample to prove the success of this business, and when that success is obtained then the balance of the Company's capital will, I am sure, be readily subscribed, and I hope at a good premium, of which the shareholders will have the benefit. Then, and not until then, will the vendors receive the balance of the agreed purchase price. (Applause.)

Mr. GREEN. Do I understand that amount has all been paid?

The CHAIRMAN. The £63,000 has been fully paid. Mr. Wiltshire asked how many cabs were to be constructed at first. The first lot which will be put on the streets will be 24 in number, but that is no exact criterion, because as soon as these are built the others will come on quickly. The actual commencement will be with 24 cabs, the others coming on as fast as there is a demand and they can be finished off. Captain Frederick inquired if the tariff for the use of these vehicles will be the same as for ordinary cabs. It will be exactly the same. That matter is not in our hands: the cabs will be all licensed by the authorities of Scotland Yard, and as they fix the fares we have no right to charge more, but no doubt we could charge less.

A vote of thanks was passed to the Chairman and directors, and the meeting separated.

New Companies Registered.

[Under this heading we intend in future giving a full list of any new Companies registered which take power to make, deal, or become interested in any manner in automotor vehicles. Where detailed particulars are not given under this heading we shall be pleased to reply to inquiries through the "Answers to Correspondents" column. All communications should be addressed to the Editor. The only stipulation which we make is that where the inquiry involves a search of the records at Somerset House—as in the case of information on the subject of the holdings of shareholders—a postal order must be enclosed to cover the Government stamp of one shilling which is charged before a search is allowed to be made.]

	Capital. £
Anglo-Bavarian Steel Ball Co. (Limited), Birmingham	50,000
"Blot" Electric Accumulator (Limited)	160,000
Britannia Cycle and Component Parts Co. (Limited), Birmingham	2,000

Westminster Engineering Co. (Limited)	20,000

New Issues.

THE LONDON MOTOR-VAN AND WAGON COMPANY (LIMITED).

THE London Motor-Van and Wagon Company (Limited), with a share capital of £300,000, is a Company formed to manufacture, sell, or let out on hire motor parcels delivery vans, motor carriers' vans, and the like. The idea of applying the motor to this purpose is eminently practical, and will be welcomed by the public for reasons both of convenience and economy. With a board of directors, composed of successful business men like Mr. H. R. Paterson (Carter, Paterson, and Co.), Mr. W. R. Sutton (of Messrs. Sutton and Co., the well-known carriers), Colonel Lewis Vivian Lloyd (director of the London and North-Western Railway), Mr. D. E. Cardinald (director of the Manchester Brewery Company), and Mr. James S. Burroughes (of Messrs. Burroughes and Watts, billiard table manufacturers), the affairs of the Company are certain to be properly administered, and the investing public can be sure that what can be done in a practical form to prove the value of motor vehicles as applied to commerce will be done to the very best of the ability of the able board of directors. With such facilities as these gentlemen have at their command for furthering the interests of this Company, the shareholders should reap a splendid harvest as pioneers commercially of this new industry. A very good feature of this issue is the fact that £150,000 is to be reserved for working capital, whilst the vendors' shares are deferred, and receive no dividend until 5 per cent. has been paid on the ordinary shares. As showing the great interest taken in this development of the motor industry by business people in London, the directors have received encouraging letters from such people as Mr. F. Colman (of J. and J. Colman, mustard manufacturers), Peter Robinson, Harrod's Stores, Liberty and Co., D. H. Evans, and many others, all of whom express their belief in the benefit which will accrue from the enterprise. The lists open on February 17th and close February 19th. Prospectuses can be obtained at the offices of the Company, 6, Old Jewry, London, E.C.

LEATHER SHOD WHEEL COMPANY (LIMITED).

WITH a capital of £300,000 in £1 shares, of which 200,000 are offered for subscription at par, the Leather Shod Wheel Company (Limited) has, the prospectus states, been formed to take over the patent rights for the United Kingdom of an improvement in wheels, namely, the leather tyre invented by Messrs. Pierron and Klein, which it is claimed should supersede all present forms of vehicle tyres, as it is elastic, durable, quiet, cheap, and light running. Although the elastic qualities of leather have long been known, it is only now that it has been successfully applied to wheels of vehicles, to lessen the shock of contact with the ground and reduce vibration, for which purpose it has proved itself an admirable substitute for rubber, being more durable and much cheaper. Orders for tyres have been received from the Bank of England, the House of Commons, the Mint, and other bodies and corporations, and the leading railways and omnibus and cab concerns. Numerous advantages are claimed for the invention over existing tyres, and large profits are anticipated. In addition to the patent of Messrs. Pierron and Klein, the Company acquires various patents and applications for patents which are considered of importance in the manufacture of tyres of this class, whether of leather or rubber. The purchase price is £100,000 in shares and £140,000 in shares, cash, or shares and cash, 60,000 shares being reserved for working capital.

MECHANICAL HAULAGE ON COMMON ROADS.

A meeting of the Liverpool and District Centre of the Self-Propelled Traffic Association was held at the Royal Institution, Liverpool, on Tuesday, 19th ult., when a paper on the above subject was read by Mr. W. Worby Beaumont, M. Inst. C.E., M. Inst. Mech. E. Mr. Alfred Holt presided. It may be mentioned that Mr. Beaumont left London on the Tuesday afternoon and returned by midnight train, special permission having been obtained from Mr. Justice Henn Collins in the Queen's Bench Division, who was hearing a case concerning oil-engine patent rights, in which Mr. Beaumont was chief expert witness. Mr. Justice Collins said he understood Mr. Beaumont was to "give a lecture in Liverpool and be back in time to lecture me to-morrow."

The Chairman said Mr. Beaumont was going to give them information as to mechanical haulage on common roads, which was a subject of greater interest than he (Mr. Holt) could easily describe. If mechanical haulage on common roads could, by the ingenuity of the engineer, be brought to anything like the perfection of haulage on railways, many questions of great importance to the world, and especially to that locality, would be solved. The very heavy charges and the clumsiness of traffic would be obviated, and we should be able to carry on a traffic in a variety of articles we had never thought of. (Hear, hear.)

Mr. Beaumont's paper was as follows :—

Since last I had the honour of speaking on this subject in Liverpool, the development of the mechanically-propelled road vehicle has not been sufficient to change the situation of the would-be user. The Locomotives on Highways Act of 1896 came into force on the 14th of November last, after the preparation of regulations under the Act by the Local Government Board, and on that day an impressive proof of the great interest taken by the public in the self-propelled vehicle was afforded by the vast concourse of people who assembled in and near London and Brighton to witness the start and run of a number of motor-cars from the Hotel Metropôle of the one, to the Hotel Metropôle of the other. This demonstration of the capabilities of the motor-carriage was organised by the Motor-Car Club to mark the end of the old regime of unreasoning opposition to mechanical power on the high roads, and the commencement of a new era, marked, as it is hoped it will be, by the advantages which belong to facility of transport for men and things.

For all practical purposes the motor vehicle, and the motor-hauled vehicle, is now free to use the roads. The Local Government Board rules and regulations are very satisfactory, and Mr. Hugh Owen and Major Tulloch are to be congratulated on so very successful a first effort. Some slight modification will no doubt be found necessary after a year or so of working, and those who made the regulations will, no doubt, in the same enlightened spirit make such modifications as may be dictated by expediency from the mechanical, commercial, and transport facilities points of view.

Until this freedom was actually obtained, British engineers were loth to spend either time or money on the design of motor vehicles to suit modern requirements, or to embark on a career of that most expensive of occupations—namely, experimenting. Hence, although they are now free, they are not ready, and it will be some time before anything like a generally acceptable design for motor vehicles for the heavier work will be reached. For the lighter vehicles, the Continental makers have already arrived at designs which must be accepted as meeting the requirements of those who are prepared to look upon the benefits derivable from the use of motor vehicles as sufficient to merit some care ; to merit the bestowal on the motor and its gear of a part, at least, of the care and consideration which would otherwise have to be spent on a horse or horses. I am quite aware that these vehicles are almost all propelled by mineral spirit motors, and that there are valid objections to the use of this spirit, because of the care necessary, the smell of the exhaust, the necessity of constant running, and the vibration when the vehicle is standing. The third and fourth of these objections will be gradually removed ; the first two belong equally to a horse, and the first—namely, the care—attaches to the possession of almost everything worth having. The amount of careful attention necessary, or of care imposed, will, however, be lessened by the use of motors in which petroleum-oil is employed as fuel, and there is reason to believe that this will ere long be found possible. Indeed, at least one kind of small motor-carriage is at present running with ordinary lamp-oil. This lessens care or apprehension of danger, but at present does not lessen trouble or smell, and the undisputed easiness which attends the vaporisation and combustion of mineral spirit, and the simplicity of the motor parts required for its use, have to be given up as the price of the greater safety and greater economy. The price of a suitable mineral spirit or oil of easy evaporation will no doubt decrease with the increased employment, as the present high price is partly caused by regulations which have now been modified, and the consequently small incentive to refiners in this country or to oil merchants to keep in stock the foreign distillate.

The use of heavy oil depends much on the achievement of a sympathy of action between the oil-feed and the amount of resistance which the engine in very varied work experiences. Even more than this must be attained, for it is necessary that the cutting off of the oil-feed shall anticipate by a working stroke the cutting off of the work. When this is done, foul exhaust as an attendant of variable work will be avoided, and one of the greatest objections to the heavy oil removed. This has been very nearly if not quite achieved in the new Roots motor, in which the governing by the exhaust also governs not only the draught of oil-vapour into the cylinder, but the supply of oil to the vaporiser.

The objections to which I have referred obtain chiefly with reference to motors and oils or mineral spirits for passenger vehicles. They do not obtain with regard to vehicles for trading purposes, or, at all events, not to the same extent. It is as well to admit that there are objections, but it is equally or more important that we should not be guilty of causing delay in the development of a much-required means of transit by indulging in that cheap wisdom that shows itself in mere adverse criticism. The feeblest vitality rarely refuses to show its activity in this occupation ; but when the end sought is one which all men admit to be desirable, all men should lend their encouragement, or at least refrain from the pitiable weakness of deprecating as incomplete a thing which is avowedly in course of development. In this spirit we must acknowledge that our Continental neighbours have produced motor vehicles which, if we never got any better, would have their uses, and many uses; but we hope to improve upon these vehicles in various ways. In the same way we should admit our gratification at the change in our laws which will permit us to make these improvements, while we at the same time hope for some modification in the regulations under the new Act. This, however, is a small matter compared with the anxiety lest local regulation-makers may not refrain from that form of criticism and activity to which I have already referred.

In England there is now considerable activity in the production of motor vehicles, chiefly of the smaller kinds or smaller powers, and there is little doubt that this limitation will for some time characterise the new industry. The smaller powers are not only more easily obtained, but construction and experiment are less expensive, and there is at the same time the encouragement of a very considerable demand.

The power required in the heavier vehicles introduces difficulties of many kinds, not only in the motor itself, but in its fuel, its working fluid, and the transmission of its power to the driving-wheels.

On the quantity of power required some remarks may be made.

The great range in the rate of doing work which a horse has at his command is the cause of the very unfavourable position taken by the mechanical horse, in comparison with animal horse. The power of a horse expressed in lbs. raised 1 foot in a minute has been measured by several experimenters, including James Watt, whose arbitrary determination of what shall be called a horse-power is used almost throughout the world. Watt found that the average rate of work of a good horse working eight hours per day was 22,000 lbs. raised 1 foot in one minute, that is to say 22,000 foot lbs. To give a liberal horse-power by a steam engine he added 50 per cent. to this, and determined that the raising of 33,000 lbs. 1 foot high per minute, or 33,000 foot lbs. per minute, should be a steam engine horse-power This horse-power may be a large number of lbs. raised a small height, or a small number of lbs. raised a greater height, and so long as the feet and lbs. multiplied together equal 33,000 they represent one horse-power. Now this is founded on the rate of doing work by a horse who has to keep on doing it during eight hours. The mechanical horse can continue this performance 100 or any number of hours, but after a fraction of this time the horse would be tired and incapable, or dead. On the other hand, however, the horse can for a short time do work at a very much, a vastly greater rate. This the mechanical horse cannot do. The horse can, for a short time, exert a pull in starting a vehicle or in pulling up a hill at a very slow speed, which may be from 200 to 800 or more per cent. greater than the average pull it can exert over a period of an hour or a few hours. In these cases the horse-power of 33,000 foot lbs. per minute will be made up of nearly all lbs. and very few feet, or may be only a few inches. The horse-power of an engine is largely made up of feet per minute or of piston speed, and in fact, from the mechanical point of view, the steam-engine, although it may be exerting a very heavy pull, does no work until that pull is enough to cause motion. A total pressure of steam of say 1,000 lbs. may bear upon a piston, but so long as it does not move, no steam is used and no work is done. The horse exercising a pull which is ineffectual does, on the other hand, suffer loss of tissue. The engine which is one horse-power running at 800 revolutions per minute is not equal to the power of a one man when running at 100 revolutions per minute, and it only exercises one-eighth of its horse-power. Thus an engine of one horse-power, driving a motor vehicle without the intervention of speed gearing, is not capable of a fraction of the power of a one-horse animal in starting a vehicle, yet the same engine, when the vehicle is moving at a speed corresponding to that of the normal speed of the engine, would tire the horse to death. The great difference then between the horse and the engine is that the horse can exercise its greatest pull when at its lowest speed, and the engine cannot exert its full power or pull until it reaches its full speed. When the horse finds that its load increases and more power is required, he slows down and gives it. The engine, on the other hand, must maintain its speed to full work and can only give out more power by increase in speed, other things remaining equal. Hence decrease in the speed of the motor vehicle is essential when the power required to move it is increased, the speed of the motor being unaltered or increased. Hence it is that an electric tramway car is, under present arrangements, fitted with a pair of 10 or 15 horse-power motors. To place the mechanical horse in the position of the animal horse, the intervention of variable speed gear, which will enable the engine to run at its normal speed, whether the vehicle is starting, moving slowly or fast, is necessary. If such gear cannot be used, the horse-power required in the engine must be many times that which is necessary for average work by horses on ordinary roads.

The relation between the power of a horse and of a one-horse engine is independent of the position of the engine, or of whether it hauls a vehicle by means of a rope from a winding drum, or whether it is fixed on a self-propelled vehicle. There is no anomaly in the fact that a three-horse mechanical horse is required on a vehicle which would be easily hauled by a one-horse animal. These things I have mentioned at length, firstly, because there is a good deal of misunderstanding on the subject, and secondly, because they are at the bottom of the question of cost.

An engine which is sufficiently powerful to propel a vehicle at legal speed on average roads would be sufficiently powerful to propel the same vehicle up the hills if the users would be content to mount the hills at horse speed. This, however, seldom satisfies them. As soon as they get mechanical motors they want to go flying up hills at from two to five times the speed of a horse, and although the pace does not kill, it costs, and if persisted in it will kill a possible industry in the construction of a splendidly useful means of transport, and other advantages to the community which such a means would confer.

One other point which is in favour of the horse should be mentioned. In ascending a hill a horse is enabled to increase its tractive power, either by an actual transfer of a part of the load to its back, or by the virtual transfer by a suitably-inclined trace, as in the Brigg attachment. Part of the work to be done against gravity is thus more advantageously performed. This advantage cannot be obtained for the mechanical horse or motor-wagon by any means at present available.* No advantage would attend placing most of the load on the front wheels, unless they were drivers, for the proportion of the load on all the wheels remains the same on the hill while the

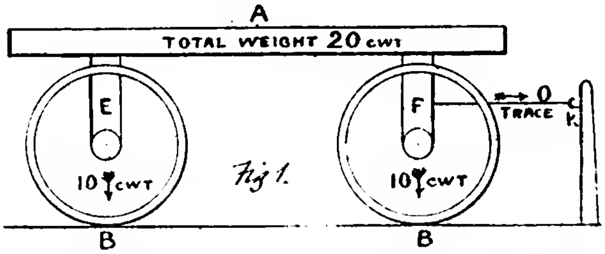

Fig 1.

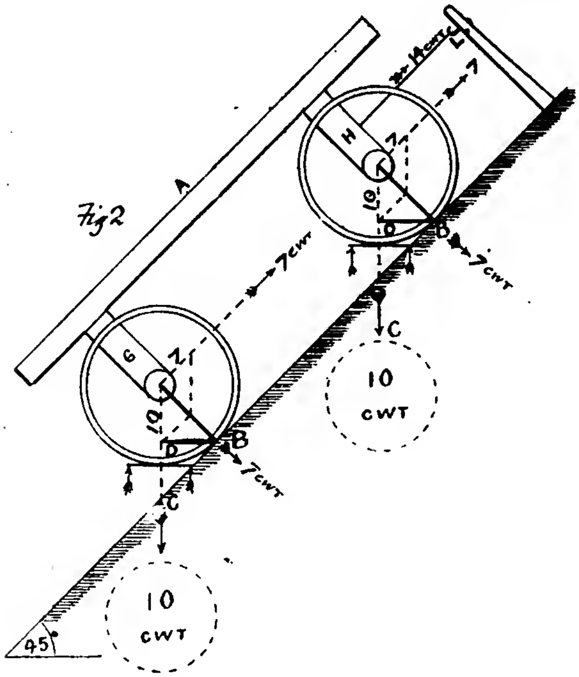
vehicle is hauled or pushed as when on the level, although it is reduced in quantity. This may be shown by the diagrams Figs. 1 and 2, first used by Mr. T. H. Brigg to represent a symmetric four-wheeled vehicle on the level and on a gradient of 45 degrees or 1 in 1. The vehicle is assumed to weigh 20 cwt., 10 cwt. being on each wheel. A trace is assumed to be attached at F, Fig. 1, or it may pass F, and be attached at K, and for simplicity of comparison it is fastened to a post at K.

It is not infrequently stated that the equality of the loads on the front and hind wheels, which is here shown while the

* In cases of haulage by road locomotives or tractors this could be done where the engine power is sufficient to utilise increased adhesion.

vehicle is horizontal, is lost on ascending a hill by a decrease of the front wheel load and increase of the hind wheel load, because the centre of gravity of the load has changed as regards its vertical position over the ground within the wheel base. It would be a very serious thing for some motors if this occurred, but it does not. Assuming that the 20 cwt. includes the whole of the vehicle, with its wheels, and that its centre of gravity is situated at some point below A. To prevent the vehicle from running back down hill, the trace in Fig. 2 is attached at L, as it would be to a horse. Now the conditions as to the loads on the wheels and no pull on the trace in Fig. 1 have changed in Fig. 2 to the lessened weight of 7 cwt. on each wheel, and a pull of 14 cwt. on the trace. The points of incidence of the load on the road are at B B, at right angles to the road under the axle, as in Fig. 1. The action of the load of 10 cwt. on each axle is vertically downward, in the direction of the arrows C C, and joining this line to the point B in each case by the line D, we have the direction and a scale of magnitude for the forces shown by the parallelogram, which gives us a total of 14 cwt. on the road under two wheels, and a pull of 14 cwt., which has to be resisted by the horse. If the load on the wheels changed with



the change of point of incidence of centre of gravity of wagon on the road, with high load the wagon would turn over, as it would be outside the rear of the hind wheels. If, instead of by a trace, the descent of the vehicle be prevented by upward reaction, as shown by the horizontal lines and small arrows, the load of 10 cwt. will fall on each, although the vehicle is inclined the gradient of 45 degrees. The effect of gravity in these cases cannot be considered without reference to the forces resisting it.

It is not my intention to bring before the Association any illustrations or descriptions of the now numerous forms of light motor vehicles, most of which have been described many times, or of the more recent vehicles described by me in November last before the Society of Arts. I propose rather to deal with some questions on which I have been more particularly occupied, relating to the choice of motors and motor vehicles for the heavier classes of traffic, and to consider what are the kinds of work which can be performed with economical advantages by motor vehicles. With regard to the lighter kinds of business goods and passenger transport, wherein the cost of moving a given number or quantity over a given mileage is the main question, there can be no doubt that mechanical haulage will become cheaper, and offer numerous advantages over horse haulage. It would, nevertheless, be folly to pretend to a belief that even for these purposes the motor-car will entirely displace the horse for some of the miscellaneous work for which its easy adaptability makes its supremacy secure. The shunting work performed in crowded railway stations is an example of this, but only an extreme one, for there is much of the miscellaneous work of business establishments, farms, and contractors' work which will ever require the assistance of the artist in haulage, which a horse is.

For the plain straightforward work, however, which is by far the largest in quantity, there will be within a year some, and within two years, many vehicles, which will perform the work at a profit compared with horse haulage. The actual cost will, however, vary in different districts and towns, and to give figures would be misleading. The vehicles which would meet the requirements of London, or the greater part of it, or of Manchester, would not suit Liverpool, which has ten main streets having long gradients varying from 1 in 17 downwards, and the mean of seven of which is about 1 in 23. For working in Liverpool, the average motor vehicle would require more power than in London. Again, for country use, as, for instance, carriers' carts and light vans, the motive power suitable for Kent would be unnecessarily large for Berkshire, and the motor not economical. The choice of a motor vehicle and the cost of fuel depend not only on these questions, but on the answer the intending purchaser will give to the question as to the gradients, and to the minimum speed on them he will be content to demand. It further depends upon the design and construction of not only the motor, but of the gearing by means of which the power is transmitted to the driving-wheels; and it is on many points in these questions that the actual cost of working depends. In a general way the cost of fuel and lubricating oil for oil motors, and of electrical ignition, when that is used, may be taken at about 1*d.* per horse-power per hour, and for mineral spirit motors 1·30*d.* per horse-power per hour. Taking, then, a four-person vehicle, requiring a three horse-power motor, capable of full legal speed on the level, and (with a good gear) somewhat faster than a horse would walk up ordinary hills, the cost would be about 0·4*d.* and 0·55*d.* respectively per car mile on a mean speed of eight miles per hour.

For steam motors worked with coke or steam fuel the cost would be less, the vibration less; but this kind of carriage-motor for small vehicles is not yet forthcoming. Steam motors worked with boilers with oil fuel will probably cost more, but will be more easily fed and handled, and will offer the other advantages of steam. These may be sooner forthcoming.

On exceptionally good roads nearly level, or with compensating moderate gradients, the cost would be less. The cost for heavier vehicles would be proportionately more. For a good size of country carrier's van weighing, say, 2·5 tons loaded, about 2·5 horse-power would be required on a good level road for a speed of 8 miles per hour, or of about 3·75 horse-power for a speed of 12 miles per hour. It is, however, the heavy gradients which run up the cost, and as showing the great cost of rapid hill-climbing it may be mentioned that the 2·5 horse-power for 8 miles per hour on the level grows to about 10·5 horse-power for the same speed up a hill of 1 in 20, and about 21 horse-power if the gradient is 1 in 10. At 3 miles per hour, however, up a gradient of 1 in 20, only about 4 horse-power is required. These quantities must, of course, all be increased for dealing with bad roads, and in all cases they may be doubled for this purpose; so that to take 2½ tons of vehicle and load up 1 in 10 at 8 miles per hour would require 42 horse-power. I have only given a few figures by way of example, so as to show the enormous increase in power required, and therefore of cost, of high speed up hill. It must also be remembered that the higher the power applied to a self-moving vehicle, the greater the rate of wear and tear of everything. The figures serve to show that mechanical traction may be very economical at considerable speeds on good level roads and at slow speeds up hill, but that it is expensive when high speeds are observed up hill. Not only are high speeds up hill costly for fuel, but they are costly because the motors in the first instance cost more, are larger, and more difficult to stow; they are heavier to carry about, they are less efficient on level and good roads, and wear and tear is greater.

These figures also serve to show how much more consideration most people ought to have for the horse on hill-roads. The craving for high speeds up hills cannot be too much condemned.

For heavier vehicles proportionately higher figures obtain. Having the horse-power required, the cost of oil or other fuel may be estimated. For very heavy vehicles, such as those proposed for carrying from five to ten tons, there seems to be no reason for departing from the opinions I expressed in Liverpool last September. Motor vehicles for such loads have not yet been offered, but when they are, they will generally be slow-speed vehicles, and built much upon the experience of steam traction-engine or road locomotive makers. Where the quantity of material to be moved regularly is very considerable, road locomotives hauling suitable vehicles will be used; but for variety work, a heavy motor vehicle with very high pressure engine and boiler, and in some cases with condensers, will be used. Generally, it does not appear that there will for the present be very much change on usual practice. The law now, however, permits the use of road locomotives under conditions which will stimulate the production of a high class of motor-wagon of large freight capacity, and low dead weight. A road locomotive under the Act may weigh three tons unloaded, and without fuel, water, or accumulators, or with an attached wagon it may weigh four tons unloaded.

The three tons rule is more favourable than the four tons rule, especially for hilly districts, as the load may be made available for adhesion, and a motor vehicle weighing three tons empty may possibly be made to carry five or six tons at moderate and slow speeds, and in some districts haul a vehicle weighing one ton and carrying from two to three tons.

Estimate of Cost of Hauling 20 tons nett 35 miles per day by Road Locomotives.

	£	s.	d.	£	s.	d.
Special road locomotive....				895	0	0
Four special wagons 15 feet by 7 feet....				400	0	0
Three spring drawbars				15	0	0
				£1,310	0	0
Interest on £1,310 at 5 per cent.	65	10	0			
Depreciation at 10 per cent.	131	0	0			
				196	10	0
One driver at 30*s.* per week	78	0	0			
One steersman at 20*s.* per week....	52	0	0			
One assistant at 18*s.* per week	47	0	0			
Oil waste, &c., 200 days at 2*s.* 6*d.*	25	0	0			
Coal, 200 days at 10 cwt., 100 tons at 15*s.* per ton	75	0	0			
				277	0	0
Total expenditure per annum				£473	10	0

Taking 20 tons each trip, being loaded both ways, journey (35 miles) to be done in one day, at 200 working days = 140,000 ton miles per year = about 0·8*d.* per ton mile; add 0·1*d.* for unforeseen contingencies which may arise, and the cost will be under a penny per ton mile. Three wagons will be used behind each engine; one wagon held in reserve. The wagons will weigh about 3¼ tons each, making the gross load hauled equal to about 30 tons, exclusive of weight of engine.

The vehicles have, however, yet to be designed, or at least to be made, and at present the steam cart-horse, or traction-engine, is the only means available for conducting continuous heavy traffic over common roads. By these means, however, it can be shown by trustworthy estimates, based on years of actual practice, that the cost of carrying heavy goods in 20-ton trains, consisting of an engine and three wagons, need not exceed about 1*d.* per ton per mile, or, say, 3*s.* per ton for a 35-mile journey. This estimate includes engine, four wagons, one being for reserve, drawbars, brakes and fuel, oil, interest, depreciation at 10 per cent., and labour. I append a detailed estimate, as made by Messrs. C. Burrell and Sons, for a 35-mile traction-train service, and the experience of other well-known firms, including Messrs. Fowler and Co., Messrs. Ransomes, Simms, and Jefferies, Messrs. McLaren Bros., and others, will, I believe, confirm it. So long as present restrictions are in force, Messrs. Burrell propose to run the trains at night, returning the next night, but when these restrictions are removed, better running could no doubt be made during the day.

To haul 3,000 tons per day would require 150 trains, making a loaded trip each way at a total cost for rolling stock, including 150 spare wagons, of £196,000. Motor-wagons for the same quantity conveyed, each motor-wagon carrying five tons, would cost £240,000, but the speed would be five miles per hour instead of four. This, however, would not be any useful gain on a trip such as the 32 miles between Liverpool and Manchester, and the number of men required per ton mile, even if each motor-wagon hauled one wagon, would be much greater than with the traction train.

Now assuming the traction trains to be adopted for this purpose, it will be readily seen that for such a constant service the roads would have to be specially prepared, and something in the nature of a plate-way, as proposed by Mr. Holt, would be required. No ordinary macadam road would be suitable, even with the wood-tread wheels for the wagons, and the rubber tyres used by Messrs. Burrell for the engines.

The road question thus presents itself as an important one in this problem, and for such a line of traffic as that under consideration, the facilities offered by the Light Railways Act, 1896, demand careful attention, while the handy road locomotive will claim for its own the work of local collection and distribution by means of wagons which will run on either ordinary road, plate-way, or rails. For this purpose numerous handy road locomotives will be required, and the well-paved streets of the greater part of Liverpool are well-suited to the work.

That mechanical haulage on common roads will be a feature of the near future for a large proportion of all the transport, and much of the passenger work of streets and roads, cannot be doubted; but the lighter vehicles and goods vans are at present most promising. For lines of continuous heavy traffic, such as that proposed between Manchester and Liverpool, there can be little doubt that the provisions of the Light Railways Act will modify procedure. The consideration of the conduct of heavy, continuous traffic thus leads me beyond the subject of this paper, as I do not consider that even haulage on tramways comes within it. How far the successful use of gas engines on tramways, as at Dessau, Dresden, and Blackpool, may be taken as an indication of possibilities for motor vehicles I am not prepared to say. It may, however, be useful to record the fact that at Blackpool the cost of gas per car mile for 40 passenger cars, and with gas at 3*s.* per 1,000 cubic feet, has fallen to 1·005*d.*, the consumption of gas per car mile, on a week's average during wet weather, when the rail-resistance is lessened, being only 28 cubic feet. In dry weather it will sometimes reach 35 cubic feet, when the cost is 1·25*d.* per car mile. The cost of haulage by gas engines is thus very low as compared with horse-power involving the keep of from 9 to 11 horses per car, a sum for renewals which includes from two to three new horses per car per year, and usually costs over 5*d.* per car mile. As with motor-cars, however, the cost per car mile depends very much upon the gradients, but as the cars are fitted with a low speed for hill climbing the increase is limited, and the arrangement of clutch and gear adopted by the Gas Traction Company permits the change to be made without shock.

The system of gas-cars used is known as the Luhrig, but a number of patented improvements have been made by the Traction Company which add materially to the success of the system, but it does not appear likely to compete with oil motors for light long-distance motor-cars.

The use of electricity in the propulsion of motor-carriages can hardly be said to have made any important strides. As

I have elsewhere said, this is almost entirely a question of secondary batteries or accumulators, and in particular it is a question of their strength more than of their capacity or rate of discharge. The London Electric Cab Company is now preparing to construct cabs of usual passenger capacity, and to be worked by secondary batteries, which will be carried in changeable boxes, weighing in all 12 cwt., carried under the cab, arrangements being now worked out for receiving the cab, removing its spent battery box, putting in a box of newly-charged batteries, and releasing the cab in three minutes.

The heaviest motor-car work done by secondary batteries at present is the experimental running of the London Electrical Omnibus Company's omnibus, weighing 2·25 tons, without its cells, of which there are 70, each weighing about 23 lbs., or a total of 1,610 lbs.

The St. Pancras Vestry are considering the use of electrical motor refuse-collecting vans, and having their own electric supply station, it is proposed to supply the charging current during the day, when the electric lighting load is small, at 2*d.* per unit, or 1,000 Watts. The vans are estimated to weigh 1 ton 2 cwt., motor and gearing 6 cwt., and batteries 12 cwt., the total weight of the van unloaded being thus 2 tons. Each van would carry 26 cwt., and cost complete £208, of which £63 is for accumulators and £65 for motor and gearing. The traction power required per ton of a four-wheeled van of the kind proposed, has been found, according to some published reports, to be 0·78 horse on dry level macadam, and 1·28 horse on the wet gravel road. These figures become 1·7 horse and 2·2, on a gradient of 1 in 26 at a low speed. It is estimated that a saving of about £30 per year, per van, would be made, assuming 2*d.* per unit for current, the use of one horse-power per ton on an average, and allowing 20 per cent. depreciation on accumulators, and 9*s.* 6*d.* per day for a horse and man.

There cannot be any doubt that secondary batteries will ere long be made capable of withstanding such jolting as cannot be avoided, with a good method of suspension of the cell-carrying box, and some such form of cell as the Fitzgerald aflnidic, will probably contribute to this result, or the Faure-King E.P.S. cells with celluloid envelope. The rates of discharge per lb. of these two kinds are given respectively as 1·1 and 0·9 amperes per lb. gross weight, and the specific capacity in ampere hours per lb. gross weight 3·36 and 4·5. The capabilities of secondary batteries are thus much higher than formerly, and with the improvements in their mechanical properties the extension of their use for what may be considered the rather heavy work of omnibuses may become practicable.

Here I must leave the haulage question and regret that the length of time now taken compels me to omit detailed consideration of the various motors—oil, gas, spirit, steam, and electrical—some of which are made under important patents although the mere cycle patents, such as the Otto, have lapsed, and on which much might be said in their suitable application to motor vehicles.

The CHAIRMAN, in moving a vote of thanks to Mr. Beaumont, said, according to the paper, it would be some time before a design for heavy vehicles would come. He (the chairman) regretted that, and wished it would come about this year. The machine one would like to see would be one that would entirely obviate transhipment.

Mr. H. P. BOULNOIS, in seconding the vote, said he agreed with Mr. Beaumont in what he had said about speed. High speed-running engines were a mistake in many ways.

Mr. R. BENNETT controverted a misconception which appeared to exist that master carters could haul goods at 1*d.* per ton per mile. Though the actual cost of haulage might be low, the expenditure at terminals brought this up to a figure that left a by no means considerable margin.

The motion was then put and carried unanimously.

A SCOTTISH branch of the Self-Propelled Traffic Association has now been definitely established, with Messrs. Mitchell and Smith, C.A., 59, St. Vincent Street, Glasgow, hon. local secretaries

THE AMERICAN MOTOR LEAGUE.

THE following are extracts from the "Constitution" of this body:—

Art. I. Sec. 2.—The purposes of this Association shall be the advancement of the interests and the use of motor-vehicles. This shall be done by reports and discussions of the mechanical features, by education and agitation, by directing and correcting legislation, by mutual defence of the rights of said vehicles when threatened by adverse judicial decisions, by assisting in the work of constructing better roads, better sanitary and humane conditions, and in any other proper way which will assist to hasten the use and add to the value of motor-vehicles as a means of transit.

Art. II. Sec. 1.—Any man or woman, 18 years of age or over, of good moral character and respectable standing, friendly to the motor-vehicle and its interests, shall be eligible to membership, and may become a member by application to the secretary of the League.

Art. II. Sec. 4.—Active members shall pay an initiation fee of 2 dollars and an annual fee of 1 dollar, payable in advance.

Our contemporary, *Industries and Iron*, commenting on the foregoing rules, says:—"From these it would appear that those responsible for its inception—and the subscriptions of its members—have not set their subscriptions at quite so high a figure as have those responsible for the inauguration of the British 'Motor-Car Club,' although, so far as we are aware, the latter did not so particularly insist upon the 'moral character' and 'respectable standing' of its members. Perhaps this was wise on their part, having in view the fact that they themselves laid no especial claim, in forming it—nor since, so far as we know—to possess any very great abundance of these traits."

THE English and French of equivalents Weights, Measures, and Distances are fully set out and explained in THE AUTOMOTOR AND HORSELESS VEHICLE DIARY AND POCKET-BOOK for 1897, which contains over 100 pages of information. Price 6*d.*; post free, 7*d.*, of Messrs. F. King and Co., 62, St. Martin's Lane, London, W.C.

To popularise motor-cars no method is likely to be more effective than enabling the public to practically use them. We therefore gladly welcome the offer now made through our advertising pages to book seats for a trip to Brighton and back. No doubt at first the fee will have to be fairly high, especially as we understand the particular carriage in question is a private one built to carry two passengers. We should not be surprised if the advertiser receives more applications than he can possibly provide for, which will probably result in others coming forward and creating a regular motor-car service between London and London-on-Sea. Success to the enterprise!

A MOTOR-CAR SHOW FOR DUNDEE.—Recently much interest has been manifested in connection with the cycle and motor-car shows which have been held in various parts of the country. Last week one took place in Edinburgh, and was attended with so much success that a number of Dundee gentlemen interested in cycling have resolved to promote one in Dundee. The Kinnaird Hall has been booked for the week beginning Monday, April 26th, and already there has been a large demand for floor-space from Cycle Companies and agents. A feature of the show will be the exhibition of motor-cars from different parts of the kingdom.

A DEFINITE start has been made this week to take advantage in a practical form of the facilities given under the New Locomotives on Highways Act for carrying goods by road. Messrs. Elder, Dempster, and Co., the well-known Liverpool shipowners, ask tenders for mechanical haulage of about 1,000 tons per week between Liverpool and Manchester, and we do not doubt there will be several firms who will be prepared to avail themselves of the invitation, full particulars of which will be found in our advertisement columns.

LAW REPORTS.

The History of Pneumatic Tyres.

THE Pneumatic Tyre Company (Limited) *v.* Marwood and Cross action was commenced before Mr. Justice Romer on the 9th inst., and is brought by the plaintiff Company against a firm of cycle manufacturers carrying on business at Nottingham for an injunction to restrain them from infringing Welch's patent (the property of the plaintiff Company) for pneumatic tyres for bicycles, &c. The defence set up by Messrs. Marwood and Cross is that of prior use. They allege that a person named Boulton made tyres in London in the early part of 1891 similar to those described in Welch's specifications—at a period nine months before Welch's patent was granted.

Mr. Fletcher Moulton, Q.C., Mr. Roger Wallis, Q.C., Mr. Walter, and Mr. Graham appeared for the plaintiff Company; and Mr. Thos. Terrell, Q.C., Mr. Houghton, and Mr. Peter Rylands represented the defendants.

Mr. Boulton and a number of other witnesses gave evidence in support of defendants' allegations, after which the plaintiffs called rebutting evidence.

Mr. Harvey Du Cros, the Chairman of the Dunlop Company, was called, and said that when he brought over the pneumatic machines from Ireland he did not believe there was a single pneumatic machine in London, and he did not believe that tyres of this pattern were made at the period which the defendants' witnesses alleged. He was appointed managing director at the end of the year 1890, when the trade was being developed. The tyres and the covers were both hand-made. Pneumatic tyres were seldom seen in 1890, and it was quite a matter of favour to procure one then. At Whitsuntide of 1890 he and his three sons came over from Ireland, and used pneumatic tyres at amateur races in various towns, when they were a novelty. At that time there was no such thing as a detachable tyre on the market. Then, in the year 1891, in the month of April, one of their workmen invented one that was afterwards patented in the joint names of the inventor and himself, and called the Roberts and Du Cros tyre. In the same year (1891) the Company purchased Woods' patent for valves and deflation. Before that they had to cut the tyre to get the air out. Woods' was the first screw valve. Cushion tyres followed the pneumatics. The former were not common early in the year 1890.

Cross-examined on behalf of the defendants, witness said that he was sure he did not know of any detachable tyre in 1890. In 1889, the moment pneumatic tyres appeared, there was a universal condemnation of them in the Press. The objection taken to them at first was that they were unreliable because they slipped. At the close of the year 1890 the merits of pneumatic tyres were largely admitted, and cushion tyres were discarded.

Amongst other witnesses called by the plaintiffs and cross-examined by the defendants was Mr. Jelly, trade manager of the Beeston Company, who stated that his Company turned out 4,000 tyres or thereabouts a week, and that when an action was brought against his Company by the plaintiffs he was most anxious to endeavour to obtain evideuce of anticipation in 1890, and called on Bolton for the purpose. It, however, did not appear that Bolton made tyres with wires in the pockets in 1890, and that Mr. Lawson pressed Bolton for documentary proof. Mrs. Bolton said they found they were oue year out, the tyres being made in 1891 instead of 1890. The action against the witness's Company was settled, but he was absolutely ignorant on what terms. The Boltons' statements were of no use to him. He gave them a sovereign.

Witnesses were called by the plaintiffs to rebut the defendants' evidence, including the captain of the Kingsdale Cycling Club in 1891, of which Bolton was a member. This witness stated that he himself bought his first pneumatic tyre in May, 1891, and had previously, in 1890, ridden with Bolton, and never remembered Bolton, in 1890, having or mentioning pneumatic tyres. In cross-examination, the witness said he could not remember how many times he saw Bolton ride in 1890. He himself did not miss more than two or three club rides, and the club-book would show the names of the riders. The witness, on re-examination, stated that he had no wish to go against Mr. Bolton, and had no interest, pecuniary or otherwise, in the case. Another witness, a member of the club, said that the first time he heard Bolton speak of pneumatic tyres was in 1892, nor had he seen any in Bolton's place in 1890.

Mr. Henry John Lawson, called by the plaintiffs, said that he was acknowledged to be the inventor of the safety, and the founder of its business. For the purposes of the Beeston Company action he scoured the country. He went and saw Bolton. Bolton showed him a bit of brass, &c., as one of his experiments. Witness told him he would pay him handsomely, and asked him for any proofs he could give that he had ever made any pneumatic tyres with wires. He also went with Jelley, and on reference to a document, mentioned by Mrs. Bolton, as fixing the date of making the articles in 1890, and which, on this second occasion, had been produced, it was found that the document fixed the date as in 1891. So there was nothing more to be done. It was not the case his Company got a licence from the plaintiffs on very favourable terms. It turned out favourably because his Company got larger. The witness declared, amongst some laughter, that he "was not taken up by Mr. Hooley." What he wanted to get for his action was documentary proof of prior user, and he could not get it. He was now very much interested in supporting the Welch pateut.

The Editor of the *Cyclist* since 1879 was called, and stated that the Dunlop came out in 1889. At the end of 1890 pneumatic tyres came into use, but it was a matter of favour early in 1891 to get them. In 1890 the only valve in use was the Dunlop one, and the tube had to be cut for deflation. The first cushion tyre was shown in the Stanley Show at the Crystal Palace early in 1890, and was very large, and was humorously styled by its exhibitor—The Rheumatic Tyre.

The evidence having been concluded, Mr. Moulton, Q.C., for the plaintiffs, addressed the Court.

After the mid-day adjournment on Friday last, which was the seventh day of the action, counsel for the defendants said he could see that Mr. Justice Romer was not in his favour, and that he would be glad to have an expression of his view.

Mr. Justice Romer said that he could not say that the defendants had proved to his satisfaction the burden that was laid upon them. There was a good deal of truth in their evidence he dared say, but it was much mixed up with what was not true. It would be a painful thing for him to have to analyse the evidence, as he would have to say a good many things he would rather not say. He should be glad if the matter could stop here.

Counsel accepted this intimation, and Mr. Justice Romer said that he would say nothing then except that the case of the defendants, not having beeu made out to his satisfaction, there must be judgment for the plaintiffs, with costs.

A Motor-Car Accident.

CHARLES *v.* ARNOLD was an action heard on Friday, the 29th ult., before Mr. Justice Hawkins and a common jury, in which the plaintiff claimed compensation for injuries suffered by him in the course of an exhibition of motor-cars and cycles at the Imperial Institute on May 1st last.

Mr. Hawtin and Mr. Scrivener were for the plaintiff; and Mr. Dickens, Q.C., and Mr. Hohler for the defendant.

The plaintiff was a photographic journalist, and his business was to attend exhibitions and other public functions, to take photographs of certain things, and, if necessary, to write a description of what took place. In pursuance of his calling, he went, on May 1st, to the Imperial Institute, where there was a procession of motor-cars. His case was that he spoke to some of those who had authority in connection with the show that was to take place, and by them he was shown into the enclosure where the procession was to be, and to a point from which it would be convenient to him to take photographs. Whilst he was engaged in photographing a car surrounded by Lord Lathom, Sir Somers Vine, and a number of other gentlemen, a car which belonged to the defendant came along in a procession, and when near the plaintiff it suddenly turned to the left, bore down upon him, and crushed him and his photographic machine against the barrier. The defendant assisted the plaintiff, offered him brandy, gave him £2 10*s.* as compensation, and hoped to hear no more of the matter. Charles, in his evidence, said that he joined in this hope, and he tried to go on with his usual work, so as to realise the season's profit. At the end of a week, however, he had to go to a doctor. There was then no objective evidence of injury, but the plaintiff experienced certain pains, and he submitted that the £2 10*s.* was by no means enough to compensate him for the injuries which he had suffered and the expenses to which he had been put in connection with the accident.

In the course of the case a placard was produced, which was headed "Display of Motor-Cars and Cycles," and said, "Visitors are requested not to stand or walk inside the enclosure near the demonstration. Any visitors disregarding this will do so at their own risk." The plaintiff said that he did not take any notice of this, and did not regard it as addressed to him, as he was not there in the character of an ordinary visitor, but as a Press representative.

Mr. Dickens, upon the conclusion of the evidence for the plaintiff, submitted that no case had been made out by him. It had not been shown that there was a breach of any duty which the defendant owed to the plaintiff; nor was there any evidence of negligence on the part of the defendant. He had, however, vidence upon the question of negligence.

The jury intimated that they would hear that evidence.

Mr. Clark, superintendent of the garden of the Imperial Institute and of the enclosure, said that on the day in question it was what was called a "trial day" in reference to a future exhibition. Men were posted to warn people not to enter the enclosure, and to point their attention to the notices. The men were told not to allow anybody whatever within the enclosure, unless they were connected with the Institute or connected with the Motor-Car Exhibition. As to the plaintiff, witness told him personally that he would not grant him admission to the enclosure, and the fact was that he did not grant admission to the enclosure to any other Press man on that day.

In the course of the evidence for the defence the jury handed a written communication to his lordship, who, in his turn, sent it to the counsel in the case.

In the result a juror was, by consent, withdrawn.

The "Silent Tyre" Patent.

On Tuesday, the 3rd inst., a petition was heard by the Judicial Committee of the Privy Council for the extension, by an additional 14 years, of a patent for "Improvements in the manufacture of grooved tyres for wheels." The petitioners were William Hasselwood Carmont, consulting engineer (the inventor and patentee), and the Shrewsbury and Talbot S.T. Cab and Noiseless Tyre Company (Limited), which Company acquired the rights in the patent in 1888 from the Earl of Shrewsbury and Talbot, who acquired them from the new Noiseless Tyre Company, to whom the rights had been transferred by the old Noiseless Tyre Company, which went into liquidation. The ground of the application for the extension of the patent was that since noiseless tyres had become popular, there had not been time to obtain adequate remuneration for the time and outlay expended upon the invention, which was a very valuable and useful one, and the validity of the patent had been proved by actions in the High Court. The application was opposed on the ground that the inventor had been adequately remunerated, and that a further extension of the patent rights would be contrary to the public interest.

Mr. Cozens Hardy, Q.C., Mr. Wilkinson, and Mr. Cozens Hardy, jun., appeared for the petitioners; Mr. Alexander, Q.C., and Mr. W. Baker for various opponents; and Mr. Sutton for the Crown.

Counsel having been heard on both sides,

Lord Herschell, in delivering the judgment of their lordships, said it had been proved from statistics produced to the satisfaction of their lordships that the profits derived in respect to the patent exceeded £25,000, and as their lordships considered this to be adequate remuneration, the petition would be dismissed with costs.

The petition was dismissed accordingly.

£15 by Consent towards a Dividend on £3,000,000.

In the Court of Queen's Bench on Friday, the 22nd ult., Mr. Fletcher Moulton applied for an injunction to restrain the Hon. C. S. Rolls from infringing in this country the British Motor Syndicate's patents, by using a Peugeot carriage operated by a Daimler motor. In the result it was arranged that the sum of £15 should be paid as nominal damages, each side paying their own costs, leave being given to the defendant to continue to use the carriage against which complaint was made.

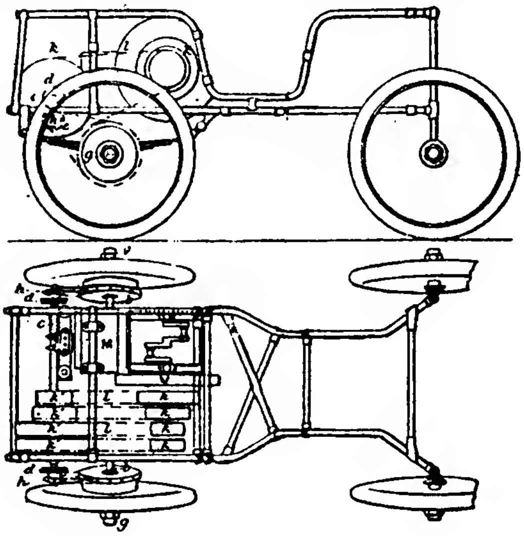
AUTOCAR COMPETITION AT THE BRUSSELS EXHIBITION.

We have in a previous issue given some particulars relating to this, and we give herewith a translation of the municipal conditions of the autocar competition to be held this year. The competition will be divided into two main classes, one for automotive carriages running on ordinary roads, and the other for autocars and locomotives to run on rails. The general conditions are as follows:—The competition for autocars running on ordinary roads is subdivided into two classes: (*a*) for passenger carriages; (*b*) commercial vans. The competition is open to all vehicles propelled by other than muscular means, and has for its principal object to encourage commercial production of the various carriages entered. The commercial production has to be considered from two points of view: (*a*) the cost of the outfit, compared with the capacity for carriage, and (*b*) the actual price per unit carried. The unit for the carriages of the first class to be one passenger, and for those of the second class to be 100 kilogrammes. The competition will open on the 1st of May, and will end on August 31st. The jury in charge of the awards will be elected at the opening of the exhibition, and will commence their duties at once. Each competitor will be called upon to work regularly a course prescribed for him in the trial ground; to declare the price at which he is prepared to furnish his machine and other apparatus in connection with it; to give all information as to its working, cost, the cost of repairs, and the method of working it; and he must also insure himself against the risks run in using his engine, vehicle, and apparatus.

An International Exhibition of Motor-Cars, Cycles, &c., is announced to be held in London from March 25th to April 15th, 1897. The actual location is not publicly stated, but we understand from those responsible that a specially suitable hall has been secured, and that already important support is assured from not only some of the chief French makers, but also by many of the leading British firms who are interesting themselves in the industry The Organising Committee consists of Mr. C. Laroche as foreign delegate, Mr. A. Villers, and Mr. W. M. Paterson will act as secretary, the offices being at No. 23, Pall Mall, London, S.W.

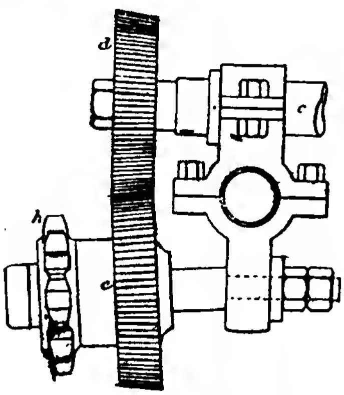
THE FOUCHER-DELACHANAL MOTOR-CARRIAGE.

The accompanying illustrations, Figs. 1 and 2, show a plan and elevation of a motor-carriage made by Messrs. Foucher and Delachanal, of 3, Rue Taylor, Paris. The vehicle illustrated is arranged to carry three persons, two at the back and one in front. The frame of the carriage is built of steel tubing (as will be seen from Fig. 1), in which the seats, the steering-handle, and the speed-changing lever are, however, not shown. A petroleum



Figs. 1 and 2.

spirit motor of three horse-power is employed, but beyond that it is fitted with two horizontal cylinders. The feature of the Foucher-Delachanal carriage is the method employed to obtain the inclination of the wheels usually adopted by carriage builders, this being shown in Figs. 3 and 4. The variable-speed gear is also claimed to be of a special kind. Three rates of speed are provided, a section of one of the pulleys on the engine shaft being shown in Fig. 4. The cones, *m*, which are fixed to the shaft, are made of brass, faced with compressed pulp. The pulleys, *k*, themselves are mounted on ball-bearings, and run loose, when not in contact with the friction cone. Altogether, there are four sets of driving and driven pulleys, three, with crossed belts for the forward motion, and one, with direct belt,



Figs. 3 and 4.

for the backward motion. The different pulleys are brought in contact with their respective friction cones by means of a lever fixed at the right-hand side of the carriage. The power is transmitted to the driving wheel through the intermediary shaft, *c*, the inclined gear wheels, *d* and *e* (Fig. 3), and the usual chain and chain wheels. The vehicle is claimed to be exceedingly light, the one illustrated weighing 270 kilogs. (594 lbs.). The frame-work and propelling mechanism being complete in themselves, any form of carriage body can be fitted to them. We are indebted to *La Locomotion Automobile* for the illustrations.

CORRESPONDENCE.

*** *We do not hold ourselves responsible for opinions expressed by our Correspondents.*

*** *The name and address of the writer (not necessarily for publication)* MUST *in all cases accompany letters intended for insertion, or containing queries.*

BRITISH MOTOR SYNDICATE (LIMITED) v. HON. C. S. ROLLS.

To the Editor of The Automotor and Horseless Vehicle Journal.

Dear Sir,—In response to your request and to those of various persons interested in automobile affairs, I here place before you the true facts relating to the above recent action, which you are at liberty to insert as proposed in your journal.

Being unable to purchase a car from the Syndicate, and having, therefore, the intention of going over to Paris to purchase one, I wrote to Mr. Lawson and the British Motor Syndicate as to who represented the firm of Peugeot in England, but they "regretted their inability to give me the desired information," and mentioned nothing about their patent rights for that firm.

In October last I imported a Peugeot carriage from Paris, and the Syndicate has since sued me for infringement, which they, however, acknowledged was merely technical, and as they also acknowledged that I had acted throughout in good faith, the following terms were arranged by them with my solicitors :—

1. That I should submit to an injunction against infringement of their patents.
2. That they should *pay their own costs*.
3. That in consideration of a nominal payment of £15, they would give me perpetual license to use my car.

It will thus be clearly seen that, not being inclined to incur the trouble and expense of disputing the validity of their patents, I did not contest same, but agreed terms which could have been carried into effect out of court had it not been that, as in all cases where the defendant is under age, the consent of the judge was in this case necessary.

There have been in your contemporary, *The Autocar*, glaring advertisements about patents being upheld, the inaccuracy of which statements is evident from the fact that no discussion as to patents was entered upon, and the case was not fought out for reasons above explained. There are also statements to the effect that "nominal damages were asked for and ordered by the court to be paid"; as a matter of fact no damages were even claimed. Trusting the facts are clear.—Faithfully yours,

C. S. Rolls.

South Lodge, Rutland Gate, S.W., *Feb. 9th*.

THE GREAT HORSELESS CARRIAGE COMPANY.

To the Editor of The Automotor and Horseless Vehicle Journal.

Sir,—Might one inquire what has become of the Great Horseless Carriage Company (Limited)—capital, £750,000, of which £500,000 was paid to the British Motor Syndicate? I am led to ask this question because, as far as can be gathered, little or no reference was made to the concern on the occasion of the London to Brighton run, and now I understand that no mention was made of it on the occasion of the British Motor Syndicate meeting at Coventry. The shareholders who visited Coventry inspected the Daimler Motor Works, the manufactory of the mysterious Pennington motor, the processes of Humber and Company, and apparently the works of the British Motor Syndicate, but from start to finish there was no reference to the Great Horseless Carriage Company. It will be observed, by the way, that the Pennington motor is constructed at the Motor works, though apparently the patents have passed out of the possession of the British Motor Syndicate. If, as is suggested, the works of the British Motor Syndicate and the Great Horseless Carriage Company are identical, it appears to me that possibly shareholders of the Great Horseless Carriage Company may presently be shown the same works as theirs! In fact, the whole arrangement looks somewhat like the cast of an ancient farce:—

Box	....	The Great Horseless Carriage Company.
Cox	....	The British Motor Syndicate.
Bouncer....	....	(His Original Character) H. J. Lawson

The £10 fully-paid shares of the Great Horseless Carriage Company are now valued at £2 to £3 in the open market.—I am, &c.,
A Shareholder.

A REVERSION TO STEAM.

To the Editor of The Automotor and Horseless Vehicle Journal.

Sir,—In your issue of last December you did me the honour to insert a rough sketch of a self-propelled carriage. The motive power proposed was a combination of oil-motor and dynamo; but further consideration of *pros* and *cons* has induced me to follow an illustrious example and look to steam as the most practicable power to employ. In order, however, to minimise vibration, I should be inclined to adhere to the same form of vehicle, the rear portion being mounted on a four-wheeled trolley carrying the steam plant, springs being interposed to absorb as much as possible the shaking due to the engine. An advantage of this arrangement would be that the main weight of the vehicle and motor would be distributed between *two* pairs of wheels, both (it may be added) being driven.

Another advantage perhaps would be that the motor, being quite distinct from the carriage proper, could be detached for repairs and its place taken by another if necessary. The large steering-wheels (shown before) are designed to facilitate the passage of the vehicles over obstacles and irregularities. In conclusion may I suggest that information as to the applicability of the Serpollet system to small powers (such as one-horse) would be interesting?—I am, &c.,

A. J. Allen (Member S.P.T.A.).

London Institution,
Finsbury Circus, E.C., *Jan. 22nd.*

P.S.—One of the numerous advantages of steam is the possibility of applying its pressure directly to the crank of the driving-wheel. Why cannot this be done on such a self-propelled car as well as on a locomotive? Also, is not a pneumatic tyre a refinement quite out of keeping with heavy steam machinery? Personally, I should prefer a good iron tyre capable of standing rough usage, and old-fashioned compression wheels to match.

MR. LORRAIN AND VAPORISATION.

To the Editor of The Automotor and Horseless Vehicle Journal.

Sir,—In your issue of the 18th ult. I notice a letter from Mr. J. G. Lorrain. For the benefit of your numerous readers I will repeat what I have already informed that gentleman, viz., that I did not refer to the method of vaporising he mentions. I experimented with it some time ago and found it of no practical value. This is corroborated by the fact of its not being in use, and I am sure Mr. Lorrain himself cannot have been successful with it.

I should like to know if Mr. Lorrain has yet found his papers. It is a month ago since I asked him to refer to them and correct himself respecting his dates.—Yours faithfully,

Walter Rowbotham.

GREAT HORSELESS CARRIAGE AND NEW BEESTON COMPANIES.

To the Editor of The Automotor and Horseless Vehicle Journal.

Sir,—I think it is a great pity that Lord Winchilsea should resign the chairmanship of the Great Horseless Carriage Company. It would be vastly better if his lordship would remain on the Board and co-operate with the large number of shareholders who would doubtless be willing to try to regain some of their money. The resignation of Lord Winchilsea, like the resignation of Mr. F. W. Shorland from the New Beeston, leaves the management of these companies in the hands of a number of persons who do not appear promising directors. The result of their management is illustrated in the prices. The £100,000 worth of £10 shares of the Daimler Motor Company are now worth, roughly speaking, £40,000. The £750,000 capital of the Great Horseless Carriage Company would now fetch little more than £200,000. The £1,000,000 of the New Beeston Cycle Company is practically unsaleable. The investing public have not benefited much by the methods of Mr. Lawson, and the application of those methods is facilitated when gentlemen in the position of Lord Winchilsea resign.—I am, &c.,

A "G. H." Shareholder.

Feb. 2nd, 1897.

AN OFFER OF LANTERN SLIDES.

To the Editor of The Automotor and Horseless Vehicle Journal.

Sir,—There are but few districts in England where people really know what a motor-car is, and it probably may be a year or more before the new vehicles are common in all our country towns. Lectures on mechanical traction have been well attended, and have doubtless been the means of interesting some people in the carriages of the future.

I have a collection of about forty lantern slides, commencing with Hancock's steam carriage of 1833, and fairly representing what has been done up to the present time. I shall be happy to lend these to any responsible individual for lecture purposes. Unfortunately some of them are rather dense, and require a good light.—Yours, &c.,
John Henry Knight.

Barfield, Farnham, *Feb. 4th*, 1897.

PATENT WHEELS.

To the Editor of The Automotor and Horseless Vehicle Journal.

Dear Sir,—I notice in your journal for January a lecture delivered at the Royal Institute, Liverpool, by Mr. G. F. Thompson, consulting engineer, Liverpool, the subject being "The Motor Wagon Scientifically Considered." Where he speaks about the wheels, their construction and their obstructions, I fully agree. It is rather remarkable that further on in the same journal, pages 167 and 168, I find a letter from Mr. W. P. W. Weatherill, of Manchester, *re* his patent wheel which appears to me to meet Mr. Thompson's views.

Now being a coach builder myself and interested in wheels, I applied to Mr. Weatherill for the particulars of his wheel, with the result that he has supplied me with a bicycle fitted with his patent wheels, which I have gone thoroughly into, and find it does its work well and easy, and really makes a pneumatic tyre a superfluity.

I am so impressed in favour of the wheel that I have placed my show-room at his service, so that anyone calling and producing their card can see it.

It is really a wheel within a wheel, the centre wheel is about one-third the diameter of the larger wheel. In the larger or hubless wheel an adjustable groove is formed, in such groove the small wheel rolls; the said small wheel is supplied with a double cushion rubber tyre, the larger wheel with a solid rubber tyre. The small wheel is also smaller in diameter than the groove it rolls in. When the larger wheels meet with obstruction the small wheels roll forward in their grooves and press the large wheels over the obstruction without a jar, even if the obstruction is a brick.

It does not matter which way the wheel is going, the effect is the same either way, and also when back pedaling the small wheel acts as a brake to the larger wheel. The wheel can be applied to any kind of wheeled vehicle, it is simply a matter of size and strength to be considered for the work intended.

For carriages and autocars I consider the rubber tyre on the smaller wheel (which cannot possibly get out) is quite enough to check jars and vibration, and the usual iron tyre may be used for the larger wheel, which is much cleaner for carriage and autocar use.—Yours truly, JOHN WILLIAMS.

Station Approach Road, Manchester.

MAXIM MOTOR COMPANY.

To the Editor of THE AUTOMOTOR AND HORSELESS VEHICLE JOURNAL.

SIR,—Having noticed a paragraph relating to the registration of the "Maxim Motor Company," capital £7, for motors, launches, flying machines, &c., and having received several communications relating to the same, I beg to state that neither myself nor my associates have any connection whatsoever with the said Company, neither have we authorised anyone to exploit the motors which we are now making. The seven shareholders whose names appear as organisers of this Company are completely unknown to me.—I am, Sir, your obedient servant,

HIRAM S. MAXIM.

18, Queen's Gate Place, S.W., *Feb. 4th.*

NEW INVENTIONS.

Claiming particularly to apply directly or indirectly to Motor Vehicles, &c.

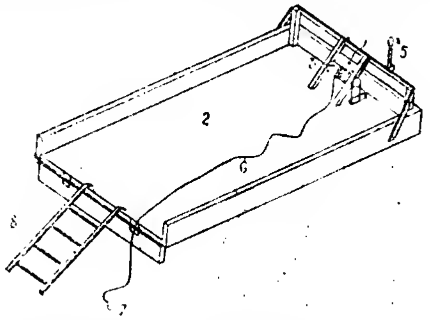
Specifications Published.

22,378. November 23rd, 1895. Road vehicles adapted to be propelled by self-contained motors. John James Henry Sturmey, 19, Hertford Street, Coventry, Warwick.

Relates to road vehicles adapted to be propelled by self-contained motors, which vehicles are also denominated horseless carriages or "autocars," and it relates particularly to autocars intended specially for the carrying of goods, and consists in



providing such vehicles with means whereby the motor can be utilised for loading or unloading the vehicles as well as for propelling them. An elevating contrivance is used and connected to the motor in such a manner that the motor may be thrown out of connection with the propelling gear and into connection with the drum, windlass, or other elevating contrivance, and *vice versâ*, at one operation. The figure is a general view, showing the body, 2, of a vehicle adapted to be propelled by a self-contained motor of any suitable description. At the forward end is mounted a drum, windlass, or the like, 3, adapted to be connected to the motor by any suitable gearing, 4, so that it may be revolved thereby when required; any suitable device, such as a lever, 5, being adapted to actuate a sliding clutch, fast and loose pulleys, or other arrangement for throwing the gear into or out of connection with the motor. A chain, rope, or the like, 6, has one end provided with a hook, 7, or is otherwise adapted to be connected to the goods, while the other end may be connected to the drum, or the like, or it may be wound around the same so that it may be drawn thereby, when the free end is pulled, in the well-known manner. The goods may be hauled up or let down, a suitable slide, 8, reaching from the floor of the vehicle to the ground. Several other methods are described.

19,029. October 10th. Road Carriages. H. S. Barrow.

Relates to a mechanically-propelled road vehicle, having a pivoted fore or locking axle and a non-pivoted rear axle wherein the driving wheels on the rear axle are driven by taper or conical band pulleys that are fixed upon hollow shafts or sleeves on the rear axle, and are driven by bands from two similar but appositely arranged taper or conical pulleys fixed on the motor-shaft, or on a shaft driven therefrom, the bands being arranged to be shafted by a band-shifting device adapted to be operated from the hand-gear provided for turning the fore or locking carriage, the arrangement being such that when the two bands are running midway of the length of their respective pulleys, the two driving wheels on the rear axle will be driven at the same speed, and that when the fore or locking axle is turned into an angular position the bands will be shifted so that the relative rotation of the inner and outer driving wheels of the vehicle will be caused to approximately conform to the angle of the fore or locking axle.

15,197. July 9th. Oil and gas motors. W. G. Heys (J. J. Heelmann).

Relates to an explosion-engine of the four-cycle type, in which equilibrium of the parts is obtained by the use of six cylinders and cranks, and in which uniform motion is secured by a succession of six explosions at regular intervals during two revolutions of the crank shaft.

17,777. August 11th. Wheels of motor-carriages. C. GAUTIER and X. WEHRLE.

Consists of a new method of construction for preventing the torsion of the driving chain and allowing the dishing and inclination of the wheels of motor-carriages, consisting of an axle of which the ends upon which the wheels turn are slightly oblique and carry a piece or disc connected to the wheel, and provided with pins projecting at right angles, which pins continually engage more or less in oblong holes in the boss of the chain-wheel, the latter being fitted and revolving freely upon the horizontal body of the axle.

2401. October 29th. Driving gear for mechanical carriages. H. AUSTIN.

Relates to driving gear for mechanically-propelled vehicles, and consists of a rotary drum or drums provided with bevel pinions and frictional devices and brake, so that the vehicle remains stationary when the drum revolves freely, but is propelled when the revolution of the drum is arrested or retarded.

THE English and French equivalents of Weights, Measures, and Distances are fully set out and explained in THE AUTOMOTOR AND HORSELESS VEHICLE DIARY AND POCKET-BOOK for 1897, which contains over 100 pages of information. Price 6*d.*; post free, 7*d.*, of Messrs. F. King and Co, 62, St. Martin's Lane, London, W.C.

JUST as we are going to press we have received from Mr. John Philipson a copy of an able work which he has written on coach-building. It is published in the series of technological handbooks published by Messrs. Geo. Bell and Sons. A detailed review shall appear in our next issue, but in the meantime we would advise all interested in the subject to buy the book, which is eminently practical and reliable.

THE BRAMBEL ROTARY ENGINE.

LAST November the Press of the country was informed by special telegrams that Mr. Grant Brambel, of Sleepy Eye, Minn., had invented and patented a rotary engine for which he was offered at that time £320,000 (1,600,000 dollars) from an English syndicate. It was reported that the whole amount of the purchase money was paid over in cash and deposited in Chicago banks by the inventor. There are a number of variations of the story, of which the following is an example, the clipping being taken from *The Chicago Daily Tribune*:—

"The engine does away entirely with the crank motion of the steam engine, a most desirable, but to all intents and purposes an impossible, thing to do. The engine uses its own plunger for a cut-off. The engine is steam-tight, and requires no ring packing. It can be made marine type, and, of course, can be either simple or compound.

"It is not a cheap machine, although it costs very much less than the ordinary engine. It weighs less and occupies only a fraction of the space of the old-style engine. Mr. Brambel says:—'When anyone can build a 50 horse-power engine that may be carried around in a hand satchel, he has something that is very valuable, particularly when that engine is adapted to any and all kinds of work wherever power is used. The Brambel engine of 50 horse-power, weighing less than 100 lbs., may be attached to the end of the armature of a dynamo and all the belting done away with, or a Brambel engine not larger than a common saucer could be attached to a creamery separator, and set it whirling at the rate of 6,500 revolutions a minute. The largest of these engines, 250 horse-power in size, is less than a foot wide at the base, and 18 inches high. It is in use in a dynamo room at Trenton, N.J., and the firm say they never had a more satisfactory machine. The patent was obtained a year ago, since which time several machines have been built and put into use.'"

The latest telegram that we have seen proceeds from Sleepy Eye, Minn., dated January 16th, 1897. We quote from *The New York Herald*:—

"The sale of Grant Brambel's rotary engine to the Allen Syndicate, of London, England, has been consummated, and the Sleepy Eye inventor has letters of credit on the Bank of England for 6,700,000 dollars. The amounts paid were: For the English patent, 1,600,000 dollars; for France and Germany, 2,000,000 dollars; for the United States, 3,100,000 dollars.

"These amounts and the fact of the receipt of the letters of credit were verified by the inventor to-day when I called on him."

It is evident that the gentleman from Sleepy Eye is a very wideawake young person, and we take pleasure in publishing herewith an extract from his specification, in which he describes the operation of the device. During the prosecution of the case some four patents were cited, one of which quite closely resembles the Brambel invention, and seems to depend upon the same general principle of operation. The extract reads as follows:—

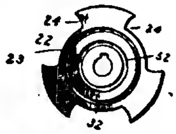
"Having described the construction of the improved motor, the operation thereof, briefly stated, is as follows: When the throttle valve is turned to admit steam or other motive agent to one of the inlet ports, said agent enters the cylinder adjacent to one of the expansion chambers, 25, and is thus admitted to one of the chambers or recesses in the piston. The expansion of the steam gives the impulse necessary to carry the piston in the direction indicated by the arrow (*sic*) in Fig. 2 a sufficient distance to bring the succeeding recess or chamber into the field of the incoming steam, the first-named chamber being meanwhile exhausted at 12. The reversal of the motor is accomplished by moving the lever, 13, to cause the admission of steam through the other inlet port.

F 2

"It will be understood that in practice various changes in the form, proportion, and the minor details of construction may be resorted to without departing from the principle or sacrificing any of the advantages of this invention.

"What I claim is: In a rotary engine, the combination of a cylinder having opposite heads provided with registering extended bearing boxes, inwardly divergent steam inlet ports communicating with the interior cylinder at their inner ends

Fig. 4.



and a common valve casing at their outer ends, a cut-off and reversing valve arranged in the said casing, a rotary piston arranged in the cylinder and provided with peripheral pockets adapted to communicate with steam chambers at the inner ends of said ports, registering cross-sectionally semi-circular grooves formed in the contiguous faces of the piston and cylinder heads concentric with said bearing boxes, said grooves combining to form cross-sectionally circular lubricating ducts, a shaft mounted in said bearings and fixed to the piston, and lubricating devices in communication with the bores of said bearings, whereby lubricating material is adapted to pass between the ends of the piston and the cylinder heads, and accumulate in said lubricating ducts to form packing to prevent the exhaust of steam or the passage thereof from one pocket to another of the piston, substantially as specified."

It had not been our intention to describe or notice in any way the above-mentioned invention, but we are in receipt of so many inquiries from correspondents, and so many requests for copies of the patent, that we have decided it was best to state the facts of the case and publish reproductions of the patent drawings, and copy the salient features of the specification and the claim.

We have not written to Mr. Brambel for any light on the subject of his valuable patent. We learn, however, that he is a telegraph operator, and we imagine that possibly his vocation may have something to do with the wide publicity which the story has attained. We do not know what object there is in foisting upon the public a story which is in such a high degree improbable. We do not need to go beyond the patent itself, and its very narrow claim, to discover the falsity of the rumour. The principle upon which the engine is operated is by no means new, while the claim confines the design to minute details of construction. If, as it is claimed, an English syndicate has purchased the patent at a price of some 7,000,000 dollars, is it not likely that before investing so vast a sum the patent itself would have been submitted to rigid examination as to scope and validity? We believe, therefore, that the story can be regarded in no other light than a hoax, and desire simply to direct the attention of anyone who may be sufficiently interested in the story to examine into the merits of the case, and they will be satisfied that the whole matter is founded on baseless rumour.

LEEDS MOTOR AND CYCLE SHOW.

A MOTOR and Cycle Exhibition was held in the Leeds Town Hall, from February 27th to March 6th, under the auspices of the Northern Counties Exhibition Company. Many of the large cycle firms exhibited; and the show, which was very well attended, proved a great success.

Messrs. Walker Brothers, of Leeds, had a stand in the crypt, and also showed an assortment of cycles in the Masonic Hall. Amongst them was a New Beeston motor-cycle. This appears to be a well-designed machine, and during a short trial which our representative was able to give it, it seemed to be very easily controlled. It is fitted with an oil-motor of the De Dion type. Petrol is used, and the smell is not noticeable in the open air. Electricity is used for ignition, an accumulator being suspended from the top stay, in front of the rider. A coil fixed on the frame near the motor gives the spark which fires the explosive mixture. A muffler is provided which efficiently deadens the noise of the exhaust. No cooling water is carried, the heat being dissipated by means of a series of flanges cast on the cylinder. The speed control has been well thought out, and is effected by means of a small regulator handle, attached to the top bar of the frame. The starting is accomplished by giving one of the ordinary steering handles—the left-hand one, which is mounted to turn on the handle-bar—half a turn to the right. This completes the battery circuit. The rider pedals the machine for a few feet until the motor catches an explosion, after which he has nothing further to do. The pedals, which are provided to assist in starting, work out the chain-wheel through a ratchet arrangement, and the rider is thus enabled to keep his feet on the pedals after the motor has got to work. The machine is rather heavy—it weighs 150 lbs.—but the makers claim that weight is necessary to overcome the vibration which is inevitable with the oil-motor which develops three-quarter horse-power. The crank-shaft drives on to the wheels through a 7 to 1 reduction tooth-gear. Sufficient oil is carried for a run of 50 or 60 miles, whilst the accumulators are said to hold out for 200 miles. Speed, we are pleased to note, is not made the great feature, although the machine will easily attain the maximum allowed by law.

Some of the objects for which the Association is established are:—

To originate and promote improvement in the Law from time to time directly or indirectly affecting self-propelled vehicular and locomotive road traffic, and to support or oppose alterations in such Law, and for the purposes aforesaid to take such steps and proceedings as the Association may deem expedient.

To popularise and assist the development of self-propelled vehicular and locomotive road traffic, and for this purpose to take such steps and proceedings as the Association may deem expedient.

To take or defend any proceedings on behalf or against the Association or its members, which in the interests of the Association or the members thereof may seem to the Association expedient to take or defend. Provided that no such proceedings shall be taken or defended on the part of the members of the Association except in the *bona fide* furtherance of some object of the Association of a public or *quasi* public nature.

To promote the scientific knowledge of the construction and propelling of all kinds of self-propelled vehicles or locomotives, by means of competitions, exhibitions, by giving of prizes, or in such manner and on such conditions as may be found desirable.

Subscription ... ... £1 1s. per annum.

COMPRESSED AIR AS A MOTIVE POWER FOR ROAD CARRIAGES.

[A Paper read by Mr. Rhys Jenkins, M.I.M.E., before the Liverpool Branch of the Self-Propelled Traffic Association at the Royal Institute, Liverpool, on February 16th.]

A detailed exposition of the advantages attending the use of compressed air for carriages would be quite superfluous. Entire absence of smell and of heat and smoke are points that will at once occur to every one.

The compressed-air engine, too, shares with the steam engine an immense range of power, rendering unnecessary the use of variable speed gearing and affording the utmost facility for starting and stopping.

These characteristics render the system particularly useful for urban traffic, and especially passenger traffic. But its application is by no means confined to towns. Wherever there is sufficient traffic to keep compressing stations of fair size in employ, compressed air will answer all requirements as well as or better than any other agency. Probably for heavy, intermittent, or occasional traffic along country roads steam will hold its own. Petroleum, too, judging from present results, will have to be restricted to country roads. It seems quite inapplicable so far for cab and omnibus traffic in the crowded streets of cities, a field which appears to be reserved for Electricity or Compressed Air. Both these being storage systems, are obviously capable of being worked only within certain definite radii of their charging stations, so that they do not present that flexibility of application that attaches to prime movers such as the steam or petroleum engine. But for cab, omnibus, and parcels traffic, or for the conveyance of goods in large quantity along definite routes, this is no disadvantage.

The great point is to apply the system only where there is sufficient work to fully employ a plant constructed on a sufficiently large scale to secure a high efficiency in compression, unless, indeed, as may very well happen in towns, we are prepared to subordinate economy of propulsion in view of the other advantages attending the system. Here it may be remarked that with steam traction an increase in the scale of operations would not perceptibly diminish the expenses per ton, whereas in the case of compressed air it not only reduces the establishment charges, but enables the compressed air to be produced with greater efficiency.

The question of cost has very commonly been regarded as fatal to the application of compressed air for power transmission; that agent has indeed enjoyed a bad name all round in reference to efficiency. But unless a plant is designed with some reference to economy in working and upon correct principles it is useless to expect good results.

Plants are now in use which demonstrate that air can be used for power transmission with very satisfactory results. And even if the compressed-air system in its application to carriages did involve a larger coal consumption than some others, it has to be borne in mind that, after all, coal is but one item among a number of others of equal importance in the total cost of transport.

Historical.

Projects for compressed-air carriages have been brought before the public long since. As far back as the year 1800, Medhurst, the inventor of the pneumatic despatch system, patented a scheme for "a new improved method of driving carriages of all kinds by means of an improved Æolian engine." Medhurst contemplated a general system of coaches and stage-wagons throughout the kingdom and the establishment of air-compressing stations at suitable points all over the country. He described compressors and engines of variable power, a rotary engine to be fixed directly upon the hind axles of light vehicles, and a gunpowder engine, this last in connection with an artillery wagon.

About 1819, Murdock and Gordon are stated to have made some experiments with compressed-air carriages, and from 1827 to 1832 quite a number of schemes were evolved.

William Mann, of Brixton, turned his attention to the subject in 1827, obtained a patent in 1829, and published a pamphlet on the subject in 1830. He advocated compression in stages, now recognised as essential for the production of air at high pressures, and the erection of power stations along the high roads at intervals of 15 to 20 miles, or a continuous iron main with power stations in the coal districts.

Fig. 1 is reproduced from the plate in Mann's pamphlet. The carriage is provided with 15 reservoirs, having a capacity of 75 cubic feet in the aggregate. This supply Mann deemed sufficient for a run of 14 miles with air at 32 atmospheres pressure; with air at 64 atmospheres he held that 34 miles could be covered, and at an average cost for power of about a penny per mile. At this period a good deal was being done in the way of supplying lighting gas in portable reservoirs, much as oxygen and other gases are now sold, and Mann and other inventors make frequent reference to the reservoirs and pumps employed for this purpose. Mann states that the reservoirs in use by the Portable Gas Company for containing gas at 30 atmospheres pressure were $3\frac{1}{2}$ cubic feet capacity, 12 inches in diameter, and $\frac{1}{8}$ inch thick. The inventor suggested a public supply of power by means of compressed air, as has now been carried out in Paris by Messrs. Popp and Conti. He thought, too, that it would be well to make persons confined in Clerkenwell and other prisons earn their dinners by compressing air for the supply of power for propelling His Majesty's mails throughout the kingdom.

Bompass, another inventor of this period, thought the most suitable pressure about 100 atmospheres. He pointed out that the weight of the reservoirs is nearly the same whatever be the pressure adopted.

Wright's project was worked out in greater detail than any of the others. Fig. 2 is reproduced from his patent specification. He had arrived at what is really the root idea in the economical use of compressed air, *i.e.*, heating it or injecting steam into it prior to its entry into the working cylinder. In the drawing, *b* are the storage reservoirs, *e* an intermediate chamber in which the air is heated by the products of combustion of the furnace *f*, *l* cylinders of engine, the shaft, *j*, of which drives the axle, *s*, of the hind wheels by belting.

There is no distinct evidence that any of these inventors carried their ideas into practice. There is, however, some reason for thinking that one Fordham did make a compressed air carriage about 1832, but particulars relating thereto are wanting. The same remark applies to Von Rathen's carriage, which was tried at Putney in 1848.

FIG. 1.—MANN'S PATENT LOCOMOTIVE AIR CARRIAGE, 1830.

References.

1. Case containing Piston and Cylinder working on the axle of the hind-wheels.
2. Case containing Reservoirs of Compressed Air.
3. Fifteen Reservoirs containing 75 cubic feet.
4. A Reservoir taken out of the case.

The first compressed-air carriage of which there is an authentic account was constructed by two Frenchmen, Andraud and Tessié du Motay, about 1840. As will be seen from Fig. 3, it was made for running upon rails; it was adapted to carry eight passengers; had the air stored at a pressure of 17 atmospheres, while the working pressure in the cylinder was three atmospheres. These inventors also contemplated the application of compressed air to road carriages; they proposed to use pressures as high as 60 atmospheres, which were to be attained in stages, and to heat the air before its admission to the cylinder. They were the first to indicate the necessity of a reserve supply of air for use in hill-climbing or for other contingencies when the pressure in the main reservoirs was approaching its lower limit.

But the only really valuable work in connection with the application of compressed air to locomotion has been done in reference to street tramways, and again by a Frenchman, M. Mékarski. The attempts of Scott-Moncrieff, of Beaumont, and more recently of Hughes and Lancaster, in this country, may be passed over as having remained more or less in the experimental stage, whereas the Mékarski system has been at work on the tramways of Nantes for about 20 years, and is now at work in Berne, and upon four lines in and around Paris. In a few words, the essential features of the Mékarski system are (1) high pressures in the storage vessels on the car. Starting with 30 atmospheres at Nantes, this pressure has been increased in each succeeding installation, first to 45, then to 60, and finally to 80 atmospheres, say, 1,200 lbs. per square inch, on the Versailles line. (2) The air on its way from the storage vessels to the cylinders passes up through a vertical cylinder containing hot water, in doing which it becomes heated and charged with vapour; (3) it also passes through an automatic reducing valve, whereby it is reduced to a constant and comparatively low working pressure. The engines work direct on to the car axles.

There seems to be no question that the Mékarski system as applied to tramways is a success both mechanically and financially.

Fig. 2.

Fig. 3.—Andraud and Tessié du Motay, 1840.

Another French system is that of Messrs. Popp and Conti, already mentioned in connection with the Paris compressed air supply. These constructors prefer low pressures, say, from 15 to 20 atmospheres, and are therefore compelled to charge more frequently. Their engine is compound, and geared to the car axle. They heat the air before using it, and on its passage from the high-pressure to the low-pressure cylinder by means of a small coke stove.

Power Required to Propel a Given Load.

There is little doubt that on this point a great many motor-carriage constructors have erred on the wrong side. The subject of the draught of carriages, and consequently of the power required to propel them, is indeed in a somewhat chaotic state. This is partly due, no doubt, to the variation in the condition of the roadways and of the axle friction. Many authorities state that the resistance is independent of speed, but it is easy to see that this cannot be strictly true, although possibly the effect of variations such as occur in practice may not be of importance.

On a good macadam road in ordinary condition it seems safe to conclude that the average pull for a four-wheel van or omnibus will not exceed 45 lbs. per ton when moving at the rate of eight miles per hour. An allowance of 47 lbs. will certainly be ample, and this, at the speed stated, is just equivalent to the exertion of one horse-power per ton at the wheels. Experiments made by the Paris General Omnibus Company give 44·8 lbs. per ton as the pull required. No doubt by the use of modern mechanical refinements, such as ball bearings at the axles, the resistance might be considerably diminished. But as it stands the allowance of one horse-power agrees with the results of Sir David Salomons' experience, as recorded in *The Engineer*, for a speed of eight miles per hour on a good level road.

It will be safe, then, to base the consumption of air upon the expenditure of one effective horse-power per ton. For starting purposes and for various contingencies the engine should be capable of exerting four or five times this power, and this is well within the scope of a compressed-air engine.

Any ordinary steam engine may be worked by compressed air, no alteration whatever is really necessary, and working pressures such as are common in steam engine practice suit best with compressed air also.

Receivers.

For storage purposes, in order to carry the required weight of air within a reasonable compass, we must adopt very much higher pressures than these.

No alarm need be felt at the pressures found to be necessary. An immense trade is now done in compressed gases, and although there have been a few accidents, their proportion in the total number of bottles charged is quite insignificant, and most of the accidents are such as could not possibly occur with compressed air. Beyond this the gas-bottles undergo far more severe usage than the receivers on a carriage need be exposed to.

Air at pressures of from 1,000 to 1,400 lbs. has been used for years in torpedoes, and so far there have been but two cases of the air-receivers bursting, and in each case the accident arose from the impact of the torpedo against rocks. Bursting is, perhaps, not the correct word to employ in this connection—the action when these receivers are tested to destruction is a very gradual and silent one.

Pressures as high as 2,000 lbs. per square inch are now in daily use for tramway work in New York. One of the cylinders employed, selected at random from a number supplied by the German Mannesmann Tube Company, was recently tested by Professor Jacobus, of the Stevens Institute. It measured $9\frac{3}{16}$ inches inside diameter by 5 feet 6 inches total length, and was $\frac{5}{16}$ inch thick. Up to 4,500 lbs. pressure there was no permanent set; at 5,760 lbs. a rent near one end started. All the cylinders had been tested to 4,000 lbs. by the makers.

At Brin's Oxygen Works the gas is stored at a pressure of 1,800 lbs. in 3-inch cylinders $\frac{1}{8}$ inch thick, and in 9-inch cylinders $\frac{5}{16}$ inch thick.

In this paper a pressure of 1,000 lbs. per square inch has been adopted as one that would probably meet the greater number of cases. Higher pressures demand greater expenditure of power in compression, but they enable us to store more energy within a given space. And as far as the receivers are concerned the question is entirely one of space; their weight for a given weight of air or volume of free air remains the same whatever be the pressure adopted. This is easily seen. Imagine a cylinder of a given thickness charged with air; let this volume of air be compressed to half its original volume. A cylinder one-half the length of the former will now enclose it, but as in halving the volume the pressure has been doubled, the thickness of the cylinder must be increased in the same proportion, if the working stress is to remain constant. The statement is not strictly true, as it disregards the effect of the cylinder ends, but this is not very important. The American tramcar cylinders referred to appear to be exposed to a working stress of 13 tons per square inch of metal. Professor Unwin's Committee on Gas-bottles recommended that the working stress should not exceed 8 tons. For carriage receivers a working stress of 10 tons per square inch for weldless cylinders is certainly not excessive. At that figure the weight of receivers (disregarding the ends) works out as $8\frac{1}{4}$ lbs. per lb. of air stored, or 630 lbs. per 1,000 cubic feet of free air. Making allowance for the ends and connections, the total weight of receivers will be ten times that of the air carried. In the Paris tramcars it works out as twelve times.

The weight of the receivers is also independent of their diameter: four 6 inch cylinders will have the same weight and the same capacity as one 12-inch, and will have the same circumscribing rectangle. It will thus be seen that there is considerable room for constructional variation.

Air Compression.

Having thus far cleared the ground, it will be well to deal briefly with the nature of the problems involved in the transmission of power by compressed air. At the power station or point from which power is to be transmitted are a set of compressing pumps driven by steam or water-power, which force the air into magazines, whence it is transmitted to the motor by a line of piping, or in the case of a vehicle it is stored in reservoirs carried thereby.

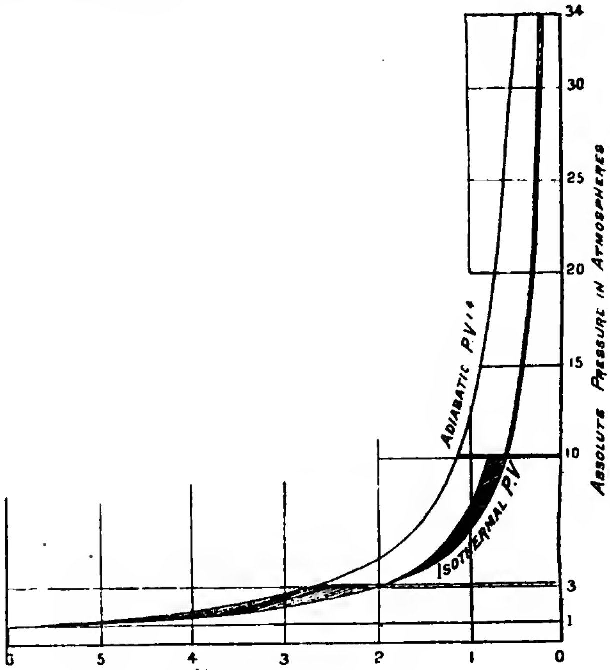
Naturally the object is to get as large a proportion as possible of the work expended in the compressing station exerted at the motors.

In a perfect gas—and air, if dry, is, for all ordinary purposes, a perfect gas—the pressure is inversely proportional to the volume if the temperature remains constant, and the compression or expansion curve is a rectangular hyperbola.

As a matter of fact, however, in compressing air the temperature does NOT remain constant—the work exerted in compression is converted into heat, and this heat acts to expand the mass of air and to increase the work required to compress it to any given pressure.

If we consider the whole of the heat so generated to be retained in the air, the curve of compression is known as an *adiabatic*, in contradistinction to the curve produced by the air at constant temperature, which is termed an *isothermal*. In the isothermal the pressure multiplied by the volume is a constant quantity; in the adiabatic the volume has to be raised to the power of 1·4 to produce a constant when multiplied by the pressure.

At first sight it would appear that no particular disadvantage attended adiabatic compression. The expenditure of a certain amount of work has resulted in the production of a corresponding volume of compressed air at a temperature which may be considerably higher than the initial temperature, and the whole of the work exerted is stored up in the air; and if this air could be transferred directly to the motor cylinder, this would be the case.



Air Compression in Three Stages

FIG. 4.

Unfortunately, however, in all cases that arise in practice, this heat cannot be retained. If the air has to be stored in reservoirs or carried any considerable distance, it must inevitably fall or tend to fall to the temperature of the atmosphere. This fall in temperature is accompanied by a corresponding contraction in volume or reduction of pressure. So that if the compressed air falls to the initial temperature before it is used, all the work expended above that required by isothermal compression is thrown away; and so, setting aside any mechanical questions, it is essential that the compressing process be accompanied by the production of as little heat as possible.

To this end it is now usual for all high pressures to adopt compression in stages, with intermediate cooling; that is to say, the air is compressed up to a certain point in one cylinder, passed into a cooling chamber, where it is cooled down to the initial temperature or as near to it as possible, then led into the second compressing cylinder, and so on. The effect of this step-by-step action is very important, as is apparent from the diagram Fig. 4, which represents compression to 34 atmospheres pressure in three stages. The shaded areas represent the lost work.

In addition to this, the compressing cylinders may be jacketed with water, and may be provided with a cold water spray injection. As to the efficacy of these methods there is some difference of opinion. Many think that the water-jacket is of very little value, and others hold that the undoubtedly powerful cooling action of a fine spray of water in the cylinder is more than balanced by the excessive wear of the cylinder due to the action of the water; it is also somewhat difficult to maintain a really fine spray, and without great watchfulness it may happen that the water is cut off completely by the choking of the orifices.

In any case it is quite safe to say that the compression curve is invariably below the adiabatic line to a small extent in consequence of the equalising action of the cylinder walls, of radiation into the atmosphere, and of the moisture naturally carried by the air.

Cost of Compressed Air.

Now as to the cost of compressed air. In Paris the Compressed Air Company supplies its customers at the rate of 4½*d.* per 1,000 cubic feet of free air. In the ill-fated Birmingham scheme the price was 4*d.* per 1,000, but it was admitted that with the plant and mains in proper order it could have been sold at a profit of 1½*d.* per 1,000. An American authority considers that 2½*d.* per 1,000 would be a most remunerative price for a public supply of air at 100 lbs. pressure.

These figures relate to the supply of air by mains laid in the public streets, and at comparatively low pressures. In charging vehicles directly at the power stations the price should be considerably less, as the cost of the mains and the loss by leakage is saved. On the other hand, the increased pressure required for carriages demands increased expenditure for power.

Possibly the most efficient compressors yet constructed are those of the Paris Compressed Air Company, designed by Professor Riedler, in which a pressure of seven or eight atmospheres is attained in two stages. The plant comprises four sets of 2,000 horse-power triple-expansion condensing engines, Figs. 5 and 5A. The low-pressure air cylinders, A and B, mounted above the low-pressure and intermediate steam cylinders, compress atmospheric air into a receiver, D, from which it is taken by the high-pressure cylinder, C, mounted above the high-pressure steam cylinder. The engine shaft, I, carries fly-wheels, H, H, and drives, by bevel-gearing, J, and vertical shafts, a lay-shaft, K, which operates the valves of the steam cylinders. This shaft also carries cams by which the valves of the compressor are closed mechanically at the required periods. Fig. 6 shows the general arrangement of the cams, rock-shafts, and connections for the high-pressure air cylinder, and Fig. 7 represents the valve chest at the top of the same, U and V being respectively the inlet and delivery valves, and O, O, their rock-shafts. The inlet valve of the low-pressure cylinder is shown in Fig. 8; the valve seat Y is prolonged to form a cylinder Y¹, which, with a piston formed on a prolongation of the valve X, forms an air spring. According to a report by M. Popp, the cost in ordinary working, including coal, water, lubricants, rents, salaries, and wages, is 1⅛*d.* per 1,000 cubic feet, that is about 1½*d.* per 100 lbs. of air. The coal consumed was 5½ lbs. per 1,000 cubic feet, or, say, 13·6 lbs. of air per lb. of coal. Per I.H.P. in the steam cylinder 2·14 lbs. of coal were burned per hour, and the lbs. of air per I.H.P. were 28.

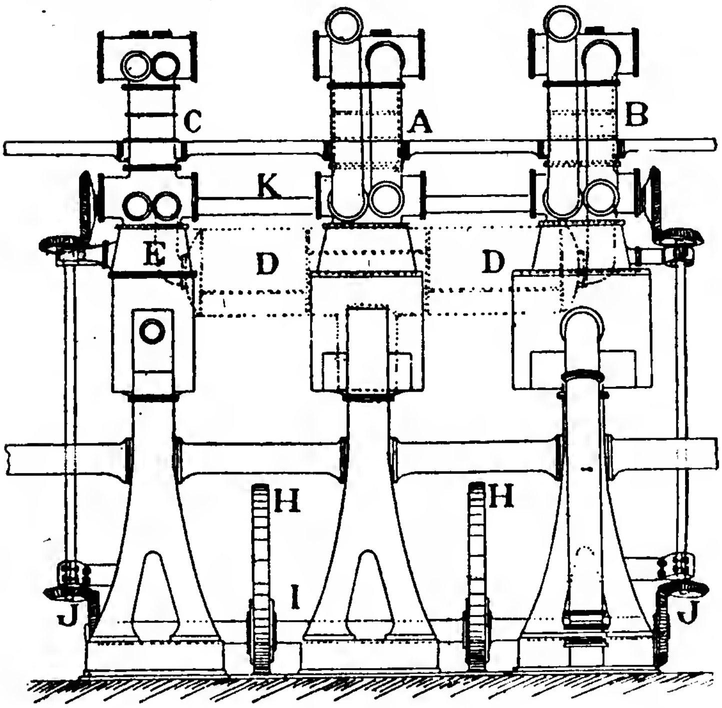


FIG. 5.

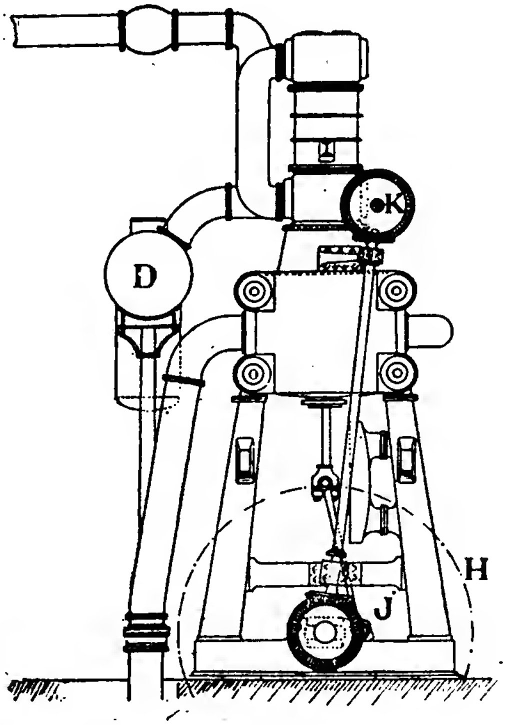

FIG. 5A.

Of the total cost, coal at 25*s.* per ton takes up about two-thirds, salaries and wages about one-fifth.

With a duplicate set of such machinery the air could be compressed to a pressure of 68 atmospheres at a little more than double the expenditure of power, say 12 lbs. of coal per 1,000 cubic feet or 7 lbs. of air per lb. of coal.

In practice, however, unless with very large undertakings, we should probably not go beyond three steps in compression. The St. Augustin-Vincennes Tramway in Paris, on the Mékarski system, is operated by three stage compressors, Figs. 9 and 9A, consisting of four single-acting air cylinders, arranged in couples, tandem. The two low-pressure cylinders are 12 inches diameter, the intermediate 10 inches, and the high pressure 5 inches; the stroke of each is 16 inches. The crank-shaft of the compressor is coupled direct to that of the steam-engine. These compressors in ordinary work produce 9 lbs. of air per I.H.P., or say 4½ lbs. per lb. of coal, the pressure being

60 atmospheres. But on the whole there appears little reason to doubt that with well-designed engines, boilers, and compressors, in a plant of a fair size, 1 lb. of coal would be a liberal allowance for producing 5 lbs. of air at 68 atmospheres pressure, and would even cover the small consumption of fuel required for preheating and intermediate heating at the motor.

Air Motors.

Turning now to the consideration of the Air Motor. The old plan was to send the air direct into the working cylinder, where the converse action takes place to that which occurs in the compressor; the work performed during expansion has to be supplied from the heat in the air itself, which accordingly falls in temperature and contracts in volume relatively to isothermal expansion. This fall of temperature causes trouble in consequence of the freezing of the moisture carried by the air, so that in most cases it has been found expedient to relinquish the gain due to long expansions and to cut off comparatively late in the stroke. It is now generally recognised that the efficiency is vastly increased by heating the air before using it, or by heating and mixing steam with it. The system, of course, ceases to be a storage system pure and simple. In some cases this might be an objection; on a carriage or tramcar, the objection, if any, appears to be infinitesimal.

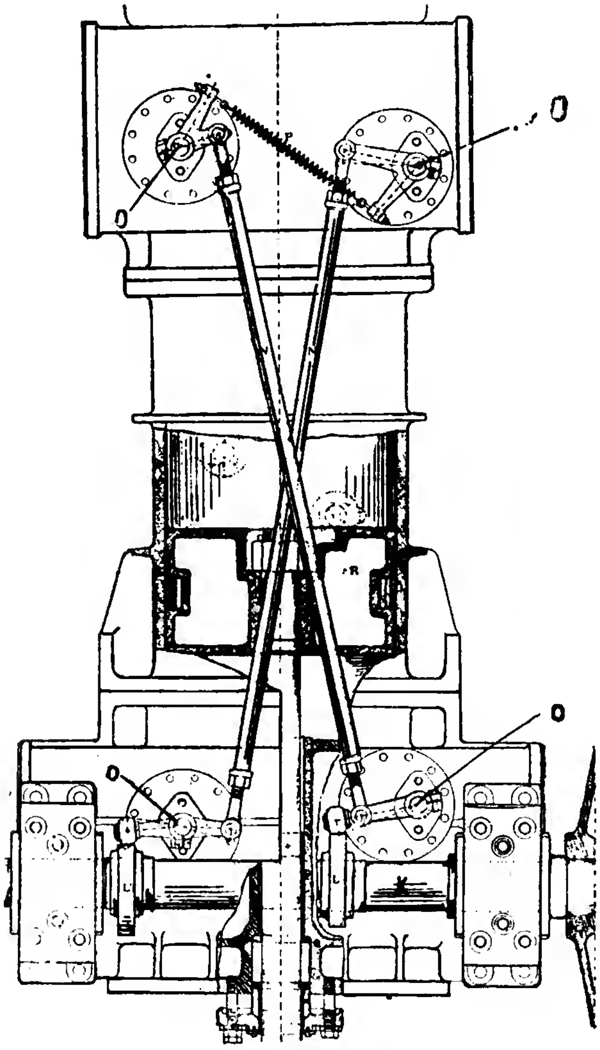

Fig. 6.

The addition of steam has the effect not only of raising the initial temperature, but of also supplying heat to the air as the expansion proceeds; the expansion curve is thus kept well up to the isothermal. The amount of steam required is very small, and the exhaust is quite imperceptible, even in the winter. M. Popp's system of passing the air through a coke stove is perhaps simpler and lighter than the Mékarski plan, although doubtless not so efficient. Fig. 10 represents a stove which may be used in connection with a 15 horse-power engine. It is 2 feet 6 inches high by $6\frac{1}{2}$ inches diameter, and consists of a series of vertical tubes, E, coupled in pairs at their upper ends by ∩ pieces, F, and mounted upon a hollow-base ring, A, formed with radial partitions and inlet and outlet branches. The air

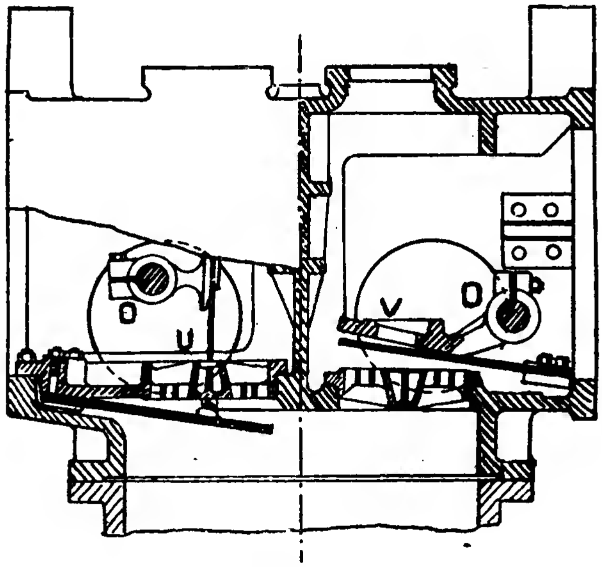

Fig. 7.

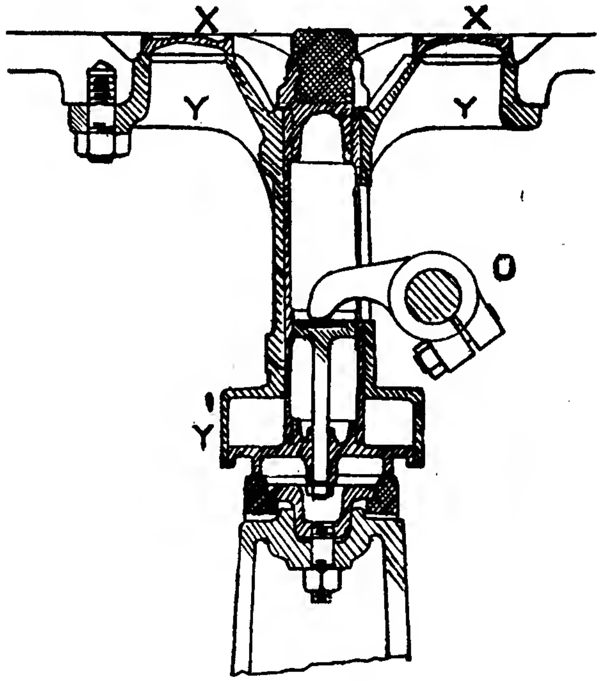

Fig. 8.

passes up and down through the entire series of tubes. The casing is provided with a chimney branch, S, and with a lid, P, for charging the fuel into the fire-clay hearth which surmounts the grate, H. A coil of tubing, N, may be provided to generate steam, a jet of which may be directed into the air delivery pipe. The same stove is employed for preheating and for intermediate heating in compound engines. The coke stove might be replaced by an oil stove, or by a petroleum lamp in the air-pipe itself, as has been done in America.

Now obviously, as the air is used, the pressure in the receivers will gradually fall until it drops too low to be usefully employed for our purpose. The volume of air then remaining in the receivers is dead, and as we have to carry not merely the weight of the air, but what is far more serious, the corresponding weight of receiver, it behoves us to adapt our motor for

We must, it appears, decide to throw away some of the advantages attending the high pressure at which the receivers are charged in the first instance, and pass the air through a reducing valve on its way to the cylinders. There are several constructions of these valves in use. That of M. Mékarski (Fig. 11) is said to be very reliable in its automatic action; it is mounted above the hot water chamber. The stem of the valve, S, carries at its upper end a disc, P, in contact with a rubber diaphragm, A, placed between the chamber, C, and the hydraulic press, H, the bottom of which is perforated. The valve opening is controlled by increasing or diminishing the pressure in the press by means of the hand-wheel. When once set to deliver the air into the chamber, C, at a given pressure, the device automatically adjusts itself to maintain that pressure constant in spite of the fall in the receiver pressure.

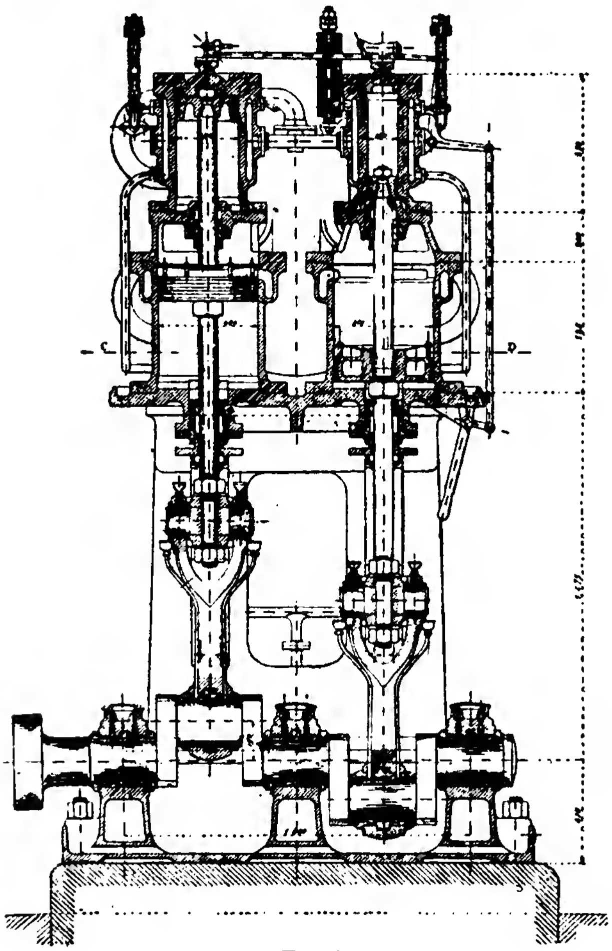

FIG. 9.

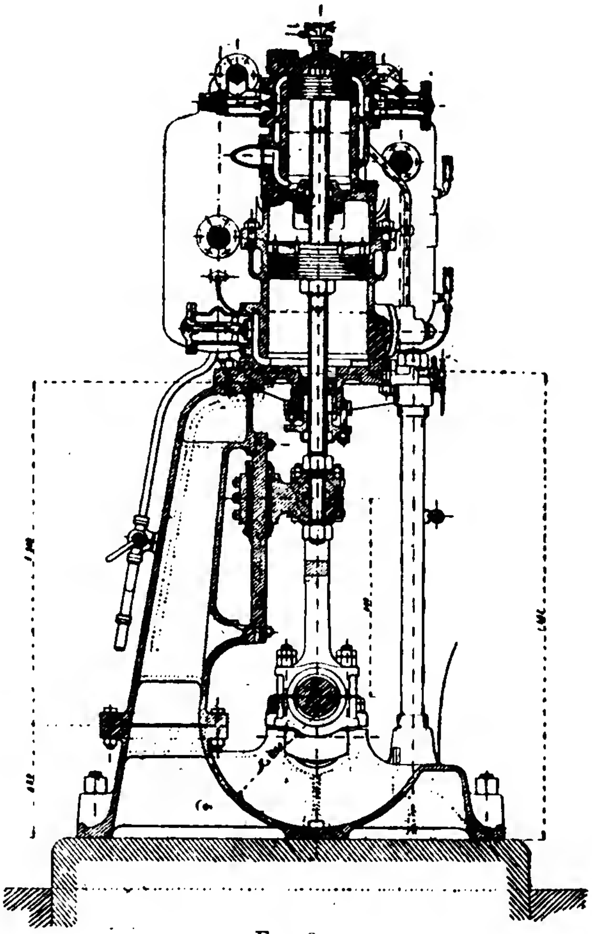

FIG. 9A.

working at as low a pressure as possible. On the other hand, there is a vast difference in the amount of work which any given weight of air may give out at different pressures. A pound of air at atmospheric temperature, 60° F., and at a pressure of 1,000 lbs. gauge, would in expanding, without addition of heat, down to the atmospheric pressure be capable of doing 67,000 foot lbs. of work, whereas at 60 lbs. pressure the same weight of air would perform 35,500 foot lbs. only—a loss of 47 per cent.

But the use of air direct from the receiver is attended with serious difficulties; it is impossible to obtain the requisite range of expansion for maintaining the work output constant without employing a multi-cylinder compound engine and other complications which are entirely out of place on a vehicle.

Let us assume a working pressure for ordinary conditions of 165 lbs. gauge, or 180 lbs. absolute. It is a pressure well within the range of ordinary engineering experience, and calls for no special conditions of construction. At that pressure the work which a pound of air at 60° F. is capable of doing in expanding down to the atmospheric pressure without the addition of heat is 49,000 foot lbs., which represents a loss of 26 per cent. as compared with air at 1,000 lbs.

It must be noticed, however, that this pressure of 1,000 lbs. obtains only at the start; the average pressure during a run until the receiver pressure falls to the working pressure of 165 lbs. would be 600 lbs., the work corresponding to which is 62,000 foot lbs.

When the receiver pressure has fallen to 180 lbs., 18 per cent of the original charge is still left. By a step-by-step regulation of the working pressure and a corresponding adjustment of the point of cut-off, this remnant may be reduced by, say, one-half, corresponding to a working pressure of 90 lbs. But this portion of the charge will be less efficient than the main portion, for, as the working pressure is reduced, considerably more air is required to do the same work in the same cylinders. Thus, at 90 lbs. pressure, $1\frac{1}{2}$ lbs. of air are required to do the work of 1 lb. at 180 lbs. pressure. If, on the average, the air is used with four-fifths its former efficiency, the additional 9 per cent. of the total charge which may be used in working down to 90 lbs. is equal to 7·2 per cent., reckoned at the original working pressure. That is to say, 91 per cent. of the charge does work which counts as 89·2, taking the work per lb. as 49,000 foot lbs.

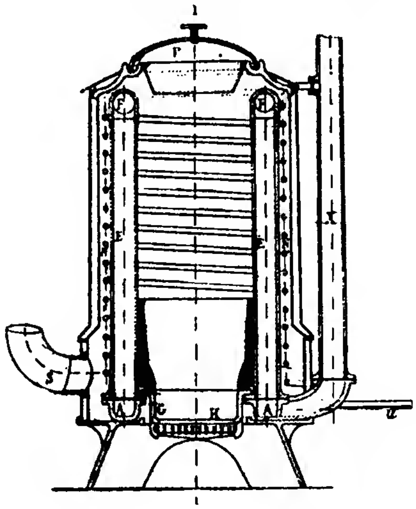

Fig. 10.

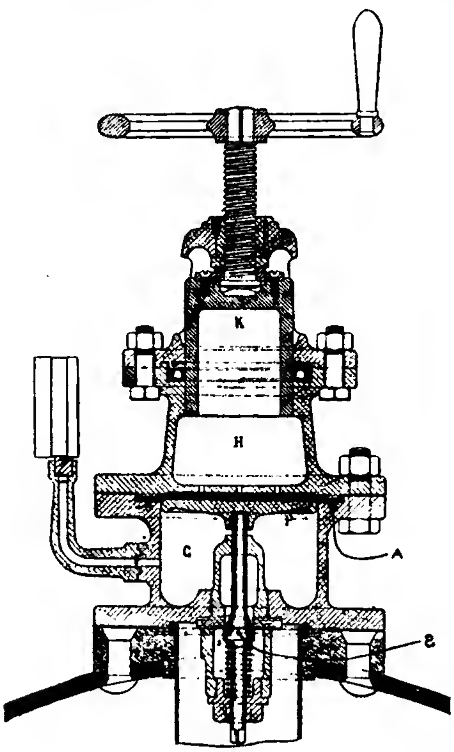

Fig. 11.

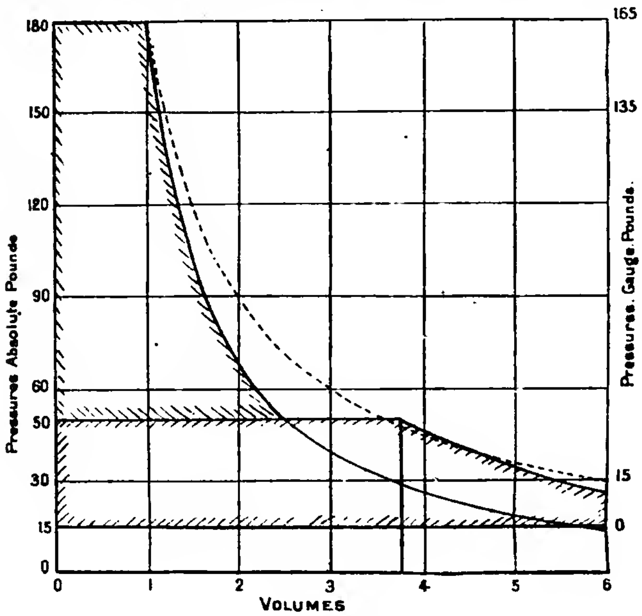
This 49,000 foot lbs. per lb. of air represents, it must be understood, the work shown on an ideal indicator diagram, in which the expansion curve is an adiabatic line; *i.e.*, it is based on the assumption that the air we are using is a perfect gas, and that no heat is supplied to it during any part of the stroke.

In practice the expansion curve invariably lies somewhat above the adiabatic line. This is due to the presence of moisture, to radiation, and to the equalising and conducting action of the cylinder walls. Thus the actual indicator diagram in the case of air, with its rounded corners and other defects, would probably not show perceptibly less work than the ideal diagram. However, to allow for valve and piston leakage we may deduct one-seventh; this will reduce the 49,000 foot lbs. to 42,000, which is equivalent to an expenditure of 48 lbs. per I.H.P. per hour. This result may be compared with an experiment made in Paris by Professor Kennedy. A small Davey-Paxman steam engine was worked with air at 67 lbs. gauge pressure. When indicating about 10 horse-power the consumption of air was 68 lbs. per I.H.P. per hour. Allowing for increased pressure and expansion, the consumption of air at 180 lbs. should be one-third less, *i.e.*, 45 lbs. per I.H.P. per hour, as against the 48 obtained by calculation.



Compound Air Motor

Fig. 12.

By heating the air before sending it into the cylinder the consumption may be considerably reduced. At a temperature of 320° F., which is that of saturated steam at 75 lbs. pressure, the volume of the air is increased by one-half, and the work done in the same proportion. Further, if, as is certainly desirable, the air be worked in a compound engine, it may in passing from one cylinder to another be again heated up to the same temperature; a saving of one-half is thereby easily effected. This brings the consumption down to 24 lbs. per hour per I.H.P. Fig. 12 represents the theoretical indicator diagram of such a motor with intermediate heating. The dotted line is the isothermal.

The heating may be effected at a trifling cost. Professor Kennedy, in the engine already referred to, found that the expenditure of one-third of a pound of coke per I.H.P. per hour sufficed to heat the air up to 315° F., and thereby to effect a saving of 25 per cent. in the consumption of air.

A larger engine, indicating about 70 horse-power, required 34 lbs. of air at 80 lbs. pressure, and 300° F. per I.H.P. per hour. A small engine, giving off about two horse-power on the brake, used per hour per brake horse-power 55 lbs. of air at 300° F. Small rotary engines consume 65 lbs. per brake horse-power per hour of air heated to 150° F.

The frictional losses between the cylinders and the wheels will amount to 40 per cent. or thereabouts of the I.H.P. So that the consumption of heated air used at 180 lbs. working pressure and a temperature of 320° F. per effective horse-power per hour will be 40 lbs. In an hour, if working continuously, a distance of eight miles would be covered, so that per mile the consumption would be 5 lbs. per effective horse-power, and it has already been shown that one effective horse-power is required per ton per mile. The consumption is really independent of the time consumed upon a journey. As many and as long stops as may be desired may be made without affecting the consumption, except in regard to the increased power required to start the vehicle from a state of rest.

Here again the figures may be compared with the results of actual practice. M. Barbet has published the results of working the Nogent tramways, a line upon the Mékarski system, with the engines on the cars. The engines are not compound, and the working pressure is considerably below 180 lbs. On the other hand, the advantage of the admixture of steam with the air is secured. The receiver pressure is 45 atmospheres. The cars carry 55 passengers, and weigh 12 tons. The air consumption taken over a long period does not exceed 35½ lbs. per car mile; *i.e.*, it is under 3 lbs. per ton mile. M. Barbet takes the resistance as 33 lbs. per ton, so that with a resistance of 45 lbs., as on ordinary roads, the consumption should be a little over 4 lbs.

Probably 33 lbs. is too high; the figures arrived at by our best authorities for tramway resistances are 22½ lbs. per ton. At this rate, the consumption for an ordinary road carriage would be 6 lbs. per ton per mile.

Evidently then, under the conditions of working assumed, the estimate of 5 lbs. of air per ton mile is fairly accurate.

We have already seen that, upon the basis of 2 lbs. of coal per I.H.P. per hour, the expenditure of 1 lb. of coal is sufficient for the production of 5 lbs. of air, so that 1 lb. of coal is sufficient to move a gross weight of one ton one mile.

For a 10-mile run 50 lbs. of air are required, and allowing for dead air and a reserve supply of, say, one-sixth, we require a charge of 64 lbs. per ton gross.

The receiver will weigh ten times as much as the air. Thus the total weight of air and receiver for a 10-mile journey amounts to 700 lbs. per ton; for an eight-mile journey it is 560 lbs., just one-fourth of the total weight moved. By reducing the length of the run or by increasing the working stress upon the metal of the receivers, as there is ample margin for in case of emergency, the figures may be still further reduced.

Then we have to consider the weight of the engine, gearing, and stove, as well as that of the vehicle itself, which would need to be strengthened on account of the machinery. It is not possible to give definite statements here, so much would depend upon the kind of vehicle and the amount of load, but, roughly speaking, the paying load would work out to one-third the gross load.

Cost of Transport.

On this basis the consumption of coal per mile per ton net would be 3 lbs., which at 12*s.* per ton would cost something less than ⅛*d.* For rough purposes we may double the cost of coal to get the total cost of the compressed air. This gives us something under ¼*d.* per ton mile as the cost of power. For vehicles making the return journey unloaded an addition would have to be made of two-thirds. So that the cost per ton of paying load would amount to ⅜*d.* To this must be added driver's wages, superintendence, interest on cost of the carriage, depreciation and repairs, lubricants, &c.

We are now in a position to consider the application of the system in particular cases, and here we must keep in view the Government regulations as to weight and speed. The limiting weight of the empty vehicle, excluding fuel, water, or accumulators, is three tons. It is quite reasonable to expect that storage vessels should be deemed to be on the same footing as the storage cells of electric carriages; it might, in fact, in some cases be expedient to place them in the carriage ready charged and to replace them by others when exhausted. We must, therefore, see that the carriage, with engine, gearing, and stove, does not exceed three tons. But here the speed question comes in: a carriage weighing three tons empty is limited to five miles per hour, whereas if the weight does not exceed two tons, the speed limit is eight miles per hour.

Now, if we assume that the earning capacity is in direct proportion to the weight of the carriage and to its speed, we find that there is very little difference whether we use the three-ton or the two-ton carriage—the proportion is as 15 to 16.

For the transport of goods over a distance of 30 miles, the lighter carriage has a decided advantage in that the higher speed would enable a round journey to be made with ease in a working day, so that a driver would return at night to the point, not necessarily a terminus, from which he started in the morning.

A vehicle weighing 30 cwt. would be capable of carrying a load of two tons and 36 cwt. of receivers. The engine, stove and gearing need not exceed 10 cwt., which makes up a total of two tons for the vehicle, or 5 tons 16 cwt. gross.

The round journey, unloaded one way, would cost for—

	s.	*d.*
Power	3	3
Driver	5	0
Oil, &c.	0	9
Interest on first cost, depreciation, and repairs	1	0
Total	10	0

or 5*s.* per ton—2*d.* per ton mile. If a return load can be arranged for, the price would of course work out still lower.

To work a run of this length three power stations would be required at intervals of 10 miles, the first and last stations at five miles from the respective terminals.

A plant of 500 I.H.P. at each of these stations would be capable of dealing with the transport of 200 tons per day. The cost of the stations would vary very much, in accordance with local conditions, situation, &c.

The efficiency of the entire system, from the engine cylinders of the compressor to the road wheels, is rather less than one-third (·28). A large proportion of the loss is due to the necessity of high storage pressures and comparatively low working pressures. It may be reduced by charging the receivers first from one of the intermediate receivers of the compressor and then completing the charge from the high-pressure receiver, or the main compressing engines may be arranged to work up to say 34 atmospheres, and a supplementary compressor employed to force this air direct into the receivers until the requisite pressure is attained therein.

The charging of the receivers is a work very rapidly accomplished. It is stated that some of the tramcars in New York are charged in two minutes. This is very smart work indeed. In Paris the cars on the St. Augustin-Vincennes Tramway are charged with steam and air from stand-pipes in the street—one for the up and the other for the down line—and the average stop is four minutes. A friend was good enough to time the stops a week or so ago. His log for one of them is:—

4.33 arrive; chock wheels; screw on junction; turn on steam; screw on junction.
4.34 turn on air.
4.35½ turn off steam; unscrew junction.
4.36 turn off air; unscrew junction.
4.37 start.

The cars run every 10 minutes, so that the men in charge are kept pretty fully employed.

For road vehicles the charging would, of course, be done at the power stations, which would be provided with a carriage-shed having a range of pipes and adjustable connections to allow of two or more vehicles being simultaneously charged. Fig. 13 illustrates the adjustable pivoted connections in use for tramway purposes.

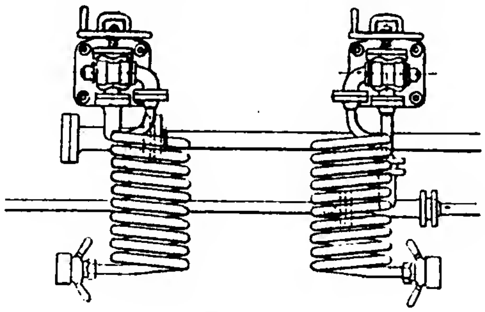


FIG. 13.

To recapitulate, it is possible with 1 lb. of coal to produce 5 lbs. of compressed air. Five lbs. of air are capable of moving one ton one mile. Allowing for receivers, &c., the paying load is one-third the gross weight, so that 3 lbs. of coal are required per ton mile.

SIR DAVID SALOMONS, Bart., will read a paper before the Society of Arts on the 12th of May, entitled "Motor Traffic: Technical Considerations."

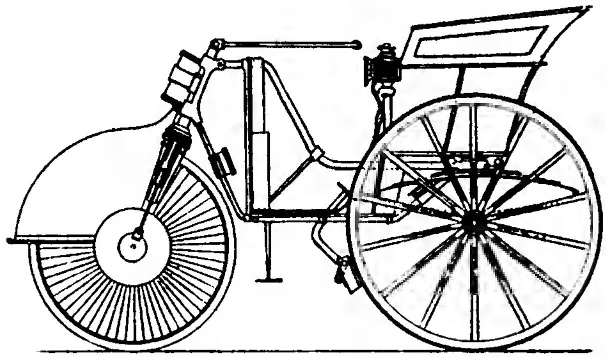
MR. DUGALD CLERK'S paper on "Oil Engines for Motor Vehicles," which was to have been read before the Self-Propelled Traffic Association this month, has been postponed till November next; and we regret to hear that Messrs. L. A. Legros and George Hopkins have—on the plea of unpreparedness owing to lack of data—requested the postponement of their papers, announced to be read before the Liverpool Branch of the Self-Propelled Traffic Association for the 16th and 30th instant respectively.

MESSRS. NEW AND MAYNE (LIMITED).

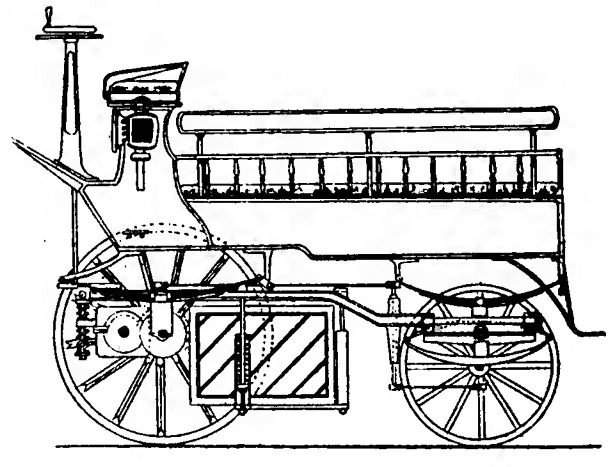
THIS firm has long been known for excellent workmanship, combined with enterprise in adapting themselves to any new thing which may come forward. It is, therefore, by no means surprising to outsiders to find that they are in the very front rank of motor-carriage builders—while to those who know how keenly the members of the firm have followed the introduction of automotors into this country it seems only in the "eternal fitness of things" that they should take a foremost place in catering for an appetite which they have done much to create. In order to standardise work the under-frames of the carriages are made to the firm's patterns, and with these as a foundation any modifications or additions can easily be made to suit the convenience of the customers. We have examined some of these frames, and unquestionably great care has been taken in designing all the parts in order that the stresses shall be properly distributed, and sufficient motive power has been allowed to negotiate the steepest hills. All the carriages run at 12 and 4½ miles an hour, the latter speed being obtainable without reducing the speed of the motor. The hand-wheels, levers of brakes, &c., are placed in positions readily accessible by the driver of the carriage, and vibration is guarded against by the employment of powerful springs between the under-framing and the carriage body. The Ricksha and dog-cart patterns have three wheels, the single front wheel being employed for steering. All the other carriages have four wheels, and steering is effected by the hind axle and turntable. The front axle carries the motor, reduction and differential gearing, and the driving road wheels. It will be seen from the above that the motor-cars are pulled along by the front wheels, an arrangement which gives several important advantages over vehicles which are pushed along. In order to keep the weight down an aluminium alloy is used wherever possible.

The oil engines employed run at a high speed, and are fitted with special spray and exhaust valves, and ignition arrangements, which they have been at great expense to work out. They work with the ordinary Tea Rose or Daylight Oils, and a gallon, costing about 7*d.*, is sufficient to propel the lighter vehicles at a speed of 12 miles an hour for several hours.

The electrically-driven carriages, which are got out to the designs of Mr. Ekilburn Scott, have the accumulators suspended from a very strong under-framing between the front and hind



axles, thus keeping the centre of gravity low down and enabling the box containing the cells to be unshipped in a few minutes. Springs are interposed between the accumulator-box and the under-frame. The motors are specially designed for lightness and accessibility, and are suspended on riding springs in the same way as the motors used for tramcars. Each motor is completely enclosed, but the commutator and brushes can be readily inspected. The brushes are built up of carbon and copper, and special arrangements are made for annulling the lead. A char-à-banc to carry 22 persons is being made, and designs for electric omnibuses are in hand.



Messrs. New and Mayne usually employ the I. E. S. Accumulator Company's special traction or A cells, as they have found that they withstand vibration and heavy discharges very succcessfully.

A 52-page diary, printed on excellent paper, is one of the features of THE AUTOMOTOR AND HORSELESS VEHICLE DIARY AND POCKET-BOOK for 1897, which contains over 100 pages of information. Price 6*d.*; post free, 7*d.*, of Messrs. F. King and Co., 62, St. Martin's Lane, London, W.C.

MESSRS. PHILIPSON AND TOWARD'S "No. 1 STEAM MOTOR-CARRIAGE."

On the last Saturday in February there was a semi-private assembly at the carriage-building factory of Messrs. Atkinson and Philipson, Newcastle, to inspect a new motor-carriage, locally invented, designed, and built, and, as to parts, patented and registered. The new autocar is the joint production of two well-known Tyneside firms—Messrs. Toward and Co, engineers, St. Lawrence, and Messrs. Atkinson and Philipson, the eminent Newcastle carriage manufacturers. The latter firm have supplied the carriage and wheels and the former the motor. The joint production is a smart wagonette, well designed, and of compact appearance, while the motor is apparently equally satisfactory, and in actual trial in the yard gave promise of performing effic:.ntly on the road. As the first product of its designers and builders, however, it was interesting mainly as giving a concrete illustration of the ideas which will probably prevail for some years in regard to the new mechanical road locomotion. In the north of England there have not been many motor-cars seen in public at all, and the majority of those that Northumbrians have hsd an opportunity of seeing in public have not been such as to inspire much confidence or hope for the future of motor traffic; they have been chiefly gasoline-motors of French or American pattern and manufacture, snd have been unpleasantly odoriferous. For the purposes of French autocar competitions, oil seems to have been a greater favourite than steam as a motive power, electricity not yet being a practical competitor; but in England the gasoline-motors have not found so great favour as steam is likely to receive when the numerous inventors who are busy with steam road-carriages show what are the capabilities of the older power. Messrs. Toward and Co.—there are three partners who have interested themselves in the design of the motor exhibited, and one of them, Mr. Meek, is a fairly old hand at the game, for he made for himself 20 years ago a very workable steam tricycle—and Messrs. Atkinson and Philipson have designed a very strong and neat frame for their autocar, all the parts of which are admirably fitted for their purpose. Instead of taking a normal carriage or trap and storing the motor somewhere about it, they have taken the motor and built the carriage round it. Mr. John Philipson, and his two sons, Mr. Wm. and Mr. John Philipson, are adepts in their art, and, while not abandoning the old principles of carriage construction, they have designed a special framework which admirably supports the motor, while at the same time carrying passengers somewhat after the style of a four-wheeled dog-cart or wagonette. As to the motor, no one who saw it at work could doubt for a moment the immense preference it must possess, other things being equal, over any kind of oil motor. Smoothness of motion, absence of vibration and smell, and simplicity of handling were at once evident. Probably something else than the rubber-tyred wheels will be required to save the motor itself from the effects of the shock and concussion of rough roads, and perhaps in futnre carriages a similar arrangement of springs to that which protects the body of the carriage will be fitted to the motor. In the carriage now made the fuel used is coke, but the intention is to employ petroleum. The boiler is of the water-tube type, and superheated steam is obtained somewhat after the same style as in the Serpollet generator, thus dispensing with ordinary boiler fittings, such as water gauges, valves, air gauges, thermometers, &c. Before starting the furnace is lighted, and the boiler tubes—which, however, are not flattened, as in the case of the Serpollet generator — arranged spirally reach a red heat. A hand pump is employed to force into the boiler just sufficient water to supply the requisite amount of steam—which is instantly generated — and, when once a start is made, the water is pnmped automatically in fixed quantities into the generator. From the time of lighting the furnace steam can be got up in about 20 minutes. Once the furnace is going, however, a few seconds' pumping suffices to start the engine. The engine is of the compound type —the two cylinders being placed on each side of the boiler between it and the hind wheels—and drives a shaft from which the power is communicated to the axle of the rear wheels by a roller chain of bicycle pattern. Here a very ingenious differential gear is fitted. The engine is three horse-power, and the weight of the whole carriage, motor included, is considerably under 10 cwt., so that it does not err on the side of excessive weight. The engine works at a pressure of about 140 lbs., and a speed of 12 or 13 miles an hour, it is estimated, can easily be maintained. The driver has few complications to attend to; once a start is made, the machinery runs automatically, with none of the multitudinous handles and levers to be turned that are found on some motor-carriages. The one lever for turning on steam regulates the speed of the carriage to a nicety, and the steering handle acting on the fore-carriage and the foot-brake (which it is intended to supplement by a screw brake) acting on both driving wheels are the only things to claim his attention. A very clever arrangement permits of stoking from the top of the boiler case, without losing heat; in fact, all the details have been thought out with great ingenuity. The trial was only an initial one, but it showed enough to demonstrate that Newcastle has at last what promises to be a very efficient autocar, serviceable for both town and country use, for rough roads and smooth, for hilly districts as well as level. It would serve for purposes of pleasure as well as for commercial uses, and, what is of the greatest importance, is not apt to get out of order, while it is simplicity itself to manage. The inventors and makers are to be congratulated upon having been the pioneers on Tyneside in the manufacture of autocars, and upon having at their first attempt turned out so satisfactory a machine. It needs improvements in details, but we feel sure that it is all right in the main.

MUNICH MOTOR EXHIBITION.

On the occasion of its jubilee, the General Industrial Association of Munich, in co-operation with the Polytechnic Association of Munich, is organising an exhibition of motors and machine tools with special regard to the requirements of small manufacturers. The exhibition is under the patronage of H.R.H. Prince Luitpold, Regent of Bavaria; it enjoys the support of the Bavarian Government as well as that of the Municipality of Munich, and the outlay is guaranteed by a special fund. The engineers' machinists of all countries are invited to send machines or models. The programme, which has been placed before us by the Consul-General in London, states that the object is to exhibit such machines and auxiliaries as tend to improve industry and the arts, as well as to instruct and encourage manufacturers, and make them acquainted with the value and importance of making the best use of the forces of nature by means of the scientific and technical inventions and improvements of our day. With this object, the exhibition will contain motors, machine tools, hand tools, implements, apparatus and machinery in motion, as well as the materials to be worked up, and the manufacturing processses in operation; accordingly, motors over 10 horse-power, and tools or machines requiring greater driving power, such as steam hammers, lathes, rolling machines, and the like, will be excluded. Popular lectures on special scientific and technical branches will be delivered, and technical literature on these subjects will be exhibited. The exhibition will be held on the so-called Kohleninsel, which belongs to the Municipality, and is near one of the most crowded thoroughfares of the capital. It will be opened on June 11th, 1898, and closed on October 10th. The exhibition comprises five groups, divided as follows:—

Group I.—Motors, gas, petroleum, benzine, steam, and hot-air engines, machinery driven by water and wind power, and electro-motors up to 10 horse-power.
Group II.—Machine tools, hand tools, and implements.
Group III.—Auxiliary machines, as pumps, ventilators, presses, cranes, clocks, parts of machines, electrical arrangements, safety appliances, apparatus, and auxiliary materials.
Group IV.—Manufacturing processes in operation and machinery in motion.
Group V.—Special technical literature.

The Board of Directors is made up as follows:—Honorary President, His Excellency Baron Max von Feilitzsch; Honorary Vice-President, Wilhelm von Borscht, Mayor of Munich; President, Max Nagler; Vice-President, Georg Leib; Deputy Vice-President, Egbert Von Hoyer. For further particulars, application should be made to M. Nagler, or the directors, 1½, Färbergraben, Munich, Bavaria.

GAS TRACTION ON TRAMWAYS.

In a paper recently read before the Paris Society of Civil Engineers, M. A. Lavezzari gives particulars of the system of gas traction on tramways, which, originating at Dresden, is now being tried at Dessau, Blackpool, and Paris. The motor used is of the Otto type, having two cylinders, and located under the seat on one side of the car. Access for cleaning, &c., is obtained through suitable doors. For ignition, electricity is used, it being thought undesirable to keep naked lights burning amidst the inflammable material of which the car is built. To change speed or direction, gearing is employed, two different speeds being available at will. The speed lever and reversing lever are both fitted on the car platform. When the former is in mid position the engine runs free, though, as at the same time its gas supply is throttled, its speed falls to 80 revolutions per minute. Pushing the lever to right or left places either the high or low speed in gear with the engine, simultaneously fully opening the gas-valve and causing the engine to run at its normal speed of 220 revolutions per minute. The gas is carried in three reservoirs, two of which are fixed under the opposite seat to that concealing the motor. These reservoirs have a capacity of about 35 cubic feet, and are charged initially to a pressure of 140 lbs. to 170 lbs. per square inch. The cooling water is carried in tubes placed in the roof of the car. At the compression stations a small gas-engine is used to drive the pumps which charge reservoirs connected to a standpipe near the track. When a car requires recharging, its tanks are connected to this standpipe and the valve opened, when about two minutes is sufficient time to completely recharge the car. At Dresden the line is about 2·2 miles long, and includes one grade of 4 per cent. The cars are small, and consume about 36 cubic feet of gas at ordinary pressure per car-mile, including that used at the compression stations. At Dessau the line was opened at the end of 1894, and is nearly four miles long. It comprises one 5 per cent. grade about 200 feet long, and a curve of 50 feet radius. There are 13 cars on service, four of which are supplied with 10 to 12 horse-power motors, and nine with those of 7 to 10 horse-power. The motor-cars weigh six tons empty and eight tons loaded, and there are, moreover, seven-ton cars. The gas is stored at a pressure of 142 lbs. per square inch in tanks of 28·25 feet capacity. With this supply a run of 10 to 12 miles can be made without recharging. The cooling water carried is only about 18 gallons. The speed is limited to a maximum of 7½ miles per hour. The consumption of gas is 30 cubic feet per car-mile, 10 per cent. of which is used at the compression stations. At Paris the experimental car tried weighed seven tons empty and 10 tons when loaded with 42 passengers. The motor of 10 to 15 horse-power was designed to run at 100 revolutions when the car was stationary, and at 250 when the latter was moving. The tanks were of 44 cubic feet capacity, and were charged to a pressure of 142 lbs. per square inch. The water carried was 19 gallons. The speed attained reached 10 miles per hour, the gas consumption, exclusive of that used in compression, being 31 cubic feet per car-mile, and about 14 miles could be run without recharging.

With reference to our description, with illustration, in January issue, of the "Damon" tyre, we understand that the tyre is Wood and Armitage's patent, which has been specially designed for carriage and automotor work, and is manufactured by the W. and A. "Safe" Tyre Company. Mr. L. Broughton Wood, of Stoke on-Trent, is the special agent of the Company, and will supply full particulars on application. The address of the London agent is 19, Dashwood House, E.C.

THE ROOTS' PETROCAR.

THE Roots' Petrocar, the newest type of which is illustrated on this page, uses ordinary oil in place of the benzoline spirit generally employed in the French and other motor vehicles. This spirit is stated to be two and a half times the running cost of oil, and cannot be obtained as readily in villages as ordinary oil, as used in the Roots' Motor, and it is calculated about 10 per cent. more power is obtained from a pint of oil than from a pint of benzoline. This motor is therefore not a benzoline motor but a true oil-motor, with a flashing-point above 73° F. (Abel's flash test).

The Roots' Petrocar is constructed with a double steel-tube frame, round which the jacket water is pumped by the motor, which so cools the water that about half the usual quantity is carried. The motor, of three horse-power, is fixed at the back of the frame and gears directly by chain on to the axle of the vehicle from the countershaft of the motor, which runs at half the motor speed. The valves are also operated by this shaft. The motor runs at 500 revolutions per minute. While pneumatic tyres are fixed to the carriage illustrated, Messrs. Roots and Venables intend in the future to fit solid rubber tyres to all Petrocar wheels. The weight of the car, as shown, is 5½ cwt. It will travel at about 11 miles an hour for level roads and 4¾ miles for hills. Many projecting parts and all nuts are nickel-plated, while the steel-tube frame is enamelled. Messrs. Roots and Venables two or three years ago, foreseeing what was coming, protected as a trade mark the words "Petrocar" and "Petrocycle." They exhibited, even as far back as 1893, a vehicle motor using oil.

The firm are making their motors up to 11 brake horse-power, and amongst their special patterns are the following Petrocars:—

Two-seat tandem car with three wheels, "hansom cab" pattern, solid rubber tyres, 1½ horse-power motor, weight about 3½ cwt.

Two-seat car, similar to "new style" car illustrated, having four wheels with solid rubber tyres of the "hansom cab" pattern, 3 horse-power motor, two speeds, weight about 6 cwt.

Four-seat car with the same specification as the foregoing, except that the weight unladen is about 6½ cwt.

A three-wheeled carrier of similar specification to the tandem car, but fitted with a carrier box instead of the front seat. This will carry about 2 cwt. of goods or parcels in addition to the driver.

Oil-motor van with four wheels, 3 horse-power motor, to carry, in addition to the driver, about 5 cwt. of parcels or goods.

The running cost of the 1½ horse-power motor is about 1*d*. for each 10 miles run; and of the 3 horse-power motor, 2*d*. for each 10 miles run, and any kerosine or paraffin of 73° F. to 150° F. (Abel's flash test) can be used.

MOTOR-CARS AT BRIGHTON.

LAST week a cycle and motor-car exhibition was held at the Brighton Aquarium. The number of motor-cars on view was not overwhelming, but Brighton is much enamoured of the new vehicles, and already has several firms and companies established ready to take advantage of any good carriages or vans placed upon the market. The Girling Cycle and Motor-Car Company (Limited), 185, Western Road, Brighton, can claim to have one of the finest shows in the whole exhibition, and Messrs. A. and E. Kessler and Co., 27, Trafalgar Street, Brighton, include in their collection a motor-tricycle. A feature at the Brighton Cycle and Motor Company's stand is a motor-tricycle and a motor-tandem, and they have also in the exhibition a Daimler motor-carriage, on which visitors were able to take frequent trips.

The opening ceremony took place in the theatre in the presence of a large audience. Sir Joseph Ewart, M.D., J.P., presided, and was supported by Alderman Brigden, J.P., Alderman Davey, J.P., Alderman Farncombe (Lewes), Messrs. R. Clowes, W. H. Baseden, W. Ling, G. J. Lenny (Chairman Sussex Centre N.C.U.), C. J. A. Rumbold, A. J. Kessler (Secretary), and W. Nicol Humphreys.

Sir JOSEPH EWART pronounced the exhibition one of the finest he had seen anywhere, and warmly congratulated the promoters upon it. He pointed out that the cycle industry was one of the many enterprises initiated and developed during the Queen's reign, and said that whereas 10 years ago there were only 70 factories in the country for this particular industry, there were now 700 in Great Britain. The motor-car industry had also come to stay, and both would add materially to the prosperity of the country. He looked upon cycling as a great sanitary invention, and believed the motor-car would create a great industrial revolution for the benefit of the country.

At the conclusion of the ceremony, Sir Joseph Ewart, Dr. Marcus Allen, and Mrs. Braithwaite were driven to Montpelier Hall in a motor-carriage. The experience, all agreed, was unaccompanied by smell from the motor, and there was comparative freedom from vibration, while the carriage was under perfect control. The ride in the brilliant weather may be well expressed in one word—delightful.

NOTICES.

Contributions and articles likely to prove of interest to our readers will receive due attention, but in all cases the name and address of the writer must be given, not necessarily for publication.

All matter intended for publication should reach us not later than the 10th of each month. Stamped envelope must be sent if the manuscript is required to be returned. The Journal is published the middle of each month.

All Advertisements should be sent to the Advertising Department, F. King and Co., Limited, 62, *St. Martin's Lane, London, W.C., where Advertising Rates may be had on application.*

The Annual Subscription is 7s., including prepaid postage to any part of the world. Single copy 7d., post free.

Cheques and Post Office Orders should be made payable to F. King and Co., Limited, *and crossed London and County Bank; otherwise no responsibility will be accepted.*

SPECIAL NOTICE.

The Automotor and Horseless Vehicle Journal *can be obtained from all* Messrs. W. H. Smith and Son's *bookstalls, and the following Agents :—*

London : Pottle and Sons, 14 and 15, Royal Exchange, E.C.
Wholesale : Brett and Co., 5, Pilgrim Street, Ludgate Hill, E.C.
Birmingham : J. McCann, 37, Union Street.
Manchester : John Heywood, Deansgate.
Newcastle-on-Tyne : C. C. Ross, 35, Side.
Paris : Homère Moreau, 97, Rue Nollet.
Victoria (Australia) : Phillips, Ormonde, and Co., 169, Queen Street, Melbourne.

When any difficulty is experienced in procuring the Journal from local newsvendors, intending subscribers can obtain each issue direct from the Publishing Office, by forwarding remittance of 7s. for 12 months' subscription, post free (or at the rate of 7d. per copy).

The Automotor and Horseless Vehicle Journal.

A RECORD AND REVIEW OF APPLIED AUTOMATIC LOCOMOTION.

MARCH 17th, 1897.

ANSWERS TO CORRESPONDENTS.

J. P. (Stockport).—(1) As already announced, the Exhibition at Olympia opened on February 20th, but we believe practically no motor-cars have been visible so far. (2) You had better apply to Mr. Hopkins, 30, Parliament Street, S.W.

Pittsburg (H. M.).—We think you are mistaken—our recollection is the reverse. A full report will be found in the "Journal of the Transactions of the American Institute of Electrical Engineers."

Steam (Cheltenham).—(1) A company was registered some little time back to work the Serpollet patents in Great Britain. (2) Your ideas are far too crude at present, but we think a good patent agent would save you much trouble, and probably point out the weak point of your patent.

Progress (Leeds).—Mr. Ward, of Tottenham Court Road, London, W.C., is making electrically-driven invalids' chairs. We gave in our January issue an illustration and particulars of one of his, fitted with a Britannia motor.

G. W. KOEHLER (Berlin).—We thank you for your letter and expressions of praise. Your frank criticisms we appreciate, and we hope in time many improvements will be made in our Journal.

COLONIES (Coventry).—No doubt the rules of the Sydney Exhibitiou, 1897, will embrace motor-cars. Yon will be able to get fnll particulars from Mr. Edward Noyes, 34, Gracechurch Street, London, E.C.

WILLIAM DIGBY (Gravesend).—It appears to us yonr own carelessness was the cause of the accident. The legal expenses you might incur renders the risk too great. For the future it would be wise to insure against such accidents.

GEORGE McP. (Aberdeen).—We admire your foresight, and an application to any engineering firm would give you the required information.

ELECTRIC (Newcastle).—The motor you refer to we have arranged to fully deal with in our next issue. Until then you must be content to wait.

GEORGE SLADE (Colchester).—The vehicle is a French electrically-driven carriage, and has only just arrived in this country. The claims put forward seem to us excessive, but we are inquiring into the practical details, and shall probably give particulars in an early issue.

W. GIFFARD (Salford).—You cannot do better than apply to the Anglo-French Motor-Carriage Company (Limited), of Digbeth, Birmingham.

J. J. (Teneriffe).—The chief engineer is Monsieur Esteve, and the offices of the Company, 2, Rue de Compeigne, Paris. Your agent, we believe, can see the carriage at Messrs. Sutton and Co., 22, Golden Lane, Barbican.

A.E.M. (Tonbridge).—Thanks for the cutting. It is hardly worth our while taking any notice of paragraphs of this description. The source is too obvious to deceive anybody.

INFORMATION (Swansea).—The leading firms for your requirements are Romeike and Curtice, 359, Strand, W.C., and Durrants, of 57, Holborn Viaduct, E.C.

THE FORTHCOMING COMPETITIONS.

TIME flies with snch rapidity that few will realise that within a few months the great automotor trials for 1897 will have taken place, and success or failnre will have to be written against the first year's work of attempting to introduce these vehicles into this conntry as au additional indnstry. In fact, so close are we to the commencement of these trials that *The Engineer* announces that on the expiry of the last day of this month no fnrther entries will be received for their 1,100 Guineas Competition. The Royal Agricultural Show contest will take place in June, and be immediately followed by the international trial of motors and vehicles to be held under the auspices of the Antomobile Clnb of France.

The greatest difficnlty attends any attempt to foreshadow whether the English mannfacturers have had time since November to feel sufficient confidence in their prodncts to snbmit them to public competition. It is sincerely to be hoped that all English-built carriages and motors which are in working order will be sent in, as it is only by trial and comparison with other makes dnring a test condncted by competent judges that weak points can be noted and the survival of the fittest parts obtained.

Which motive power will win, depends very much npon the maker; for the moment we are inclined to think that in a rigid test, covering all the points which an engineer of eminence may be expected to reqnire, steam will win. The makers of the engines have no difficnlt points to cope with, and with Continental experience of water-tube boilers and liqnid fnel to help them, the only problem to tronble is that of weight, which can be dealt with in connection with power.

Oil motors, with many natnral advantages, also possess decided disadvantages which need hardly be pointed out here, and it is to remedy these, and to place oil as a motive power in the high position it should hold, that some thousands of more or less skilled inventors are ceaselessly working in this and other countries. Electrical motors—except for ont and home—are impossible in the absence of some arrangement of charging stations, which wonld render this comfortable method of transit certain and convenient. What the makers will do is "wrapped in the womb of Time," bnt we trust that they will at any rate make an effort to sustain the credit of this conntry for mechanical skill and ingenuity.

⁂ Just as we go to press, we understand that Messrs. Roots and Venables have had the hononr of receiving a solicitor's letter on behalf of the British Motor Syndicate, stating it has been determined to take proceedings against them for iufringement of the Syndicate's patent rights. We can only hope, in conjunction with Messrs. Roots and Venables, that this threat is meant seriously, as that firm welcomes being able to have the opportunity of thrashing ont and finally settling the claims of the British Motor Syndicate to dictate terms to all British nsers of motor-cars. So far from Messrs. Roots and Venables' patent being an infringement of any patent owned by the Syndicate, we understand that the firm claims that the facts are absolntely reversed, and that they have snbstantial canse of action for infringement of their patents. This opinion is, we believe, backed up by eminent counsel's opinion npon the subject, and we trnst that for the general good of all those interested in the motor-car industry, the pretensions of the British Motor Syndicate to the ownership of so-called "master patents" may be disposed of once and for all. Whatever the result, a legal decision would be welcomed by everybody and clear the way for increased efforts on the part of engineers to place all kinds of motor vehicles on the market. At present the industry is suffering by reason of a number of engineering firms, who have a natural dislike to complicated legal actions, holding back nntil a decision has been arrived at one way or the other.

INTERNATIONAL EXHIBITION OF MOTOR-CARS AT THE ROYAL AQUARIUM.

WE are glad to know that this exhibition is being energetically engineered to what looks like a successful result. Mr. A. Villers, whose portrait we produce below, is the mainstay of the executive, and, although still quite young in years, has already earned an excellent reputation for practical work in organising and carrying out various schemes which require a man of strong character to pioneer to a commercially successful end. Mr. Villers has gained most of his practical knowledge at several of the best known Polytechnic Academies of Europe, and a pleasant personality assists him very greatly in obtaining the co-operation of leading gentlemen in connection with the various undertakings with which he associates himself. At the present time Mr. Villers is applying his very best energy to organise and ensure the future success of the International Exhibition of Motor-Cars, which will be inaugurated on May 1st next at the Royal Aquarium, and it is very satisfactory to hear from the promoters that they have received the most encouraging promises of support from various firms and gentlemen who are associated with the motor-car business, and their prospects of being able to let the public see some practical results of the working of several leading British engineering firms seem in a fair way of being realised. A number of private owners are also inclined to come forward and assist in making a good display, and we trust that the work which has now begun so well will be carried out to a successful conclusion with the co-operation of the makers and gentlemen who have already undertaken to accord it their active support.

THE NEALE CAR.

THIS car is the invention of Mr. Douglas Neale, of Edinburgh, who has for some time past been giving a great deal of attention to motor-car building. The car is electrically driven, with a range of speed from 3 to 12 miles per hour, the type of cell being Planté or pure lead, and the number of cells 15, the duration of charge 35 miles, and the commercial capacity of each cell 115 ampere hours = 3,450 Watts total output, or 4·62 E.H.P. hours, for a total weight of 405 lbs. The motor is 1 B.H.P., and weighs 100 lbs., the car itself totalling up to 448 lbs. For a run of 35 miles the total weight of the car fully charged is 9 cwt.

Mr. Neale's system of electric traction is covered by seven patents, and the following advantages are claimed for it:—(1) Owing to the direct drive from the armature shaft on to the wheel of the vehicle all necessity for intermediate shafting and gearing is obviated and a considerable amount of energy is saved. (2) The arrangement of steering gear is such that it is not necessary to multiply the motion of the handle, so that the axle is moved at the same rate as handle; this renders the steering quicker and more under control than in methods necessitating multiplied motion. (3) Besides the steering lever there is only one switch, which enables the driver—

(1) To go ahead at any desired speed.
(2) To go astern at any desired speed.
(3) To apply the brake, which is electric.
(4) To ring the electric gong.
(5) To stop.

All of these effects can be obtained at will by the one switch handle without removing the hand from it. The electric brake is a great convenience, especially to ladies, as no muscular exertion is required in stopping the vehicle quickly. An ordinary brake operated by the foot is also fitted to comply with the Board of Trade regulations.

ANY of our readers who are desirous of acquiring a very excellent motor-car would be well advised to communicate with "Automobile," who advertises one for sale in the present issue. As we have had an opportunity of personally testing its capabilities, we can speak very highly of its powers, and as we notice that it has the privilege of carrying the perpetual license plate of the British Motor Syndicate, any purchaser need have no fear of incurring unlimited liability in respect to possible damages, confiscation, and other little pleasant surprises promised by the Syndicate to purchasers of motor vehicles through any other channel than that of 40, Holborn Viaduct.

A "BIN GHORA-KA-GHARRY."

ONE of the earliest English Companies to put motor-cars on the market was the Anglo-French Motor Carriage Company, of Digbeth, Birmingham, and from the business-like catalogue which they have now issued, containing every sort of motor vehicle, it looks as if they meant to maintain their position as one of the leaders in the new industry. Some of the work which they are turning out is excellent in every detail, and we have very much pleasure in reproducing the accompanying illustration of an autocar manufactured by this enterprising Company, and supplied to Mr. J. B. Foster, of Bombay.

The photo was taken in Bombay, just after the car had completed a most successful trial trip, during which it was followed by a crowd of interested natives, loudly calling attention to the "bin ghora-ka-gharry" (carriage without horses). This car has now been sold to an Indian Prince, who has evinced his complete satisfaction with it and frequently uses it for long rides, and we are not surprised to hear that since this event the makers have received several valuable orders from this part of the globe.

We hope to give in another issue a more extended notice of this Company's doings and the enterprise being displayed by Mr. Gascoine, the able director of the Company's undertaking.

THE AUTOMOTOR AND HORSELESS VEHICLE JOURNAL DIARY contains over 100 pages of information. Price 6*d.*; post free, 7*d.*, of Messrs. F. King and Co., 62, St. Martin's Lane, London, W.C. See it for the Irish and Scotch Regulations of Motors.

CARDIFF STILL WANTS MOTOR VEHICLES.

AT a meeting of the Cardiff Health Committee held on the 10th inst., under the chairmanship of Alderman T. W. Jacobs, Councillor T. Andrews moved a resolution, notice of which he had given, to the following effect:—"That in consideration of the large and continually increasing amounts paid by that committee for the maintenance of horses, and with a view to facilitate scavenging and watering and cleansing the streets, a small sub-committee be appointed to report (1) as to the practicability and possible economy of employing carts and vans driven by electric, steam, or other automatic motors; (2) as to the advisability of fitting suitable motors to the water-carts and other vehicles; and (3) as to the advisability of the purchase by the Council, for experimental purposes, of a motor-van of the most approved pattern, designed for the collection of refuse and scavenging; and that the sub-committee be authorised to obtain the necessary estimates, plans, and all information." Councillor Andrews considered the time had arrived when they should move in the matter in the same way that other towns had done, and argued that there would be no expense in altering the wagons if several were drawn by one motor. He understood the committee spent £800 a year in horses, whilst feed and harness cost another £5,000 per annum. If the matter was taken up in a proper spirit they would save £5,000 a year. Councillor Ward seconded the resolution, which received the approval of the entire committee, several members agreeing with Councillor Andrews that the matter was one well worth going thoroughly into. The sub-committee appointed consists of Alderman Jacobs and Councillors Hughes, Andrews, and Allen.

DOINGS OF PUBLIC COMPANIES.

Daimler Motor Company.

An extraordinary general meeting of the Daimler Motor Company (Limited) was held on the 4th inst. at the Motor Mills, Coventry, for the purpose of making certain alteratious in the articles of association, chiefly those required by the Stock Exchange Committee, with a view to an official quotation of the shares. Mr. Harry J. Lawson, the Chairman of the Company, presided. Previously a large number of shareholders were shown over the works, and inspected the extensive machinery with which the buildings are equipped.

Mr. J. J. H. Sturmey (Director) said he had been deputed by his colleagues to lay a few facts before the shareholders in reference to their undertaking. If they were to believe the statements which had been made about the Company by a certain newspaper, they would conclude that the Company was a ghastly failure; but he thought that after what they had seen that day in going over the works, and when he had stated the position of the Company, they would agree with him that the criticism he had referred to had been made with absolutely no knowledge of the facts. It was true that the shares had gone down on the market, but market prices were regulated by supply and demand, and, as a result of the attacks, there had been but few buyers apart from the directors themselves. It would be a consolation to the shareholders to know that not only had the directors not sold a single share, but they had, he believed, in every instauce largely increased their holdings. (Hear, hear.) That should prove to the shareholders that, at any rate, the directors believed in the Company. He honestly believed in it himself, and he hoped to have a still larger holding before he was finished with it. It was necessary that he should look a little into the history of this Company, in order to show them some of the trials and tribulations they had had; and in doing so he was practically giving them the history of every other company of the kind in the kingdom. He believed this Company was at least six months ahead of any other company in the country. It had been formed just over a year, having been registered in February, 1896. Those who had had experience in such matters knew that it was impossible for a company to begin work immediately it was formed. An entirely new company, having to establish a new business, had many things to consider. The first week or two was occupied in legal preliminaries, the allotment of shares, completion of contracts, and so on. The directors were also handicapped from the fact that they had to learn the business themselves, and their first study had been to gain full information about the industry. They went to Paris, where they inspected the Daimler works of MM. Panhard and Levassor, and MM. Peugeot Frères, and were also shown over the works of the Count de Dion aud Bouton, and other autocar manufactories, by which means they got a very fair idea of what was required of an autocar company. They then took a journey to Germany, aud inspected the works of the Daimler Motoren Gesellschaft, near Stuttgart, the parent company of all the Daimler coucerns, and where Herr Daimler was in charge. The knowledge they thus gained had proved very useful to them, aud they were more convinced than ever that they had the best motor for horseless carriages in existence. When they got back they looked about with a view to purchasing works, and by a lucky fluke the magnificent works they were uow in came into the market, and were offered them on what they considered reasonable terms. They purchased the works in April, and proceeded to orgauise a staff. It was impossible to find a man who was used to the trade; but they looked about for a thoroughly practical and scientific engineer. They were fortunate in securing the services of Mr. J. C. Critchley, of Bradford, and that gentleman had worked most assiduously in the interests of the Company. Moreover, they had gradually built up a staff which was secoud to none in the autocar world, amongst them being one or two who had occupied prominent positions in the German works for some two years. Their next duty had been to obtain machinery. All these industries had been during the past year exceedingly busy, and the result had been that the makers of machine tools had been equally busy; so that there was great delay in the execution of their orders. However, they had now got pretty well organised, and equipped the factory with most of the tools. Mr. Sturmey proceeded to detail further changes which arose in connection with the designs and drawings. Then they were disappointed in the matter of the delivery of cars from Paris. Two cars were to be delivered every month until September, when six were to be delivered. As a matter of fact, they got nothing until September, when two cars were received. They had not received one since. As soon as they found they were relying on broken reeds they set to work and built four carriages on experimental lines, but there were further delays in obtaining castings.

They had now not only completed their factory, but finished the first of their commercial carriages, which shareholders had seen that day. They were very well satisfied with their first efforts (Hear, hear.) They had started building them with a view to a regular supply, and had now completed in their works nearly all the parts and fittings for 50 carriages. To-day they had work in hand for a regular output of motor-cars; so that, practically speaking, the actual work of the Company, so far as trading was concerned, commenced from now. In addition to motor-cars, they were making motors for stationary purposes, and also for launch building. They supplied about 35 launch motors last year. That was fairly satisfactory, but now they were started on a regular output from the factory. He believed their capacity would be something like 250 carriages this year. If they could increase it they would do so but they were already cramped for space. They were commencing work at once for the extension of the factory, specially with a view to the building of the carriages and frames, which was a very bulky business. When they got that at work, in six or eight weeks' time, they expected to nearly double their weekly output of complete carriages. So far as their busiuess prospects were concerned, he had not the slightest doubt they could sell three times the number of cars they could produce. They had actually on order between 200 aud 300 motors, frames, and carriages, and had a contract with a firm in the north of Scotland for 50, amounting to about £13,000; that was for a part of the frames and carriages. He might mention, too, that they had not really looked for orders; but the secretary had something like 10,000 applications for catalogues aud prices and particulars of their motors, with a view to purchase. They were first in the business to-day, and hoped to keep in that position. (Applause.) With regard to the financial position, they would remember that the Company was started with a capital of £100,000. Statements had been made that the capital was not subscribed, but they were incorrect. The actual amount of capital subscribed was in the neighbourhood of £110,000; consequently they had to return about £10,000. Having got all their capital, they were pledged to £40,000 for the licenses. That was certainly a large sum, but he ventured to assert that even if the patents were uot worth a cent—which he did not believe for a moment—he considered that the position they were in, of being six months ahead of any other company, was worth every penny of the money; it was equivalent to buying a goodwill.

Although the directors had been greatly delayed in actual trading, they had been looking after the interest of the Company in other ways. They purchased the mills—the estate covered 12½ acres of ground—and had sold the four-storied building close by these works for more money than they gave for the whole estate. (Applause.) He thought that was something to begin with, and showed that the directors had not been unmindful of the interests of the shareholders. (Hear, hear.) They had a factory which had been valued at £8,500. They had in addition some 10 acres of unoccupied ground, the ground rent of which was more than covered by rents received, and that, taken at a low estimate, should be worth another £2,500. That made £11,000 clear profit in the assets of the

Company. Then they had £12,000 worth of machinery, and they had finished stock ready for making up into carriages, the work of 160 men for four or five months, which could be put at £17,000, taken at factory cost. Furthermore, they had made other deals which were not trading deals in the ordinary sense of the term, and which had netted to the Company £2,000 in shares in other companies and something like £3,500 in cash; so that altogether, although they only to-day commenced their trading profits, they had made profits in cash and shares, by the use of their capital in other ways, and by taking advantage of opportunities which occurred, of £16,500. (Applause.) Thus they had done a very good year's work for the Company without actual trading. The board had left of the capital nearly half of that which was placed at their disposal. They had in the bank and elsewhere a sum of close upon £30,000. (Applause.) It would be seen the Company was not crippled for capital, but, on the contrary, had sufficient with which to go on trading under very satisfactory conditions. (Applause.) In conclusion, he explained that application had been made to the Stock Exchange Committee for an official quotation, and certain alterations in the articles of association had been required. It would be observed that the qualification of a director was put at £100; but, as a matter of fact, not one member of the board held so small an interest. Three or four of the directors had between £2,000 and £3,000 each in the Company, and he himself had nearly £3,000. For that interest—which amounted altogether to over £10,000—they had paid in cash. (Applause.) He then moved the formal resolution approving the alterations in the articles in accordance with the notice sent to the shareholders.

Mr. JAMES A. BRADSHAW (Director) seconded the motion.

A discussion followed as to the alterations in the articles proposed, and the board accepted two suggestions from shareholders, one fixing the amount of a director's qualification at £500, and the other substituting the following words for those providing for an additional remuneration of 7½ per cent. on the net profits to the directors after the shareholders received 10 per cent. dividend, "such additional remuneration as the shareholders present in person at the general meeting shall determine."

Mr. B. NICHOLSON proposed a vote of thanks to the Chairman and directors and staff for their services during the past year.

Mr. W. B. AVERY seconded the motion, which was carried unanimously, and, after a brief acknowledgment from Mr. Sturmey, the proceedings closed.

The London General Electric Omnibus Co.

THE London General Electric Omnibus Company (Limited), says the *Financial Times*, has yet to win its spurs. So far it has done nothing except to take an omnibus occasionally on an experimental tour through one or two streets. We are asked to believe that these trips have been wonderfully successful, and that they fully demonstrate the superiority of the electric omnibus over all other omnibuses. That may be so for all we know, but the Company has yet to prove itself a financial success, and the mere assertion that the omnibus is a good one is hardly sufficient inducement for the shareholders to subscribe for another £50,000 in £1 shares at par. This they have been twice asked by circular to do during the past ten days. There is an uncalled liability of 10*s*. per share on the shares already issued, but it is suggested that shareholders would rather increase their holding than get rid of this liability. In our opinion that is the wrong way to go to work, and the directors are making a mistake in endeavouring to commit their shareholders more deeply in a new and untried undertaking. Prudent shareholders would, we should say, prefer to have something more tangible to go upon before planking down another £50,000 for electric omnibuses.

The following are the circulars of the London Electric Omnibus Company (Limited), marked "Private," referred to above:—

"Broad Street House,
"New Broad Street, E.C.,
"*February 26th*, 1897.

"Dear Sir or Madam,—You are probably aware that one of the Company's omnibuses of the latest type has been running with marked success on many occasions through the streets. The omnibus has been re-designed, and the construction being entirely novel, there has been some difficulty in getting it built. The time has, however, come when the directors, having satisfied themselves that they have the best, smoothest running, and most comfortable omnibus which has ever been built, and which can be steered through crowded traffic without difficulty, are desirous of placing a number of them on the streets for the use of the public. You are aware that the ordinary shares of the Company carry a liability of ten (10) shillings per share, which the directors can call up in sums of £5,000, but it has been suggested that several of the shareholders would rather avail themselves of the opportunity of increasing their holding in the Company by applying for a fresh allotment of shares, than pay up the whole outstanding liability on the shares which they now hold. Before, therefore, determining whether to make a call or to go to the public for capital, it has been resolved to give the shareholders and their friends an opportunity of subscribing amongst themselves for an additional 50,000 ordinary shares of £1 each at par. When the Company is fully working, and paying a good dividend, the shareholders who avail themselves of this opportunity will thus reap the advantage. I enclose a form which, in the event of your wishing to take any additional shares, please fill up and return with cheque to the Company's bankers for an amount of 10*s*. per share. This offer will only be open until the 5th March, 1897. I enclose extracts from several of the leading London newspapers, showing the success of the Company's latest type of omnibus. The directors have now under consideration the acquisition of a freehold site, admirably adapted for the Company's purposes, and are also negotiating with several gentlemen who are desirous of establishing local subsidiary companies in large towns, from which the parent Company will derive considerable financial profit. As this letter might be considered a notice inviting persons to subscribe for shares within the meaning of Section 38 of the Companies Acts of 1867, it should, therefore, technically specify the dates and the names of the parties to all contracts; subscribers will be held to have had notice of all contracts, and to have waived their right to be supplied with particulars thereof. —I remain, your obedient servant,

"ALFRED CAILLAT, Secretary (*pro tem.*)."

"Broad Street House,
"New Broad Street, E.C.,
"*March 2nd*, 1897.

"Dear Sir or Madam,—With reference to my circular letter to the shareholders of the 26th ult., regarding the proposed issue of 50,000 shares to the shareholders and their friends, of the unallotted capital of the Company, I am instructed to inform you that the directors to-day received a deputation representing several influential shareholders, and afterwards, in accordance with the wishes of the deputation, passed the following resolution:—'That should the directors make any further issue of the present unallotted capital, they will issue such shares at a premium, provided that at the time of such issue the already issued shares are saleable above par.' In consequence of this change, the time for receiving the applications from the shareholders, referred to in the circular letter of the 26th ult., is extended from the 5th inst. to Saturday, the 20th inst.—I remain, your obedient servant,

"ALFRED CAILLAT, Secretary."

WE understand, in regard to the organisation being formed among the shareholders of the British Motor Syndicate, that nearly 40 holders have now signed the agreement undertaking to bear the costs of the law proceedings, and that it is expected some 50 further signatures will be obtained. The action has already been commenced.

New Companies Registered.

[Under this heading we give a full list of new Companies registered which take power to make, deal, or become interested in any manner in automotor vehicles. We shall be pleased to reply with detailed particulars to inquiries through the "Answers to Correspondents" column. All communications should be addressed to the Editor. The only stipulation which we make is that where the inquiry involves a search of the records at Somerset House—as in the case of information on the subject of the holdings of shareholders—a postal order must be enclosed to cover the Government stamp of one shilling which is charged before a search is allowed to be made.]

	Capital. £
Albert Eadie Chain Co., Worcester	65,000
Alfred Appleby's Twin Roller Chain	40,000
Anglo-French Pneumatic Compensation Cycle Co.	120,000

Thrupp, Holmes, and McNaught (Limited)	1,000
Trench Tubeless Tyre Co.	200,000
Victory Cycle Manufacturing Syndicate	7,500
Woodhead Manufacturing Co.	25 000

Australian Cycle and Motor Co. (Limited).

THE first ordinary (statutory) meeting of the shareholders in the Australian Cycle and Motor Company (Limited) was held on the 4th inst. at Worcester House, Walbrook, the Chairman (Mr. William Calcott) presiding.

The CHAIRMAN said:—I am pleased to see such a large company present, which is an intimation to me and my fellow-directors that you are taking an interest in the business. I need scarcely remind you that this meeting is called to comply with the Act of Parliament—"that every company shall hold its first meeting within four months of its registration"; and much as I should have liked to have waited a little longer before calling you together, I found that I could not postpone the date longer than to-day. You will be glad to hear that some 34,837 shares were subscribed for in this Company, and 21,500 fully-paid shares were allotted to the vendor in part payment of the purchase consideration, making together a total of 56,337 shares allotted out of our capital of £75,000; so that, you will observe, you have a working capital of nearly £35,000, which your directors consider should be ample for the purposes of this business. We lost no time in despatching the managing director to Australia, and that gentleman (Mr. Edward Whitten Rudd) sailed on December 6th last, and from that date we have been forwarding large consignments of cycles and cycle fittings of the best makes to him; and we have no doubt, as he has wide experience of this class of business, and is fully cognisant of the colonial taste with regard to cycles, &c., that he will be able to develop a very profitable business for this Company. I regret that the time that has elapsed since his departure has not given him an opportunity of letting us know by mail what business he has done; but I may tell you that, from the letters that we have had from him, he is as confident as when he started that a very large trade can be done, and will be done by him for this Company. He is opening up as rapidly as possible depôts in the large towns, making the headquarters of this Company in Melbourne. I may advise you that we have applied to the London and other Stock Exchanges for a special settlement in our shares, and the same will, we have little doubt, be very shortly granted. We have also taken steps to have our shares quoted in the daily papers, and I feel quite confident that before long they will be in great request.

London Electrical Cab Co. (Limited).

THE statutory return to February 12th has been filed. 62,523 shares have been taken up out of a capital of £150,000, in £1 shares, and the full amount has been called, and £61,223 has been received, leaving £1,299 10*s.* in arrears.

Ernest Scott and Mountain (Limited).

THE annual return to November 12th has just been filed. The whole nominal capital of £70,000 has been subscribed for and allotted, and 2,200 shares have been issued as fully paid. The full amount has been called on 1,982, and £6 5*s.* on each of the remaining 2,818 shares.

NOTES OF THE MONTH.

A PARIS correspondent says that a marriage which aroused considerable interest on the 2nd inst. was that of a couple who drove to the Batignolles Town Hall in an open autocar. The bride was Mdlle. Ponson, daughter of an autocar manufacturer, who was seated with her bridesmaid and the best man in a landau driven by petroleum. After the ceremony and lunch at a neighbouring restaurant, the autocar marriage proceeded to the Bois de Boulogne. The landau was, of course, decorated with white ribbons. Crowds ran along beside the vehicles, or stood outside the Town Hall and restaurant, cheering the bride. A great sensation was created in the Bois de Boulogne.

ELECTRIC cabs are promised in Paris by the summer by M. L. Krieger. An experimental cab constructed to perform a journey of 60 kilometres (37·2 miles) without recharging the battery has already travelled 2,500 kilometres (1,552 miles) in Paris at a mean speed of 10 kilometres (6·2 miles) per hour.

IN connection with complaints which have been sometimes made of unpleasant smell and excessive vibration of the motor-car, it is interesting to recall Mr. Charles Greville's description in his "Memoirs" of his first train journey. He says nothing of any jolting or vibration. "The first sensation," he writes, "is a slight degree of nervousness and a feeling of being run away with, but a sense of security soon supervenes, and the velocity is delightful." Mr. Greville mentions, however, certain "occasional whiffs of stinking air which it is impossible to exclude altogether." They have, nevertheless, since disappeared, and presumably means will be found to banish the perfume of paraffin from the motor-car.

A SPECIAL committee appointed by the Cardiff City Council to consider the desirability of establishing a system of electric tramways in the borough met on the 20th ult. Referring to what was being done in other towns, the chairman remarked that a private company working electric tramways at Bristol had just paid 6 per cent. on its capital and carried over £2,000 to the reserve fund. He thought Cardiff should not be behind in providing the public with the most up-to-date-facilities for travelling. It was decided to ask the borough engineer to prepare a plan of desirable routes.

THE *Velo* states that the French War Office is considering the advisability of adopting autocars for the Army. The present idea is to use them for ambulance purposes only, although it is, nevertheless, proposed that each autocar should be armed with a light quick-firing gun.

THE Paris correspondent of the *Weekly Sun* writes last week:—"On the Bois on Tuesday I noticed Mrs. Crawford, the correspondent of the *Daily News*, in a new, easily-moving motor-car. She looked very much absorbed, and the gentleman accompanying her was gesticulating, and, I fancy, explaining the working of the car to her. I have not seen her yet to ask her opinion. A number of these cars ply up and down and Bois, moving quietly among the horses, who now seem to have lost all fear of them."

THUS *The Echo*:—

"Shareholders in motor-car companies are looking in vain for the gradual appearance in the streets of these vehicles. According to various Press statements—or mis-statements—and prospectuses, the leading tramway and omnibus companies were going to sell up their stock of horses, and quickly replace old 'buses with new motor-cars. Were time only required there would be no need for premature comment. But on Monday last the London Tramways Company, which for years past has run a service of single-horse halfpenny omnibuses over Waterloo Bridge, opened a new service of well-equipped and well-built double-horse omnibuses, whose yellow wheels and scarlet bodies could not but attract considerable attention."

"This movement, or, perhaps, this reversion to last century methods of transport, on the part of a leading tramway company must deal a blow at the so-called advantages of the motor-car business, seeing that the entire equipment is new throughout. The old and somewhat odorous single-horse vehicles have disappeared. If motor-cars are so economical and handy, it is nothing short of extraordinary that the directors of the London Tramways Company should not have moved with the times and used steam in lieu of horseflesh. We prefer to believe that the Company knows its own business best, and that there must be many and serious drawbacks to the efficient working of a line of motor-car omnibuses in the crowded streets of London."

WE can only assume that the directors of the London Tramways Company are not keeping themselves in touch with what several of our leading engineers are doing in the motor-car line, or we think they would have postponed making the change recorded. It is possible before long they may have substantial reason to regret their action.

A TRIAL was made last week in London of a new electrically-driven carriage, which, however, will not be on the market for some time yet. The new system is an invention of a French engineer, M. Darracq. From particulars supplied by the inventor, we understand that the accumulators, to the number of 44, are carried in two boxes, with a gross weight of 600 lbs., and sufficient power obtained for a run of 50 miles, whilst the cost of recharging does not exceed 4*s.* for a similar distance. Any speed can be acquired, from a quarter of a mile up to 20 miles per hour, if need be. Furthermore, all the accumulators discharge at the same time, and, in descending an incline, to some extent recuperate themselves. It is claimed the extra power which is required to maintain the same speed uphill is regained coming down.

DURING a run through Oxford Street and other crowded thoroughfares, the carriage, which is at present in the hands of the Gladiator Cycle Company, ran most smoothly. The body of the vehicle itself is shaped like an ordinary brougham, with the exception that the driver is perched behind, as in the case of a hansom cab. A long handle does the steering, whilst the customary switch regulates the speed. The wheels and mechanical portions are so arranged that a carriage of any shape can be slung on them, and changed at pleasure. The brougham itself presented a neat appearance, and afforded comfortable riding, besides being fitted throughout with electric light, and the result may certainly be regarded as an indication that another forward step has been achieved in the progress towards the ideal of the motor-car.

AN application has been made to the Board of Trade for the registration of the Tramways and Light Railways Association without the addition of the word "limited." The Association is being formed for promoting, encouraging, and facilitating the construction, extension, and working of tramways and light railways, and the development of electric and other modes of mechanical traction.

A CARDIFF paper states that there is a movement in that town to abolish horse wagons and introduce motor-carts for scavenging purposes. According to our contemporary "the new method of locomotion has been successfully adopted by several of the London Vestries." This is hardly correct, although several of the London local Vestries are seriously considering the matter, and we understand one or two contracts are likely to be shortly signed. In the meantime the Chiswick Urban Board can claim the distinction of being the first official body to start motor dust carts, three of those vehicles being ordered, as we recorded in a previous number, from Messrs. Thornycroft, of Chiswick Mall, delivery to take place about the end of this month. We have little doubt that the economy which this innovation is likely to effect, will speedily cause all the other London Vestries to follow the lead of the sensible and practical members of the Chiswick Board.

SEVERAL of the London Tramway Companies are also seriously considering the possibility of mechanical traction in place of horse-power. At last week's meeting of the Highways Committee of the London County Council a request was reported from the London, Deptford, and Greenwich Tramways Company for permission to use experimentally the "Ribbes" electric accumulator car on a portion of the Company's lines in Rotherhithe New Road. Permission was granted for one year.

THIS departure emphasises our suggestion in another paragraph that tramway and omnibus companies should exercise judicious caution during the next year in increasing their ordinary car stock in case they should find it advisable to adopt or obtain powers to use mechanical traction in order to hold their own in the competition for the patronage of the riding public.

MESSRS. BROWN AND BUCKTON, cycle makers, &c., of Hipperholme, are just completing a motor-car, which is their own invention, and very shortly the same will be on view in their Halifax shop in Crossley Street. The car, which is made to carry two persons, is constructed on a frame of weldless tubes. The wheels are placed similarly to those of a tricycle, the two on either side being pneumatic with tangent spokes. The motor, which is about one horse-power, containing two cylinders, is at the back of the car, and this, together with all the gearing, is enclosed in a wooden case. The car is worked by petroleum, which is fed to the lamp near the motor from a can which is placed at the end of the carriage. The can will contain a sufficient supply of oil for a two days' journey, and it is computed that the cost of working it will be about ¾d. per hour. The motor-car can be started in about three minutes after the lighting of the lamp. The steering, starting, and brake appliances are within easy reach of either rider, and the machine can be run at four different speeds for different gradients. The whole weight is about 3 cwt., and the cost will be between £80 and £100.

TRULY, there is nobody like your thorough-going retrograde Russian, says the *Westminster Gazette*, for going "full steam ahead" once a so-called advanced idea has taken possession of him. Here is Prince Oldenburg, the uncle of the Czar, preparing for a tour through the Caucasus on board a caravan which is to be drawn by an automotor! This autocar is to be a veritable *train de luxe*, for trust a Russian noble for inventive genius when his own comforts are concerned! There is to be the automotor, and attached to it a couple of vans, the first of which is to be in turn the dining-room, the *salle de jeu* (which is as indispensable to a Russian Prince as is his tub to the Britisher), and the bedroom of his Serene Highness. The second car is to combine all the culinary and domestic offices, including a safe in which the Prince's roubles and raiment are to be stored. We wish him joy in seeing the beauties of the Caucasus under such original conditions.

THE last of the series of lectures arranged by the committee of the Science and Art School, Camborne, was given this month by Mr. J. C. Keast on "Motor-Cars" before a large audience. The lecturer gave a concise history of motor-carriages, and went on to speak of the improvements made in France, of the races in that country during the last three years, and also the recent run in this country from London to Brighton. The lecture was well illustrated by the lantern.

FASHIONABLE Leamington does not believe in progression. The motor-car movement seems especially to have upset this exclusive town. Last week the Town Council occupied considerable time in a discussion on motor-cars. It appears the Coventry manufacturers send their motor-cars over to Leamington on experimental trips, and residents in the more fashionable town have come to regard them as constituting an unmitigated nuisance. To fashionable nerves they seem to whizz along the principal streets at incredible speed, with a tremendous clatter, and emit in many cases an abominable effluvium of paraffin. Councillor Purser described them as "ugly stinking machines," and another councillor said that in their present state of development they were neither comfortable nor pleasant. It is fortunate all people are not like unto Leamington folk.

ABERDEEN is unlike Leamington. In the former city the advent of the motor-car is regarded as likely to favourably affect the interests of the inhabitants than otherwise. At the Annual Social Meeting of the Aberdeen cabmen last week in the Albert Hall, Baillie Brown, who presided, was accompanied by several leading members of the Council, and in the course of his speech referred to the probable effect of the introduction of motor-cars upon cabs and cabmen. He did not think the prospect was at all a gloomy one; he was not one of those who believed that the motor-car would drive the cabmen out of existence. There had not been wanting croakers who imagined that railways, and after railways tramways, would result in the extinction of the cab as a mode of conveyance, but their pessimistic forebodings had been falsified, for instead of cabs having entered upon a period of decline they had increased in numbers and embarked, as it were, on a sea of greater prosperity than ever. In the same way he believed that the cab, in whatever way motor-cars might be developed, had nothing to fear in the future. Councillor Gray was not quite so much in their favour, but thought that the wives of cabmen might rest assured that their husbands would not lose their situations because of the motor-car; and in the same way the sweethearts of cabmen need have no fears on the ground of the insecurity of their lovers' employment.

A CONTEMPORARY states that recently one of the American electrical papers published a lively rumour to the effect that trolley-cars and bicycles had caused such a revolution in means of transit that a small army of horses (100,000, we believe, was the number stated, but a few odd thousands more or less don't matter) was practically running wild in one of the States alone, and that the farmers, after disposing of all they could sell at any price from 5*s.* to 10*s.* each, were hoping for a hard winter to kill off the rest. No doubt this is a trifle exaggerated, but as feathers show which way the wind blows, so, even after allowing for Yankee "hatchet-throwing," rumoured acts of this sort should act as a timely hint to keep well in touch with the motor-car movement, so as to take full advantage of the improvements and economies which will presently be daily in evidence.

DUBLIN is great'y concerned at the prospect of that city being made one of the leading centres for motor-car building. The Dublin papers state that Mr. Pennington has arrived with the object of extending his manufacturing business in Ireland. His motors are to be seen running around Stephen's Green at the rate of 12 miles an hour, and not in the slightest degree interfering with the public traffic. This is evidently only the beginning of the introduction of a number of similar machines. Already arrangements have been made for the adoption of auto-cars to carry passengers and to make a connection between railway termini and the steamboat lines in different parts of Ireland. A company has been organised to erect in Dublin an immense manufacturing place for the purpose of building cars, and will be known as "The Irish Motor-Car and Cycle Company (Limited)." This factory is to be run on American lines for the manufacture of motor-cars, cycles, &c. Mr. Pennington is at the present moment considering a number of sites for the purpose, and his mind will be made up in the course of a few days. He wants a site with acreage sufficient for the establishment of a huge series of workshops, with plenty of space for future extensions. The necessary tools, lathes, &c., for the works are now on their way to Ireland from America.

THE first factory will employ 2,000 hands, who will be chosen from amongst the skilled and unskilled workers of Ireland and placed under trained Americans, who will act as managers of departments. They will start the concern with orders in hand for cars, &c., to the value of £140,000. When the motor-car business extends, as it must extend as surely as night follows day, an industry will exist in Ireland second only to the great brewery of the Guinness firm.

A HORSELESS steam fire-engine of great size and power is in course of construction for the Boston (U.S.A.) Fire Department. The contract capacity is 1,350 gallons of water per minute, but the builders are confident that the engine will throw 1,850 gallons in the same time. Very little machinery in addition to the ordinary mechanism of a fire-engine is necessary for the propulsion of the engine. The road-driving power is applied from one end of the main crank-shaft to an equalising compound, and two endless chains running over sprocket wheels on each of the main rear wheels permit the latter to be driven at varying speeds when turning corners. The driving power is made reversible. When it is not necessary to use the power of the engine for driving purposes, the driving mechanism can be disconnected by the removal of a key, so that the pumps may be worked with the engine standing still. An extra water-tank is carried at the rear of the engine to supply the boiler until connections can be made with a hydrant. The engine can travel on a fair level road at a maximum rate of 12 miles an hour. From the ground to the top of the engine the height is 10 feet, its length over all is 16 feet 6 inches, and the width 7 feet 3 inches; the weight, equipped for service, is 17,000 lbs. Steam-propelled fire-engines are by no means novelties. Among the first was one constructed by Captain John Ericsson, of *Monitor* fame. In the main his engine was a success, but the opposition was so strong against it that, after a brief period of service, the engine was abandoned.

INTERNATIONAL MOTOR-CAR COMPANY.

THIS Company has opened offices at 369, Edgware Road, London, W., and is now prepared to deliver their "Parisian" carriages and vans almost immediately on receipt of order. These carriages, which have had a considerable test in France, are driven by oil-motors, and it is claimed that they fully meet all the requirements of the new Locomotives on Highways Act, are not liable to get out of order, are run at a very low cost, and are particularly suitable as hill climbers. The prices also seem reasonable, starting from £150, and we shall have the pleasure of referring again to the vehicles turned out by this Company when we have had an opportunity of personally testing their power and quality.

REVIEWS OF BOOKS.

"Coachbuilding." By JOHN PHILIPSON. (London: Geo. Bell and Sons.)

THIS volume, which forms one of the admirable series of technological handbooks edited by Sir H. Trueman Wood, is an excellent example of the manner in which such works should be prepared. The author is one of the best known carriage builders in the United Kingdom, but, not being content to rely on his own extensive knowledge, he has called in the assistance of some five or six friends to correct his proofs, who, like himself, enjoy the distinction of being past-masters of their craft; the result is, that the accuracy of this text-book cannot be questioned, and the student, the practical man, or the general reader may refer to it with complete confidence. The arrangement of the book—which is carefully illustrated throughout—is such that the reader is led by easy stages from a consideration of the general principles of carriage construction and design to the various stages involved in producing the highly finished modern carriage of to-day. At every successive step full particulars are given, to enable the reader to thoroughly follow all the details involved, and to obtain a complete mastery of the subject. It is just the book which engineers interested in road motors should obtain, for in a short time they will obtain from it all the information they require, and get it, too, from a practical and trustworthy source. A very valuable appendix is given, containing many useful tables on standard sizes and dimensions, while it concludes with a useful list of text books on carriage building.

"Modern Cycles: their Construction and Repair." By A. J. WALLIS TAYLER. (London: Crosby Lockwood and Co.) Price 7*s.* 6*d.*

THIS is a capitally compiled book on a subject which must necessarily attract the attention of very many readers, as the number of followers of the wheel is ever on the increase. We have no desire to intrude into the cycle world, which has a literature distinctly its own. This book, however, is written by one who is eminently qualified for the task, and much of the matter will be of as much use and interest to those concerned in automotors as it is to bicyclists. More particularly does this relate to such chapters as those relating to repairs, the sections, construction, and method of holding together the various parts constructed of tubes. The book will be found to be of great practical utility to all interested in the design or manufacture of motor-carriages.

"Costing: as Applied to the Carriage-building Industry." By JAMES BOARLAND. (London: John Kemp and Co.)

"The Best Method of Ascertaining Prime Costs." By WM. STRACHAN. (London: John Kemp and Co.)

THESE are reprints of the first and second prize essays on the subject of taking out the true cost in each department of carriage building, and the subject matter is well worthy the consideration of those concerned. The reprints are from *The Saddlers', Harness Makers', and Carriage Builders' Gazette.*

A NEW work by Mr. A. J. Wallis Taylor, C.E., A.M.I.C.E., entitled "Motor-Cars, or Power Carriages for Common Roads," will be published shortly by Messrs. Crosby Lockwood and Sons. The work will be fully illustrated, and will contain descriptions of the most notable early and modern examples of self-propelled vehicles.

LAW REPORTS.

Koosen v. Rose.

THIS was an appeal heard on the 4th instant, from a judgment of Mr. Justice Wright at the trial of an action without a jury. The action was brought to recover a sum of £150, the price of a motor-carriage, which the plaintiff alleged he had sold to the defendant. The plaintiff having taken out a summons for summary judgment under Order 14, Mr. Justice Day at chambers made an order giving the defendant liberty to defend, and directing that the action should be put into the Short Cause List, and that the costs of the application should be costs in the cause. At the trial Mr. Justice Wright gave judgment for the plaintiff with costs, but, thinking that the case was not a proper case to be dealt with under Order 14, he disallowed the plaintiff all the extra costs incurred by the application for judgment at chambers. The plaintiff appealed from that part of the judgment which related to the costs of the application at chambers. It was argued on his behalf that Mr. Justice Wright had no jurisdiction to interfere with the order of Mr. Justice Day, which directed that the costs of the application should be costs in the cause.

Mr. Wheeler, Q.C., and Mr. W. H. Nash appeared for the plaintiff; Mr. C. W. Mathews for the defendant.

The Court allowed the appeal.

The MASTER OF THE ROLLS said that Mr. Justice Wright at the trial had assumed to himself the power of altering a decision which had been come to by Mr. Justice Day at chambers with regard to the cost of an application heard by him. The rule must be that a Judge could not interfere with an order made by a Judge of co-ordinate jurisdiction unless some statute expressly gave him the power of reviewing that order by way of appeal. Therefore, the order made by Mr. Justice Wright with regard to the costs of the application at chambers was without jurisdiction and void, and must be overruled.

LORD JUSTICE LOPES said the question was whether Mr. Justice Wright had jurisdiction to interfere with the costs of the application at chambers. In his opinion he had no such power. The costs of an application under Order 14 were provided for by Rule 9 of that order, which said that they should be dealt with by the Judge on the hearing of the application, who should order by and to whom and when they should be paid, or he might refer them to the Judge at the trial. The defendant relied on Rule 9 (*b*), which said that, if the plaintiff made an application under the order where the case was not within the order, the application might be dismissed with costs, to be paid forthwith by the plaintiff. But that applied to proceedings at chambers, and not to what took place at the trial. The appeal must therefore be allowed.

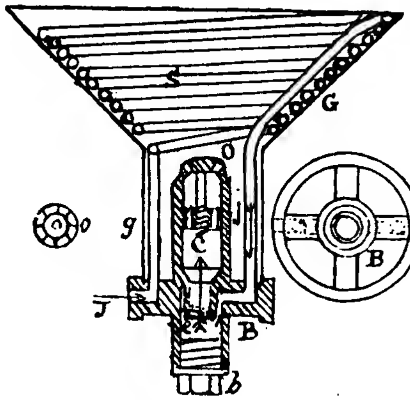
LORD JUSTICE CHITTY delivered judgment to the same effect.

AMERICAN MOTOR VEHICLES.

BEFORE the New York Electrical Society, receutly, Mr. Joseph Sachs lectured ou "Horseless Carriages." He referred to the history of the development of motor-cars, and spoke on the questions of speed, weight, and construction. After dealing with steam and gas in connection with such vehicles, the electric motor was referred to. Mr. Sachs considered the advantages of the electric system were simplicity, ease of control, and facility of connection of power with driving wheels. The steering devices and brakes can be operated by electric power, and such a machine cannot be stalled. Since it is necessary to depend upou the storage battery for supply of power, tho disadvantages of the electric system were the great weight of the battery, the limited supply of energy, the mechanical disintegration of the plates, and the lack of facilities for charging the batteries. The horseless carriage service, the speaker stated, was harder on storage batteries than traction work. He thought that a vehicle *par excellence* would be one combining the electric system with an outside source of supply. A dynamo operated by a gas motor, *à la* Heilmann locomotive, wonld probably produce effective results. With all its disadvantages, however, the electric vehicle was superior to either of the other types.

THE LONGUEMARE BURNER.

AT the request of several correspondents we reproduce a sketch of the Longuemare burner from "Voitures a Petrole," par Louis Lockert, and the following freely translated description:—The lower part is a cross-shaped bronze casting (shown on



plan to the right), of which two of the arms are pierced with ducts. By one of these, J, the oil enters under a pressure ½ to 5 kilogrammes per square centimetre, circulates through the coil S, and returns by tube *j* to the burner. The oil is vaporised in S by the heat of its own burning vapour. The oil vapour strikes on the exterior and the capsule *e*, so as to deposit any foreign matter, which can be removed by the plug *b*. It passes through layers of gauze at *e* to chamber C, and then through eight holes at top of C to the burner O. This is formed of an opening closed by a copper cone, on the periphery of which are cut eight very fine grooves, seen in plan at O, to the left of the figure. From these grooves the vapour issues, producing eight blue and vibrating flames of 50 to 60 centimetres long, which spread over the sheet-iron coue G. A cylinder, *g*, also of sheet-iron, serves as a duct for the air supply coming through the cross-piece B. The heat is greater, the greater the pressure in the oil reservoir. One of these burners is sufficient for the steam tricycle of M. Serpollet. Neither dimeusions nor scale are given.

THE KRIEGER ELECTRIC ROAD CARRIAGE.

A PAPER was recently read before the Société des Electriciens, in Paris, by M. L. Krieger, giving a descriptiou of some electric carriages recently brought out. The first carriage, converted from an ordinary horse-cab, has for some time past been driven about Paris. In this vehicle the driving power is applied to the fore-carriage by means of an electric motor geared to each wheel. To the armature shaft of each motor is attached a pinion with helical teeth engaging with a similar wheol rigidly attached to the corresponding driving wheel. The ratio of gearing is as 1 to 10. The field magnets of the two motors are coupled in series, and the two armatures in parallel. The use of an independent motor to each driving wheel enables the steering to be effected electrically. For instance, if the armature of the motor on the inside of the curve it is desired to traverse be short-circuited, the fore-carriage will turn to that side. The short circuiting is brought about by means of a special commutator arrauged for this purpose. The fore-carriage turns to an angle equal to that made by the steering handle. Hand steering gear of the usual type is also fitted to the carriage. The second carriage was made by transforming a cab belonging to the Compagnie l'Abeille. It weighed 1,150 kilogrammes (2,535 lbs.), and has taken trips of 30 kilometres without recharging the battery of "Fulmen" accumulators, which in itself weighed 285 kilogrammes (628 lbs.). M. Krieger very naturally points out that the ancient build of the carriage, constructed 10 years ago, for horse traction, shows his system at a disadvantage, owing to the great strain on the fore-carriage, which was not designed for such a purpose. Another carriage, especially constructed for electric traction, weighs, when empty, 1,880 kilogrammes (4,144 lbs.). This includes the weight of the fore-carriage, which is 1,630 kilogrammes (3,593 lbs.), and it is possible to travel a distance of 80 kilometres without recharging the batteries. This battery, especially designed by M. H. Meynier, commercial agent for the Julien accumulators, has a capacity of 450 ampere-hours, with a total weight of 640 kilogrammes (1,410 lbs.). It consists of 16 cells, each weighing 33 kilogrammes, and enclosed iu an ebonite case having three compartments. Each compartment contains 13 plates, 6½ millimetres in thickness, that is to say, 39 plates per element. The capacity being 450 ampere-hours, one obtains about 15 ampere-hours per kilogramme of plates. The ebonite cells are protected by thin oak boxes. A layer of special luting is poured on to the surface of the liquid of each cell. This compositiou, once dried, performs the function of a thin sheet of slate, sealing the cell hermetically, and preventing splashing over, which is one of the serious drawbacks in the carrying of accumulators by road. Two motors of 150 kilogrammes, running at au angular velocity of 600 revolutions per minute, give a maximum couple of 13 kilogrammes, the normal couple being 1·5 kilogrammes. The rate of discharge of the accumulators is from 60 to 80 amperes, at 30 volts on the level, at a mean speed of 10 to 12 kilometres per hour, and the same speed can be maintained over such gradients as those on the road from St. Cloud to Garches. With a load of five passengers this carriage has run 65 kilometres at an average speed of 11 kilometres per hour. It has also covered a distance of 2,500 kilometres in the suburbs of Paris at an average speed of 10 kilometres per hour. M. Krieger is having constructed an ordinary brougham with two seats, which is to travel 125 kilometres without recharging, and is to weigh only 800 kilogrammes (1,723 lbs.), 350 of which are for some new accumulators, the name of which M. Krieger does not divulge, a single charge being sufficient during the night. This is notable, as the price of the kilo-watt hour of electric energy is very high in Paris.

CORRESPONDENCE.

*** *We do not hold ourselves responsible for opinions expressed by our Correspondents.*

*** *The name and address of the writer (not necessarily for publication)* MUST *in all cases accompany letters intended for insertion, or containing queries.*

MASTER PATENTS.

To the Editor of THE AUTOMOTOR AND HORSELESS VEHICLE JOURNAL.

DEAR SIR,—I see in your Journal a discussion *re* Horseless Carriages, Master Patents, &c. I cannot see why the British Motor Syndicate may not have good master patents, but some of the gentlemen who are writing on the subject seem to be well up in it. A Mr. Sennett says the foreigner has not advanced the horseless carriage in this country; but, if it had not been for the foreigner, he and others would not now be discussing the subject as they are. He says there is a vast field in store for petroleum motors when they are able to fulfil the conditions required. He does not say what those requirements are, but as I have had a hand in the erection of steam engines up to 15,000 I.H.P., marine, locomotive, and stationary, and have been making and experimenting on oil and gas engines for about 16 years, I might be able to guess what he requires the petroleum motor to do. I think he will require it to stop, start, and reverse the same as a steam engine; if that is all, the petroleum motor will fulfil his demands with ease. As Mr. Sennett seems to know a great deal of the past, present, and future of the horseless carriage, I wish he or some of your readers would try and dispel the delusion that I am troubled with, that I was the first person to design and make a horseless carriage with engine gear, the same as is now employed by Daimler and other petroleum engine makers; and a patent specification of mine some years ago will show belts, chains, ropes, and engine as employed by these people. I would like to know the earliest date they claim to have made a horseless road carriage driven by an internal combustion engine. I have now designed an oil engine which will start and reverse the same as a steam engine; no extra gear is employed for that purpose.—Yours truly, J. M.

[With a desire to give "J. M." all the publicity we can, in order that he may reap the advantage of any substantial improvements he may have made, we have inserted his letter with some modifications. If he wants information or assistance, however, he must write less in the shape of riddles.—ED.]

A DISCLAIMER.

To the Editor of THE AUTOMOTOR AND HORSELESS VEHICLE JOURNAL.

SIR,—We have just noticed a Company being brought out for £300,000 as "The London Motor-Van and Wagon Company (Limited)." Now some months ago we registered in the name of the London Motor-Car Works Company (Limited), our memorandum of association specially providing for the manufacture of vans, wagons, &c.

It is only fair to us to state that we are in no way, directly or indirectly, associated with the London Motor-Van and Wagon Company (Limited), and shall take the necessary steps to stop them using a colourable imitation of our title.

Thanking you in anticipation.—Yours truly,

THE LONDON MOTOR-CAR WORKS CO. (Ltd.)
(James Rickard, Managing Director.)

The Albert Mills, Hammersmith, W.,
Feb. 17*th* 1897.

A QUESTION TO MAKERS.

To the Editor of THE AUTOMOTOR AND HORSELESS VEHICLE JOURNAL.

SIR,—May I ask how makers of self-propelled vehicles provide for their being turned in a narrow road? A rear-driven carriage can only turn in a circle of some considerable diameter, whereas a horse-drawn vehicle can be turned on its axis. Driving on to the front axle (this being also used for steering) would make the conditions of turning the same as in an ordinary carriage. Query, then: Why not rest the fore end of the carriage or wagon on a four-wheeled bogie carrying and driven by a compact steam plant? Load up forward.—I am, &c.,

March 6th. LOCO.

THE ELECTRICAL CAB COMPANY.

To the Editor of THE AUTOMOTOR AND HORSELESS VEHICLE JOURNAL.

DEAR SIR,—In your issue of February 17th you give a report of a meeting of shareholders of the Electrical Cab Company. One hesitates to say anything to discourage such a venture as putting electrical cabs for the use of the public on the streets of the metropolis, but surely the claim Mr. Mulliner makes to the exclusive right of use of "the most valuable improvement" is somewhat exaggerated. I may be wrong, but I know of nothing special in the Johnson Lundell Series Parallel Controller beyond the magnetic blow-out. For this feature other makers have devices which they contend are more satisfactory, but this does not seem to come into Mr. Mulliner's calculations. I therefore am compelled to assume that the controllers made by the Westinghouse people, the Walker Manufacturing Company, and others, are equally as serviceable for this purpose. Personally, I know of one carriage that is being built and fitted with a series parallel controller, about which the makers are, I suppose, equally comfortable as to its satisfactory working as the London Electrical Cab Company are about their cabs.—Yours faithfully,

March 9th, 1897. F. H. SOMERVILLE.

To the Editor of THE AUTOMOTOR AND HORSELESS VEHICLE JOURNAL.

DEAR SIR,—Referring to the report in your last issue of the statutory meeting of the London Electrical Cab Company (Limited) and the statements contained in other reports that after the meeting several shareholders had the opportunity of riding in an electrically-propelled carriage, equipped by Mr. W. C. Bersey; after the prominence given in the report to the name of the E.P.S. Company, we think it only fair the fact should be made public that the cells used in the carriage referred to were manufactured and supplied by the I.E.S. Accumulator Company (Limited), and that it is this Company that has supplied Mr. Bersey with the cells used by him during the last twelve months with very satisfactory results.—Yours faithfully,

For the I.E.S. ACCUMULATOR Co. (Ltd.),
(Herbert Woodfield, Secretary.)

3, Delahay Street, S.W.,
March 12th, 1897.

THE DAIMLER AND HORSELESS CARRIAGE COMPANIES.

To the Editor of THE AUTOMOTOR AND HORSELESS VEHICLE JOURNAL.

SIR,—Will you allow me, as a shareholder in the above two Companies, to state, for the benefit of any of your readers who may be interested, the result of my experience gained by a personal visit to the works of these Companies? I must confess that I went to Coventry with a certain suspicion in my mind produced by reading the many adverse criticisms on the promoters of these ventures which have appeared in the public Press—that I had, to say the least, made a bad investment.

Dealing first with the Daimler Company, I was courteously received by the deputy-manager and conducted all over the works, which are very spacious and convenient, and filled with machinery of all kinds, most of which was busily running. I saw several completed motors—I mean the engines, not the carriages—which were then being tested, and was informed that 50 had been already made, though not yet put together. I also saw the frames and bodies of certain vehicles which are ready to have the motors fitted. The first complete motor-car had been turned out and tested the previous day and I had the opportunity of seeing it running, and was very much pleased with it. I was especially struck by the fact that the great vibration noticeable in the foreign cars exhibited last year had been very much reduced. I was told that there were about 200 men employed in the works, and on all sides things looked like business.

The Horseless Company has, of course, been at work a much shorter time, but I found they were rapidly getting things into "ship-shape." The bottom floor of the large mill, which was temporarily let to the Humber people, had just been vacated, and is fitted up with benches, &c., ready for active operations. On a higher floor, I found a number of men engaged in making the bodies and wheels of carriages and carts of all descriptions, and was shown over the other departments, which space forbids me to particularise, by Mr. Crowden, the courteous manager.

Might I suggest that others who are interested in the progress of the above concerns should, instead of making or accepting random and hysterical assertions, pay a visit to Coventry and qualify themselves for forming an opinion on the subject?

With best wishes for the success of your useful and well-written Journal.—I am yours, &c., EDGAR SOAMES.

Bromley, Kent, *March 13th*, 1897.

MOTOR-CAR CLUB SPRING TOUR.

To the Editor of THE AUTOMOTOR AND HORSELESS VEHICLE JOURNAL.

DEAR SIR,—I send you a programme of this Club's first motor-car tour of the season. Already 60 of our members have expressed their intention of taking part in the run, which has been postponed in order that several English-made motor-carriages now approaching completion should be displayed in actual running for the benefit of members.—Yours obediently,

C. HARRINGTON MOORE,

March 10th, 1897. Hon. Secretary.

This tour, which has been postponed to secure settled weather and a good display of English-made motor-cars, has been arranged to enable members of the Motor-Car Club to inspect the various motor factories at Coventry and observe the progress that is being made, and also to enable them to take part in a short motor journey between Coventry and Leamington and neighbourhood.

PROGRAMME.

The train leaves London (Euston) for Coventry at 9.20 a.m., and a special first class saloon carriage will be attached for members journeying to Coventry and returning, should the number exceed ten.

The train arrives at Coventry at 11.12. Motor-cars will, if possible, meet this train and convey members at 11.30 to the Coventry Motor Mills.

At 12, members will assemble at the Motor Mills and inspect the works of the British Motor Syndicate, the Daimler Motor Company, the Great Horseless Carriage Company, and Mr. Pennington.

At 1 o'clock the motor-cars will start for Kenilworth, where a light luncheon will be served at the Abbey Hotel at 2 o'clock.

At 2.30 the motor-cars will leave Kenilworth for Leamington. On arrival at Leamington, members will have about two hours either to visit places of interest in the neighbourhood or to test the various motors.

"ARNOLD'S" MOTOR-CARS.

WE understand that, to meet the special requirements of the British public, Arnold's Motor Carriage Company, of 59, Mark Lane, E.C., and East Peckham, Kent, has arranged to offer an entirely new pattern of motor-carriage fitted with the well-known "Benz" motor. This improved type may now be obtained with double cylinders, and is made in three sizes, giving 3, 5, and 8½ horse-power respectively. The motor, which is placed horizontally on the carriages, and therefore easy of inspection, is run at the reduced rate of 300 revolutions per minute, this reduction of speed minimising wear and tear, and practically doing away with unpleasant vibration, when travelling at full speed.

The engines are fired by the electric spark from an induction coil worked by a two-volt accumulator. The connecting up of the coil is done in a very simple manner: one wire from the coil runs direct to the sparking tube, which is fixed in the end of the cylinder, and the return wire from the tube is led to an insulated spring, and makes and breaks contact by the action of the engine, the framework of the engine being used as a return for the current.

The exhaust box is placed directly under the engine, and the carburettor, being fixed at the back of the carriage, is easily accessible. The shaft of the engine is fitted with a conical pinion or cam, working a small shaft, which revolves at half the speed of the engine, and the cams put in and out of gear the exhaust valve, whilst the air valve works automatically.

The intermediate shaft, which carries the balance gear and two speeded pulleys, is driven by means of belts from the English shaft, this means of transmitting power being found to be very suitable for motor-carriages, as the slight slip in the belt causes the carriage to start very gently.

The motor is fitted with a tank holding sufficient water for cooling the engine for three or four hours.

THE MOTOR-CAR AND RELIGION.

HOW PROVIDENCE INSPIRED MR. H. J. LAWSON TO FLOAT COMPANIES.

IN the *Protestant Echo* of December 1st last, there appeared the following amusing article, which ought to have wider circulation than it obtained in the pages it originally adorned :—

HORSELESS CARRIAGES AND THE TRIP TO BRIGHTON.

Let God in all things be glorified. It has often been said that "necessity is the mother of invention." Granted. But we would look higher and give unto the Lord the glory due unto his name. When the Tabernacle and its furniture were required God gave wisdom and understanding to Bazaleel and Aholiab, "and in the hearts of all that are wise hearted," said God, "I have put wisdom, that they may make all that I have commanded thee" (Exod. xxxi, 2, 6).

Motor-cars, or horseless carriages, have now become as much the necessity of this age as the locomotive engine was the necessity of the age when God inspired the pit-engine boy—George Stephenson—with wisdom to invent and skill to construct his first locomotive, the "Rocket," which is now to be seen as a relic of antiquity in the South Kensington Museum.

Before the commencement of the present century neither the population of England nor that of other nations required the locomotive to run 50 or 60 miles an hour. But what should we now do without it? When, therefore, a bountiful Providence saw the growing necessity for the peoples of the world to be brought into closer commercial touch with each other, and their congested towns to be relieved of their dense populations, He anointed with wisdom and instructed the boy who was working for twopence a day in the coal pit. And by him God gave the world the idea which has developed into our railway system.

"OLD LONDON."

Those who have known our great metropolis for 60 years can remember "Old London," with its narrow streets, and now look upon "New London" with its marvellous improvements.

It is a singular circumstance that on the very spot where 40, Holborn Viaduct—the offices of the Motor-Car Company—now stands, was in the time of Old London Holborn Hill, of which all the horses in London had a dread. It was steep, slippery, and narrow. There every day in the week, and often several times in the day, might be seen the busy and eager crowds of spectators who witnessed the struggling horse, or helped to hold his head down while he was unharnessed, and the poor animal raised from his perilous situation. Busy times they were. Yes, the Jews of "Fee" Lane, who bought and exhibited for sale all the silk pocket-handkerchiefs which the thieves "found" in those crowds, drove a brisk trade in those days. Cheapside also was then a narrow street, with its long team of omnibuses moving as fast as the police could make room for them. About one mile an hour was perhaps the average rate.

NEW LONDON.

Now, new and widened streets, underground railways, Thames Embankment, river steamboats, cheap postages, electric telegraph and telephone all help to lessen the traffic of our great city, and other congested towns.

Yet the ever-increasing population still cries, Give us room. And

THE AUTOCAR

may be regarded as the gift of a Divine Providence to meet the want of the age. Prejudices against every improvement may be expected, but they are not worth noticing. While the motor-cars were in Brighton, on November 16th, we had the pleasure of about two hours' ride on the best of them, up and down the front and through the town. Our car was provided with pneumatic tyres, and could travel, we were told, at 30 miles an hour. At what rate we went it is not possible for us to say, but all that we could compare it to was a bird resting upon his pinions and gliding through the air.

LONDON TO BRIGHTON.

On November 14th an Act of Parliament came into operation which emancipated our roads and road locomotion from a singular law, which compelled the drivers of autocars to have a man walk in front of them with a red flag. To commemorate this event the leading spirit in this great movement organised a procession from London to Brighton, in which about 52 cars took part. Thousands of bicyclists determined upon accompanying the inventor of the "safety" in this bold undertaking.

The weather was wet, and a mercy it was, for such was the interest of the people in this movement that no motors would ever have reached Brighton that day had the weather favoured outdoor sight-seeing. As it was, the leading car arrived about 4.30 p.m. The Mayor, on behalf of the Corporation, met its driver, took a seat by his side, gave him a welcome, and presented a gold medal in commemoration of the event.

A feeling of overwhelming gratitude for safe arrival of all the cars under his command filled the heart of the leader, and many other hearts, too. This he testified by giving £20 as a thank-offering to the poor.

NEW INVENTIONS.

Claiming particularly to apply directly or indirectly to Motor Vehicles, &c.

Specifications Published.

19,468. October 16th, 1895. Motor-driven road vehicles. THOMAS NIXON DARE, 13, Monmouth Road, Westbourne Grove, London, and CHARLES DIXON, of 5 and 6, Downing Street, Cambridge.

The principal object is to convert existing vehicles with as little interference as possible with their present construction.

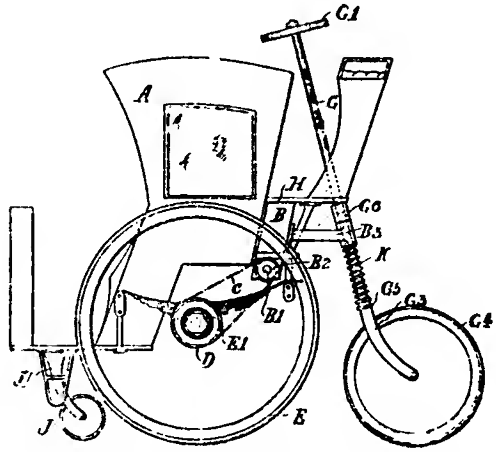
The figure is a side elevation of a hansom cab to which the invention is applied.

The motor, B, is fixed to the rear of the vehicle and geared to the road wheels, E, by chain wheels, B^2, D, and a chain C.

A small wheel, J, carried at the end of a readily-detachable bracket, J^1, is fixed under the front of the hansom to prevent any possibility of its tilting too far forward.

The steering arrangements in the hansom are as follows:—At the rear of the vehicle there is a rod, G, in two parts, with a hand-wheel, G^1, at its upper end in proximity to the driver; this rod is journalled in a bracket B^3, extending from the motor casing. At its lower end it has a fork, G^3, in which is a rear wheel, G^4, preferably fitted with a solid rubber or pneumatic tyre. Between the head G^5 of the fork G^3 and the bracket B^3, a spring K is interposed to permit the rod G, with its wheel G^4, to rise and fall in running over inequalities in the ground. Preferably the rod, G, is made in two parts, so that in putting it in place the driver's seat need not be disturbed; the upper part can be passed through a hole in the foot-board, H, of the driver's seat into a socket, G^6, on the lower part of the rod below that platform; this, however, is only for convenience, and is not essential.

In four-wheeled vehicles the motor may be carried upon the fore-carriage instead of being attached to the vehicle body; or it may be slung to the underside of or otherwise carried on a fixed axle if desired. An extra wheel or wheels such as J, arranged as a castor or otherwise, can be fitted to the motor casing, or to the vehicle if found desirable, as it might be in certain cases; for instance, those in which it is found that the



addition of the motor to the vehicle would otherwise affect the trim or the running of the vehicle.

Brake power may be applied to the periphery of the wheels, and to any required number of the wheels, or to the hubs, or to special drums provided upon the wheel or axle for the purpose.

MISCELLANEOUS TRADE ADVERTISEMENTS.

CONTENTS.

AN ELECTRIC HANSOM.

DURING the past year, says the *Scientific American*, we have received hundreds of letters either anxiously inquiring whether the automobile vehicle was in reality a practical means of transportation or where such vehicles could be purchased.

The number of American-built motor carriages which have been offered for sale has been small, and the few manufacturers who have pretended to do any business have been somewhat reluctant to put carriages upon the market. In this respect they have been wise, and their action will only result in doing good to the motor industry. In its present state of development the horseless carriage can hardly be trusted in the hands of those who have not some acquaintance with machinery or those who may not be favourably disposed toward the new vehicle. The three races which have been held in America have had the effect of awakening public interest in the subject. If the manufacturers had greater capital at their command the perfecting of their machines would have proceeded at a more rapid rate, but the results would probably not have been more satisfactory. We are glad to be able to chronicle the fact that for the first time in America the horseless vehicle has now entered into competition with the public cab in the city of New York.

The Electric Carriage and Wagon Company, which has offices at 66, Broadway, and a depôt where cabs may be hired at 140, West Thirty-ninth Street, has now several electric hansom cabs which can be hired at the legal rate of the public cabs. In a short time 12 of these vehicles will be at the disposal of the public and an electric brougham will probably be added. It will be little wonder if the public does not take favourably to these handsome vehicles, which seem the perfection of the carriage-maker's art.

Unlike the ordinary hansom cab they are mounted on four wheels. It will be seen by our illustration that to an ordinary cab body a battery box is attached, forming an extension in the rear. Upon this is situated the seat for the driver. The weight of the carriage is about 2,500lbs., the weight of the batteries alone being from 800 to 900lbs. The diameter of the large wheels is 43 inches, while the diameter of the small wheels is 32 inches. The wheels run on ball bearings, have tangent wire spokes, steel rims, and thick pneumatic tyres. Each of the front wheels is connected with a motor of the Lundell type, of nominal 1½ horse-power. Each motor is inclosed in an iron case and drives each wheel independently. The pinion from the armature shaft meshes with the internal gears of the wheels The internal gears permit of turning corners with ease. The storage batteries which are used are supplied by the Electric Storage Battery Company, of Philadelphia, Pa. They are chloride accumulators of 70 ampere hours capacity. It is arranged so that automatic connection is made when the batteries are run into the battery container, by means of contact plates, and fuses are provided as a safeguard. The controller is situated at the left side of the driver's seat, so that it is easily manipulated with the left hand. There are three speeds forward and one speed backward. The first notch of the controller gives a speed of five miles per hour; the second notch, eight to 10 miles; the third, 13 to 15 miles. Fifteen miles may be regarded as about the maximum speed which is desired or can be obtained with the hansoms. These speeds are obtained by various groupings of the batteries and motors in series and parallel.

Directly in front of the driver is a lever which controls the steering mechanism, which is extremely ingenious. The steering is accomplished by turning the rear wheels parallel with each other from a point directly over the tread of the wheel. The wheels are connected by rods to a vertical lever of a convenient height to be operated from the front seat of the carriage. In reality the steering mechanism looks like an enormous hollow hub which turns freely, horizontally, upon the vertical rod which supports the body of the carriage. The steering mechanism enables the carriage to be turned completely around in a very short space.

A powerful roller brake adds to the safety with which the carriage can be driven, but one of the things that is remarked by persons who ride for the first time in the horseless carriage is the ease with which it may be stopped. In this respect it compares very favourably with any horse vehicle. From the driver's seat the doors of the cab are also opened and shut and the electric light is turned on or off. An electric bell under the footboard gives warning of the approach of the almost noiseless vehicle, and when used with discretion will add very much to the safety of the carriage.

Each of the carriage lamps has an incandescent lamp, and there is also an incandescent lamp in the cab, so that the passenger can sit and read if he desires. A speaking tube runs from the interior of the cab to the driver's seat, where the mouthpiece is secured by a holder, connection being made with a flexible tube. The attention of the driver of the carriage is attracted by a whistle which is actuated by a rubber bulb in the inside of the cab. This bulb forms the mouthpiece of the speaking tube, a plug being removed when conversation is to be held with the driver.

The motion of the cab is pleasant in the extreme. There is no vibration such as is often found in carriages driven by one of the petroleum products. The ease with which the electric carriage can be started and stopped, the absence of vibration and disagreeable odours, are points in its favour. The batteries afford power sufficient to propel the carriage from 18 to 25 miles on the level, depending upon the state of the road. With a private plant the batteries may be charged at an expense of from 10 to 12 cents. The cost is increased where the electricity must be purchased. It is estimated that the carriage can be run at an expense of about a cent per mile. Riding in a hansom cab of this kind is pleasurable in the extreme. There is nothing whatever to interrupt the view of the passenger.

An Electric Hansom.

The carriage proper was built by the Charles Caffery Company, of Camden, N.J., and the motors were built by the Interior Conduit and Insulation Company, New York City. The carriage was invented by Messrs. Morris and Salom, of Philadelphia, Pa.

SYDNEY ENGINEERING AND ELECTRICAL EXHIBITION.

The exhibitions held in 1883 and 1886 having proved so successful in affording exceptional opportunities for useful and instructive recreation, the Engineering Association of New South Wales, in conjunction with the Electrical Association of New Wales, have decided to hold a similar exhibition during the months of June, July, and August, 1897, and cordially invite the co-operation of manufacturers, engineers, electricians, mechanics, and others interested, in order that it may be carried out with success. In view of the great success attained by the previous exhibitions, and the vast strides that have been made during the past few years in engineering, and more particularly electrical science, it is anticipated, says *The Engineer*, that the proposed exhibition will considerably surpass the previous ones, and prove worthy of the engineering enterprise of the colony. By the courtesy of his worship the Mayor of Sydney and the City Council, the use of the exhibition building, Prince Alfred Park, has been granted free of charge for a period of three months. It is proposed to open the exhibition on June 26th, and for it to remain open during the months of July and August. The exhibition is intended to embrace engineering in all its branches, and the exhibits will consist of raw materials, manufactured articles, machinery and models (in motion and otherwise), drawings and photographs of all kinds relating to scientific, mechanical, and educational works, in classified sections. No charge will be made for space allotted, but the executive committee reserves the right to limit the space of each exhibitor. The object of the exhibition being solely for the advancement of engineering science, and the promotion of a general and practical education therein, it will be non-competitive, but prizes and certificates of merit will be awarded to apprentices and students. Among the various groups we notice —Group IV—prime movers, comprising steam engines, gas, electric, hydraulic, hot air; water-wheels, turbines, wind-mills, steam generators, accessories of engines or boilers, &c.; and Group VI comprises railway, tramway, and vehicular appliances, and embraces rails, switches, signalling apparatus, locomotives, goods wagons, carriages, &c., tramway cars, rails, permanent way brakes, couplings, ticket-checking apparatus, bicycles, tricycles, and auto-cars. Further information may be obtained from Mr. Edward Noyes, 34, Gracechurch Street, London, E.C.

A Motor-Car and Motor Cycling Engineering and Machinery Exhibition is announced to take place at the Royal Agricultural Hall, Islington, from Monday, August 23rd, to Saturday, September 4th, of this year, under the auspices of Messrs. Cordingley and Co., from whom full particulars can be obtained at 39 and 40, Shoe Lane, London, E.C.

DESIGN FOR AN ELECTRICAL OMNIBUS.

(Illustrations Copyright.)

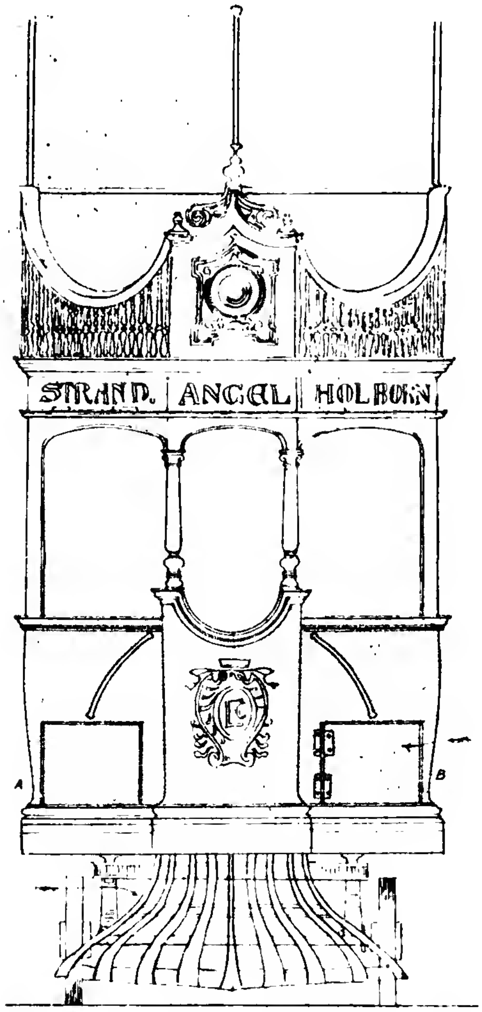
By the HON. A. McGAREL-HOGG and MR. J. T. MURRAY.

THIS design was submitted in a recent competition for an electrical omnibus of artistic design.

The conditions required that the vehicle should appear complete in itself, without any suggestion of horse traction, and be thoroughly expressive of its self-contained power of locomotion. How well these terms have been complied with is at once apparent on reference to the design, which also shows that the structure does not present any special difficulties over the ordinary construction of a modern omnibus, the points specially aimed at being adaptability to the purpose required and general attractiveness.

Several entirely original features are embodied, such as the destination indicator in the front, in the bus illustrated the "Elephant and Castle," and the road indicator at the back, and by including the driver's car in the main design space is gained for luggage above, while by combining the front and rear platforms with the main passenger portion the whole structure is given the appearance of a self-contained car independent of animal traction.

Structurally the car is held together longitudinally by a lower and upper frame, the lower one being immediately above the under carriage, and the upper one constituting the roof. These frames are connected together by slightly curved posts, five along the main structure, and one on the driver's platform, an intermediate upright subdividing the central subdivision on either side. The frames and posts are of hard wood, braced and strengthened where required by iron straps. The lower sides of the car may be of thin wood or canvas, the floor and roof being of 4½-inch ploughed and tongued boarding. The outer roof covering is of canvas stretched on steel ribs, supported at intervals by adjustable struts. The car is ventilated throughout by ordinary hit-and-miss ventilators arranged



behind the frieze, and lighting is effected by means of two circular roof lamps, one on either side, a large circular lamp being provided in the front above the driver, and a smaller one at the end of the car above the conductor. The destination and road indicators are placed as shown in the drawings, and we understand that the latter device forms the subject matter of a patent by the designers.

While due provision has been made for ample strength in every detail, the design is light and neat in appearance, and its authors are to be congratulated upon having so successfully complied with the requirements of the competition.

MOTOR VEHICLES FOR ROADS.*

By W. Worby Beaumont, M. Inst. C.E., M. Inst. Mech. E.

So much has been said and written concerning mechanical road-vehicles,† their motors and gear, that I cannot avoid some repetition in dealing with the subject again, especially as there is not yet much to be said concerning the recent and pending advances. It is unnecessary now to occupy space on the history generally, and I will only refer to those vehicles which, though made 60 years ago, are of interest now as still affording some indications of what may be usefully done to-day. At the time (1831) when the Select Committee of the House of Commons was appointed to inquire into and report upon the tolls and prospects of land carriage by means of wheeled vehicles propelled by steam and gas upon common roads, there were numerous coaches and other steam vehicles which had achieved a considerable degree of practical success, and would have been of great commercial value had not powerful influences been brought to bear against their adoption, or acted so as to render their use less necessary. Between the years 1824 and 1831 so much had been done to prove the possible value to the community at large of steam vehicles on common roads, that not only was the powerful organised opposition of various interests and of the ignorant classes directed against the steam carriage, but the rapidly-growing importance of the railroads caused every other method of mechanical transit to sink into comparative insignificance. The opposition which was successful as against mechanical vehicles running on the common high roads, public property, was impotent as against the locomotive running on rails and on land the property of the railway company. The one could be subject to the vexatious interference of everybody, and to extortionate demands for tolls, while the other was protected by being on its own ground; hence the arguments levelled against the road carriage as to the ill effects which would result from the displacement of a large part of the 2,000,000 of horses then in use for transport uses, were powerless against the railway locomotive running under statutory powers. The steam coach, therefore, which had reached a high state of development between the years 1825 and 1832, came at an unfortunate time, and died of inanition. By the year 1830, however, England had acquired the right for ever to the credit of originating the greatest blessing man ever conferred on man, namely, the means of locomotion on high roads and railroads by mechanical power.

We may glance at the results of the work of Gurney, Hancock, Dance, Summers, Ogle, Church, and others, with a view to extracting therefrom some useful hints after the lapse of 65 years.

Goldsworthy, Gurney, and Walter Hancock were, amongst those who achieved success, perhaps the best known, but Maceroni and Squire, Summers and Ogle, and Hill, must also receive credit for very successful construction and working, while Sir Charles Dance, Church, and others should not be forgotten. When we remember the difficulties as to materials and as to machine tools, and as to the complete absence of precedent under which those men worked, our admiration of the great things they did is much increased.

Hancock made a number of coaches, including the "Autopsy," the "Enterprise," the "Era," and others, all of which were fitted with powerful engines and a remarkable high type of boiler, working at a very high pressure, and containing points of great interest to us at this day. It is, moreover, quite probable that his method of constructing wood wheels will yet be found worthy of imitation. The "Automaton," for instance

* Two papers, one read on the 27th ultimo, before the Manchester Association of Engineers, and one on the 29th ultimo, before the Cleveland Institute of Engineers, the two papers being here combined.

† See The Automotor and Horseless Vehicle Journal, December, 1896, and February, 1897, Cantor Lectures, *Society of Arts Journal*, 2nd, 9th, and 16th December, 1895, and 27th November, 1896. Also Lectures to Liverpool Chamber of Commerce, 9th September, 1896, to Self-Propelled Traffic Association, 19th January, 1897.

(Fig. 1), was constructed to carry 10 or 11 passengers and conductor and driver on seats in the front part of the vehicle in char-a-banc fashion; the rear part of the vehicle carried the engine and boiler, and contained between them a place for some inside seats. The engine was vertical, placed nearly midway in the length of the vehicle, and it had two cylinders of 9 inches diameter and 12-inch stroke, and with a crank shaft which was which would be adopted to-day if gearing of any kind, or a chain such as Hancock used, were employed.

The boiler which Hancock invented, and with which he was very successful (Fig. 2), provided steam for his engines ordinarily at a pressure of from 60 lbs. to 100 lbs. on the square inch, with an ordinary safety valve load of 70 lbs., but he had used pressures as high as 400 lbs. The boiler consisted of 10

Fig. 1.– Hancock's Steam Carriage "Automaton" (1827).

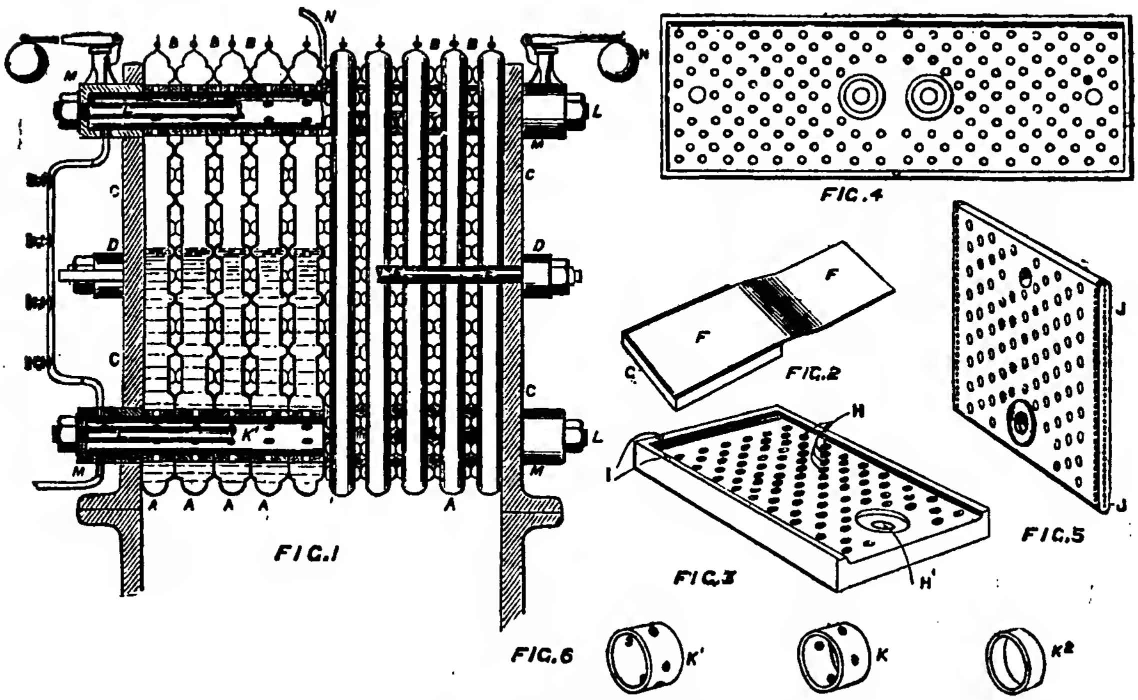


Fig. 2.—Hancock's Boiler (Group Fig. 2).

geared to the driving axle by means of a stout common chain, running on grooved and pocketed chain wheels 10 inches in diameter. The coach in working order weighed about 3½ tons, and the driving-wheels were 4 feet diameter. Running at 10 miles an hour the engines would thus make only about 70 revolutions a minute, and hence the necessity for the large dimensions of the engines as compared with the dimensions chambers, each about 30 inches by about 20 inches and 2 inches in thickness, made of charcoal plate ⅛-inch thick. The sides of these chambers were embossed all over, so that when the chambers were assembled the bosses met and acted in the place of stays to prevent the distortion of the chambers under pressure, and at the same time leaving ample space for the passage of the products of combustion between them. The heating surface in one of these boilers was about 100 square feet and the grate surface 6 square feet. That is about 3 square feet of heating surface, and 0·3 square feet of grate surface per horse-power, taking an average pressure of 35 lbs. per square inch in the cylinder. The chambers were riveted together at the vertical edges and the top, each chamber being formed of a single plate bent up in the middle, the bend forming the bottom edge without a seam. Towards the top and bottom of each chamber holes about 3 inches in diameter were made in the

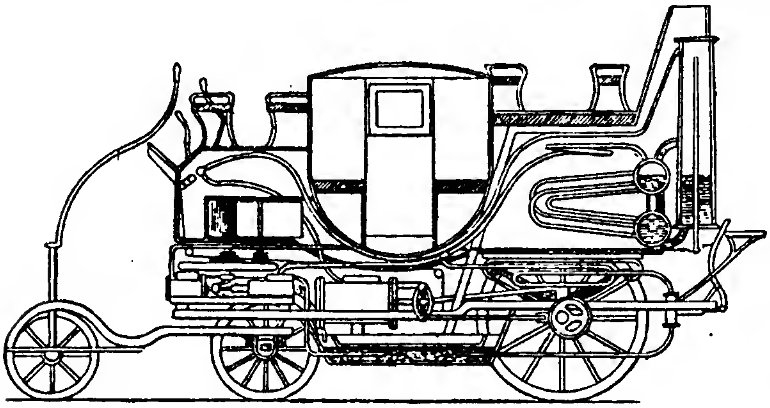

Fig. 3.—Gurney's Steam Carriage (1825–8).

chamber sides, and gunmetal rings acting as distant pieces were placed within the chambers at the bottom, and narrower rings within and between the chambers at the top. Through all these rings and through strong side plates, and small end chambers carrying the safety-valves and for the attachment of fittings, were passed strong bolts, by which the whole structure was firmly held together, the collars forming chambers, the lower one for the receipt of the feed-water, and the upper one acting as a steam chamber; the boiler so constituted was kept from half to two-thirds full of water, and only on one occasion did the boiler ever show any weakness, and even then, although one of the plates split, nothing more happened than the mere stoppage of the engines. Besides the two bolts mentioned for holding the

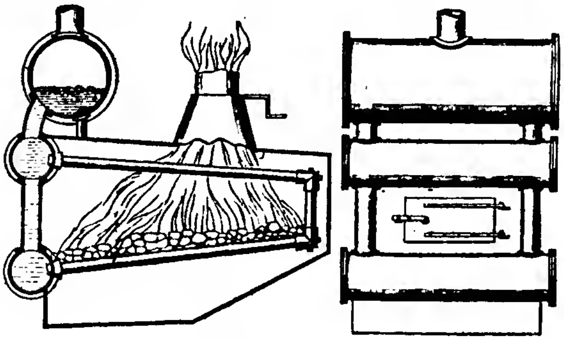

Fig. 4.—Gurney's Boiler.

boiler together, two others passing through the ends of strong bars at the centre of the end plates were used. One of the coaches in which this boiler was used, used to run an 8-mile stage, and from 7 cwt. to 8 cwt. of water, or, say 115 lbs. per mile, were used; at the same time about 2 bushels, or 80 lbs. of coke, were used, hence making an allowance for the full fire at starting the boiler evaporated at least 10 lbs. of water per pound of coke burning, say, a total of 11½ lbs. per mile. I think, therefore, I am justified in again referring to Hancock's boiler as one which is not without suggestive value.*

* For further particulars as to Hancock's boiler, wheels, and coaches, see the Author's Cantor Lectures, *Society of Arts Journal*, 1896.

Gurney's coaches and tractors have been referred to on many occasions, but I would draw particular attention to Gurney's boiler and to some figures concerning it, to which attention has not been drawn. The coach (Fig. 3), unlike Hancock's, was driven by a pair of horizontal engines, and the road wheels were 5 feet in diameter; the driving axle was the crank shaft of the engines; the crank shafts in the different coaches were the cause of considerable trouble, trouble which was avoided by Hancock by using a straight axle and a driving chain. So many of Gurney's coaches were made and used by himself, Sir Charles Dance, and others on different roads, that a short description of the arrangement of the machinery may be given.

The engines were of what was then known as 12 nominal steam horse-power, with cylinders 9 inches diameter, 18-inch stroke, and about ¾ inch in thickness; they were at first made of gunmetal, but cast iron was found to be best; cut-off took place at about half stroke; being direct coupled the engines were, of course, slow-speed engines; forced blast was used as it was by Hancock, Hill, and others, but Gurney's fan was on a vertical spindle driven by the little vertical crank shaft of a little engine on the fore carriage, which also worked two feed-pumps; the exhaust steam from the engines passed into and from a tray-formed tank under the coach by means of which the water was heated on its way to the boiler, the feed-pipe being taken into the uptake space and heated on its way to the delivery into one of the steam receivers of the boiler. The exhaust steam finally passed into the uptake and escaped highly superheated into the atmosphere through one of four chimneys. The boiler shown in Fig. 3 is of the kind which Gurney made when he fitted them with vertical separators, two of which were used as steam chests in which the water from the steam was deposited and found its way back to the lower water trunk of the boiler; steam was taken from the top of these receivers by a pipe which passed along under the coach body to a point below the driver's seat, whereat was situated a regulating cock and lever. Subsequently Gurney gave up the use of these vertical receivers and used an upper horizontal receiver (Fig. 4*). This boiler was

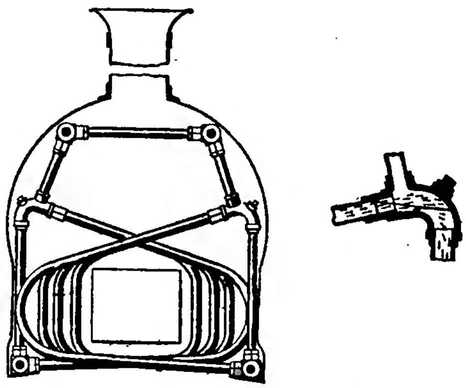

Fig. 5.—Dance's Boiler (1831).

remarkably successful, but I have not been able to find the amount of heating surface it contained; at first a great deal of trouble was experienced by the splitting of the tubes, but afterwards tubes with lap welds were obtained and little further trouble was met with. The boilers were tested to 800 lbs., and worked at from 70 lbs. to 120 lbs. With 70 lbs. Gurney estimated that he got 20 lbs. per square inch in the cylinders, presumably meaning an average pressure with cut-off at half-stroke. Various sizes of tubes were tried, and tubes 1 inch internal diameter were preferred. With a coach weighing

* Cantor Lectures.

about 3½ tons ready for the road, about 10 gallons of water were used per mile and about 20 lbs. of coke, a consumption which, though only approximate, seems very high, for it gives an evaporation of only about 5 lbs. per lb. of fuel; and the water consumption, as far as can be gathered from Gurney's statements before the Select Committee in 1831, would seem to have reached as much as from five to seven gallons per horse-power hour, or from 50 to 70 lbs. This is assuming the horse-power to be 20, but if we take only the average pressure of 20 lbs. in the cylinders, and the speed of slightly over 11 miles per hour, giving 60 revolutions of the crank per minute, the estimated indicated horse-power would be only 14.

Fig. 6.—Summers and Ogle's Boiler.

Fig. 7.—Maceroni and Squire's Boiler.

Gurney's estimate of 20 lbs. is, however, probably far below the mark, for even assuming that the 70 lbs. steam fell 20 lbs., on the square inch on its way to the steam chest, the average pressure throughout the stroke was probably much nearer 40 lbs. than 20 lbs. In any case, however, it would appear that Gurney's tubular boiler was not as efficient as Hancock's thin, flat chamber boiler, and this is borne out by the fact that Sir Charles Dance, who had several of Gurney's coaches, found it desirable to improve the boiler, and he invented and patented certain modifications which he embodied in the boiler known under his name (Fig. 5). Gurney had about five years' experience of the running of his coaches and tractor vehicles, and

Fig. 8.—Maceroni and Squire's Coach.

he concluded by experience that a piston-speed of 220 feet per minute was as high as it was desirable to use, and this affords a further check on what was the maximum horse-power of his engines. With regard to the weight of his coaches and tractors, he used to reckon each 10 cwt. of vehicle and its machinery as equivalent to one horse of the four horses usually used on an 18-passenger coach. It is noteworthy that in his experience, as well as in that of Hancock, one driving wheel was found sufficient for all ordinary running. One of Gurney's tractor vehicles was sent down to Cyfarthfa, where Mr. W. Crawshay fitted it with cast-iron flanged wheels early in 1830, and ran it on a piece of railroad three miles in length, when it hauled 16½ times its own weight. Dance's boiler (Fig. 5) was an interesting form of tubular boiler in which the fire was completely surrounded except at part of the ends by tubes which formed grate bars, water-heating tubes, and steam tubes, but we do not find much evidence as to the performance of this boiler, for it was only finished a few months or a year before the coaches ceased running.

Another boiler of considerable interest is that of Maceroni and Squire, which was a tubular boiler and a modification of Summers and Ogle's combined water and smoke-tube boiler. These are shown by Figs. 6 and 7. Maceroni and Squire ran their coach about 1,700 miles almost without repair, and the cost of coke was only from 3*d.* to 4*d.* per mile, which, as was the case with Gurney and Hancock, was only a fraction of the cost of the food of the four horses otherwise used, including the spare horses

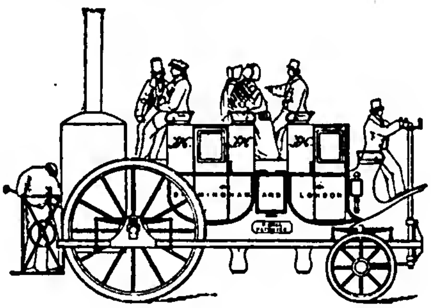

Fig. 9.—Hill's Coach.

which were necessary. The engine used was a double-cylinder horizontal, mounted on the perch pole, and with cylinders 7½ inches diameter and 15¾ inches stroke. Fig. 8 shows Maceroni and Squire's coach. Summers and Ogle's coach weighed three tons in running order. The boiler shown by Fig. 7 had 250 square feet of heating surface, and about 6 feet of grate surface; it weighed about 8 cwt., and consisted of vertical water-tubes, through which the smoke-tubes passed, these tubes being fitted and fixed in horizontal top and bottom cross-tubes of rectangular external section and circular internal section, and apparently made of cast iron.

The boiler was 3 feet 8 inches in height by 3 feet by 2 feet 4 inches, and was worked at a pressure of 250 lbs. It supplied

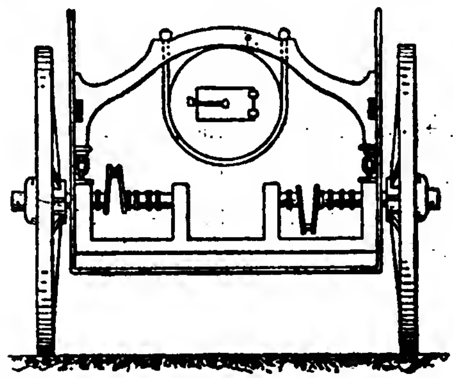

Fig. 10.—James's Carriage.

a double-cylinder engine, the cylinders being 7½ inches diameter and 18 inches stroke, coupled direct to a crank driving axle, the driving wheels being 5 feet in diameter. The engine was stated before the Select Committee to be of 20 horse-power, and this, with the statement as to fuel and water used, gives an evaporation of 7 lbs. of water per lb. of coke, and about 56 lbs. of steam per horse-power per hour, running the coach at an average speed of ten miles, with from a ton to a ton and a half of passengers.

Hill's coach (Fig. 9) differed considerably in general design from those previously mentioned, the under frame being more

T

like that adopted in railway work, including the springs and horn-plates used for the main bearings of the crank-shaft, which was worked by a double-cylinder vertical engine; both wheels were drivers, and the crank-shaft was apparently in two parts, connected by what is now known as a compensating motion, this being the first instance of its use. The boiler, as

FIGS. 11 and 12.—Church's Boilers.

seen, was a vertical boiler, which was adopted by Hill after previous experience with his partner, Burstall, who in 1824 designed and patented an arrangement of steam coach in which an instantaneous steam generation boiler was employed, and in which all four of the wheels were driven.

An arrangement of coach with two double-cylinder engines actuating independent crank shafts, one to each driver, and

FIG. 13.—Church's Steam Carriage.

a well thought out arrangement of spring suspension was patented by W. H. James (Fig. 10) in 1824, this being the first suggestion of the use of independent engines for each driving wheel, making compensating gear unnecessary.

I will only refer to one more illustration of the ingenuity and practical character of the designs of many of the inventors of 60 years ago, namely, the water and smoke tube boilers of Church (Figs. 11 and 12). One of these (Fig. 11) is, it will be seen, a combination of vertical boiler with smoke tubes and horizontal shell boiler with completely water-cased firebox, and with a water bridge or a row of vertical stop-ended tubes forming a bridge. The air for combustion was supplied by a fan below the large grate. Fig. 12 shows the arrangement of the same boiler converted into a water-tube boiler. Dr. Church's coach, or one of his designs, is shown by Fig. 13. These are only a few examples of the designs of coaches, boilers, and motors made, and many of them used at a time when the country was not ready for them, and it will have been seen that in many points the boilers and other details were forerunners, very closely followed by things of very recent date. Reference may be made to the high steam pressures used by some of these men, and it is much to be regretted that the courage and ability with which these high pressures were provided for and used were discredited by the adverse opinions of some of those who were supposed to be more scientifically informed than those who used them.

On many questions connected with steam engineering matters, no circumstance has done more to prevent the attainment of highly desirable achievements and knowledge than the possession of knowledge by contemporary educated men. With regard to high pressures, and the immense value thermodynamically, this has been particularly the case down to within very recent times.

The records of the doings of the men of 65 years ago are in many respects imperfect, but enough remains in the chronicle of their times to constitute monuments to their ingenuity, and to make the Patent Office publications extremely interesting with respect to mechanical invention and development. The periodical literature may also be consulted with much profit as to the bearings of invention and design of many things of recent date.

The great movement which these men had originated having, for many reasons beyond their power, proved commercially unsuccessful steam traction on common roads ceased to occupy anyone seriously. From time to time after about 1835, attempts were made to produce a steam vehicle of one kind or another, but a very few years was sufficient to cause men to forget or to ignore the teaching of the work of Hancock, Gurney, and others. With a few exceptions, from 1840 to 1895 the steam road-vehicles which occasionally appeared were of the heavier kinds, more of the nature of a self-moving engine or of traction-engines; steam cart-horses in fact, when compared with the steam carriages of 1832. Latterly, the English laws, passed chiefly in the interests, contradictory as it may seem, of slow speed traction-engine makers, and of the public opposed to anything mechanical on the roads, were absolutely prohibitive of development in any direction, and they have enabled our foreign competitors to enter upon and make considerable strides towards the occupation of an industrial field which, by virtue of British ingenuity, should have been an important one in the United Kingdom.

The interregnum was relieved from complete stagnation by road steamers, such as those made by Ricketts, of Stafford (Fig. 14) for the Earl of Caithness and for the Marquis of Stafford, road steamers which weighed about 30 cwt., and only carried three or four persons, in very considerable discomfort, and a stoker. The steamer made for the Marquis of Stafford in 1858 had a locomotive form of boiler supplying steam to a horizontal engine, on one end of the crank-shaft of which was a pitch chain pinion, by means of which, at a ratio of 1 to $2\frac{1}{2}$ the 3 feet driving-wheels were driven. The road steamer made by Ricketts for the Earl of Caithness was very similar to that of the Marquis of Stafford, but the engine drove the main axle by gearing instead of by chain, and it weighed 50 cwt. A road steamer was made in 1861 by Messrs. Carrett and Marshall, and like those of Rickett ran on three wheels; it carried seven or eight passengers and a stoker, but as it weighed over six tons it is not of very great interest now, although it, known as the "Fly-by-Night," acquired a very high degree of notoriety.

In 1845 R. W. Thompson invented and patented (No. 10,990) the pneumatic tyre for wheels, and he called them his aerial wheels. His pneumatic tyre consisted of an outer cover which he made of leather, and of an inner tube which he made of indiarubber and canvas. His outer cover was held on by bolts passing through the leather and the felloes and tyres of the wheels, but of course he was not confined to that method of holding, and I believe he attached the leather cover by other modes than those shown in his patent specification. Thompson experimented with these tyres, but being born long before the days of cycles his experiments were made with tyres of very large size, and on very heavy wheels. A trial on a brougham showed that they might be run 1,200 miles without much or very serious wear. Experiments were also made to ascertain the difference of the draught of a vehicle with aerial wheels and those with ordinary tyres. The result was a saving of over 60 per cent., it was stated, on ordinary roads, and a gain of 300 per cent. on newly-metalled roads. Experience, however, did not encourage Thompson, and many years later he departed from his promising aerial tyre, and was the cause of the infusion of new life into road steamer construction through the introduction, in 1871, of solid indiarubber tyres. The road steamers were,

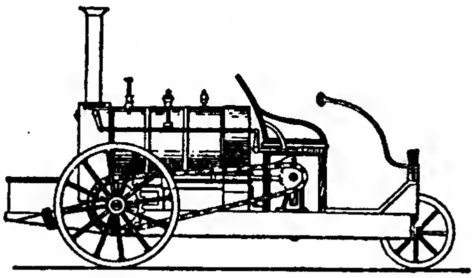

FIG. 14.—The Marquis of Stafford's Steam Carriage (1858, Rickett).

however, of the heavy kind, that is to say they were vehicles carrying a heavy vertical shell boiler of the Field type, with small heating surface, and, therefore, small horse-power per unit of weight. One of these road steamers is shown by Fig. 15. Others were made with the horizontal or ordinary locomotive type of boiler, but the cost of the tyres, which were put loose upon the wheels, was so great, and the wear and tear so heavy, even when shod with a form of linked iron tyre, that the system was ultimately abandoned; a set of three tyres for the Ravée costing £241, the tyres being 5 inches in thickness and 10 inches in width. Mr. R. E. Crompton attached these encircling linked tyres in various ways by wires, one of them resembling that of the wire used for holding pneumatic tyre covers. Somewhat similar tyres are, however, now used, but the interior part is made of harder rubber, and this is vulcanised on to the rim of the wheel. In this way Messrs. Burrell have overcome the difficulty which attended the rolling out and breakage of these massive solid rubber rings. About the same time, and a little later, numerous forms of spring wheels with steel and with rubber springs and buffers were invented and tried, but none of them have withstood the test of prolonged experience.

As we now know, the pneumatic tyre provides, above all others yet known, the most perfect form of spring wheel; for there is in it the minimum quantity of imperfectly elastic material, namely, indiarubber, with a maximum quantity of a perfectly elastic material, *i.e.*, air; while the rubber is so used that the amount of working it receives, tending, as in a rubber-kneading machine, to convert it into a soft, gluey material, is comparatively small. There is, however, a point beyond which it is not at present advisable to load pneumatic tyres, and a problem of some interest on this subject remains to be solved: Up to a given and somewhat limited load, the necessary thickness and weight of the rubber-canvas envelope of the circular air spring column does not injuriously interfere with the elastic action of the air spring, or with the functions of the rubber envelope as an equalising pad neutralising or equalising the inequalities of a stony, pebbly road. Beyond that limit, however, the strength and thickness of the envelope begins to approach the dimensions of a mere rubber cushion and canvas tyre, and although increase in the diameter of the tyre increases, in the ratio of the square of the diameter, the quantity of the perfectly elastic material, the strength of the envelope must be increased in direct proportion to the increase in diameter. Thus, with large diameters for large weights, the pneumatic tyre, as at present made, becomes a heavy and costly tyre as compared with that for light loads.

Numerous road steamers about this time, and down to 1876, were made by Mr. A. F. Yarrow, the well-known torpedo-boat builder, Mr. H. P. Holt, Messrs. Tangye Bros., Mr. A. Paterson, Mr. H. A. Mackenzie, Loftus Perkins, J. G. Inshaw,

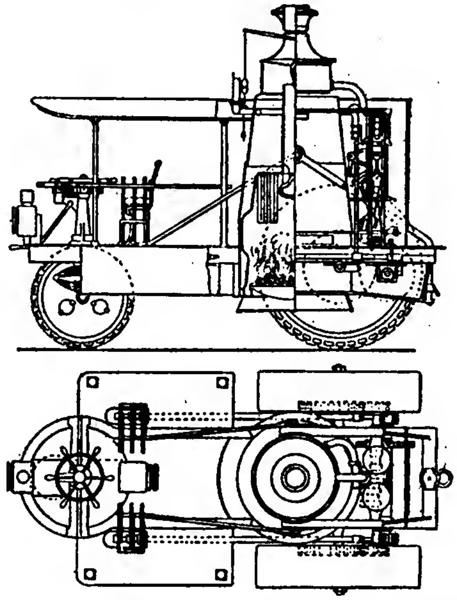

FIG. 15.—Thomson's Road Steamer "Ravee" (1871).

J. W. Bolton, Leonard Todd, and others, for particulars of which I must refer to my Cantor Lectures, already mentioned. In all these, with the exception of Perkins, who used a Perkins' tubular boiler and a pressure of 450 lbs., the boiler was of the heavy, large water space kind. One of the most original of these was that of Mr. Holt made in 1866–7, in which the two driving wheels were independently driven by two little double-cylinder engines, the crank-shafts of which were connected by pitch chain to the driving wheels, the engines running independently, as was partly suggested 42 years previously by James. Mr. Holt used a higher type of boiler than the other designers I have mentioned. It was a fire-engine boiler with Field tubes, and there were several points of mechanical interest in his carriage; the exhaust from the engines passed into a cast-iron box, which formed a baffle-plate at the bottom of the uptake. From this, highly superheated, it issued almost noiselessly, and generally invisibly, from five jets. A similar device for this purpose was used by Mr. Mackenzie in his steam brougham. The Perkins road steamer was a one-wheel steam-horse or tractor, the one wheel being fitted with a Thompson rubber tyre and steel chain-link tyre outside it. The boiler was carried immediately over the driving wheel, which was 25 inches in diameter, and 12 inches wide, and it only occupied a space of 26 inches in height, 15⅝ inches wide, and 20⅜ inches long; on one side of the boiler was carried a water tank, and on the other, a little high-speed engine connected by bevelled gearing to the road wheel. The average steam pressure used in the engine was 250 lbs. during experiments which Perkins made with a light van, which with load weighed 57 cwt. The steam from the engine was passed by a pipe to a condenser with a water tank under the vehicle it hauled, the speed was only three miles an hour, but the system was, of course, applicable to larger powers and higher speeds; the weight of the steam-horse was 32 cwt., so that it only hauled about double its own weight, but if arranged to receive more of the weight of the vehicle hauled, and if carried on two wheels instead of one, this proportion might be considerably improved.

During the period which I have just been dealing with, the traction-engine and the self-moving and agricultural-engine and road locomotive made great strides in the hands of Messrs. Garrett, Aveling, Burrell and Sons, Fowlers, G. and H. McLaren, Ransomes, and others, and there can be no doubt that with the traction-engine and road-locomotive builders rests a good deal of the future of the steam road vehicle for the heavier work. They have, during many years, acquired immensely valuable stores of practical information concerning the design, form, and behaviour of materials as used in road-engines for all kinds of heavy work, and, however much we may in future change the character and reduce the weight of the boilers used, and however much we may increase pressures and engine speeds and decrease engine dimensions, this information, with ability to apply it, will be required. Whatever the other changes made in future may be, the actual net power required to move a ton of vehicle and load will remain the same. There is no doubt, however, that the difference between the work done by the engine and that given off at the periphery of the road wheels will be tremendously lessened, in other words, the efficiency of the transmission between crank shaft and road wheel will have to be enormously increased. The masses of heavy cog-wheels and heavy shafts and large bearings, the one high qualification of which is that they cannot be broken, will have to give place to gearing of much higher efficiency. In some cases chain gear will be in many respects preferable to any other, and in a few cases engines directly coupled to the main shaft will be used. On the other hand, for that road traffic which requires the employment of trains of loaded vehicles only comparatively small modifications or departures from existing road locomotive practice, or from the double chain traction-engine made by Burrell's nearly 30 years ago, will be required. Considering the requirements of high-class traffic on the roads in days to come, and the facilities which the Light Railways Act should afford for that class of heavy traffic which requires trains to carry it, it is questionable whether it will be policy to allow the ordinary roads to be permanently used for it. It is unnecessary here to describe the main features of these traction-engines or their bearing on future motor vehicles, but the value of the experience acquired by their use must not on the one hand be neglected, and on the other must not be allowed to misguide us with regard to what is really necessary as to weight and strength for things which are not heavy traction-engines, with heavy boilers and heavy gear, and the roughest of usage.

Turning now from this digression to the new-born interest of the past three years in motor vehicles, an interest which has been the means of freeing British engineers from legal restrictions which made any development impossible in this country, we come to the era of the light high-speed motors and of vehicles propelled by a motor, which is one of very recent times, *i.e.*, the oil and mineral-spirit motor. Untrammelled by oppressive enactments, our neighbours across the channel have been free to take advantage not only of the development of this motor, but also to experiment with the steam engine for passenger carriage purposes. It remains yet to be seen to what extent this new era motor can be successfully applied to the heavier classes of vehicles, but there can be no doubt of its practical sufficiency for vehicles of the lighter kinds.

Each year since and including 1894 our French neighbours have organised races of mechanical road vehicles propelled by steam, mineral spirit, and electricity, and encouragement was given to makers by the proprietors of the *Petit Journal*, who offered prizes of considerable value for the best and fastest motor vehicles of numerous kinds, including motor-cycles. Races were run in 1894, 1895, and 1896, the race of September last being from Paris to Marseilles and back, a total distance of 1,070 miles. The main features of this race, and the extremely adverse conditions under which a greater part of it was run, are generally very well known, and the fact that 13 vehicles accomplished this race of 1,070 miles, the best of them at an average speed for the whole distance of 16 miles per hour, shows that, notwithstanding the slight repairs which were necessary in some cases, these vehicles have reached a considerable state of efficiency. In this race none of the steam carriages were amongst those which were successful, although in 1894 and 1895 the De Dion and Bouton and the Serpollet carriages were amongst the winners.

Again, in a race last January between Marseilles and Monte Carlo, a distance of 144 miles, the race was won by two of De Dion and Bouton's tractor vehicles, hauling landaus or wagonettes. The road is very hilly, but an average speed of 18·7 miles an hour was maintained during the whole run, which was performed in three sections. There were 37 starters, including nine motor-cycles. Most of the motor-carriages were constructed by MM. Panhard and Levassor, and by MM. Peugeot Frères, and were propelled by mineral-spirit motors. Only half the starters went through the race, the circumstances of which were not favourable to the comparatively small power of the petroleum-spirit motors, although several of these were fitted with more powerful motors—namely, 6 to 7 horse-power —than the makers usually employ. The steam tractors were heavy vehicles, and succeeded because they did not meet with any of the mishaps which had troubled them in 1895 and 1896. Their victory, however, does not necessarily point to the general applicability of the system for carriages, for which minimum weight with maximum seating capacity is the most essential quality. The winning of the race was, moreover, only a question of a quarter of an hour and upwards as against several of the lighter and far more convenient spirit motor-carriages.

Doubt may be expressed with regard to the utility of these races as means of ascertaining the working qualities and durability of any motor-carriages. The use of unusually powerful motors on vehicles of given seat capacity detracts from the value of these races as indications of the sufficiency, in ordinary hands, of carriages with lesser powers; on the other hand, they prove that with the power used high speeds can be maintained under conditions much more severe than those of ordinary running, and that, in fact, machinery and gear which, according to English notions is deficient in strength, has been sufficient to pass through a very heavy ordeal.

It may, therefore, be fairly concluded that for those users who would be satisfied with a lower power than that necessary to maintain a speed of 18·7 miles an hour on a hilly road, smaller motors might very well be employed, especially if a slow or reasonable hill speed were deemed sufficient. It cannot be too often repeated that well-constructed motor-carriages can be driven on good ordinary roads with very small power, and in a general way it is not until the carriages have to be lifted up hill that the demand for considerable power arises. A little consideration will show how much greater this power is than is usually supposed, and how much more advisable it is for many reasons that a moderate hill-climbing speed should be adopted.

A few figures, by way of example, may be given. Taking a vehicle which, when fully loaded, weighs, say, 2½ tons, the power required on a good level road would be about 2·5 horse-power for a speed of eight miles an hour, or of about 3·75 horse-power for a speed of 12 miles an hour. To mount a hill, some parts of which may be on a gradient of 1 in 20, the 2·5 horse-power rises to 10·5 horse-power, but if a speed of three miles per hour were deemed sufficient for climbing the gradient of 1 in 20, only about four horse-power would be required. Now, for dealing with bad roads these quantities ought to be doubled, so that to take 2½ tons of vehicle and load up a gradient of 1 in 20, at the rate of eight miles, would require about 20 horse-power, whereas if a reasonable speed for the hill climbing were adopted only about eight horse-power would be wanted. This, of course, means that some form of speed reducing gear for hills must be employed, but this may be of a simple kind, and it would secure lessened first cost of motor, lessened cost of working, smaller weight, better arrangement, and more room for the machinery, and if a steam motor be employed a lessened weight of boiler and of condenser, and practical possibility of producing a vehicle of moderate weight instead of the prohibitive weight which high speed hill climbing means.

Among the vehicles which first attracted attention in Paris were the steam vehicles of Le Blant, Serpollet, Scotte, Bollée, and De Dion and Bouton. The Serpollet and the Dion and Bouton with, on one occasion, the Scotte, have been most prominently before the public during the recent racing periods. The carriage of M. Serpollet (Fig. 16) is distinguished from all others by the form of instantaneous generator boiler which is known by his name. There is nothing new in the instantaneous generation of steam, but M. Serpollet, as is now very generally known, adopted a peculiar form of tube and numerous devices connected with it, so that the manipulation by the driver of the vehicle becomes very simple. As at first made the tubes were flat and with only a capillary passage in them, but at the present time the tube instead of being flat is crescent form in section, seen at G (Fig. 16), and the passage is from $\frac{1}{16}$ inch to $\frac{3}{16}$ inch in thickness or width, and about 2 inches in length. There is no water space in the boiler, and steam is only generated when the engine is running and driving a pump which sends water into the heated tubes stroke for stroke of the engine. Formerly the tubes, which were placed within a casing over a coke fire of considerable size, were cast into a cast-iron covering, but now the tubes are made of thicker section and the cast-iron covering dispensed with. A hand-pump is employed for injecting by two or three strokes enough water into the boiler tubes for starting the engine, and a by-pass is provided by means of which some of the water pumped by the engine returns from the bottom row or rows of tubes to

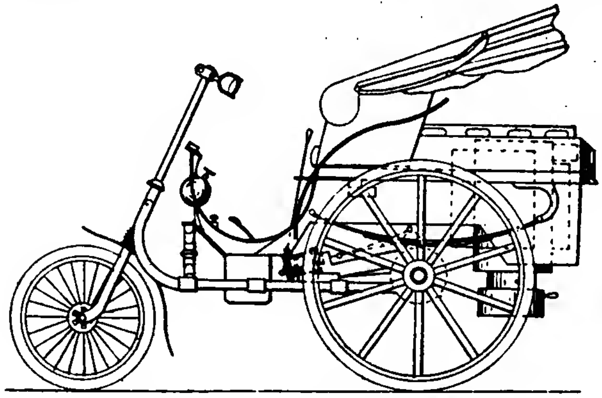

Fig. 17.—Serpollet Steam Carriage (Latest Type).

the feed tank, when the engine has only light work to perform. An advantage of the system is that the user has no concern respecting the water level in the boiler, and experience seems to show that with clean water no trouble arises from incrustation in these very narrow tubes, and this is the experience not only of French users, but of Mr. J. Brown, of Belfast, who has been running one for a considerable time. The occasional high temperature of the tubes with no water or steam in them, and the scouring rush of the steam when formed by the introduction of the small spirts of water, appear to keep these tiny passages open. In a more recent carriage (Fig. 17), which originally appeared in this Journal in January, M. Serpollet has modified his generator to some extent, and is using a petroleum burner (Fig. 18), known as the Longuemar burner. In it ordinary lamp oil is supplied under pressure at *A* to the coil *B*, and after circulating through it passes away as oil gas at *C*, down the pipe *D* into the central chamber of the burner, which is closed by means of a valve on the end of a rod, *E*, actuated by some form of lever *F*. From the central chamber the gas can, when the valve *E* is opened, pass to the burners *G G G*. It also passes to two burners

Fig. 17.—Serpollet Steam Carriage (Latest Type).

Fig. 18.—Longuemar Burner.

at the ends of arms at right angles to the arms carrying the burners *G*, and shown by dotted lines, but as it enters these from the lower chamber below the valve, these burners are not extinguished when the three first mentioned are: thus, when it becomes necessary to stop the engine three-fifths of the power of this powerful burner is shut off, and two-fifths remain to keep the boiler warm and to act as pilot lights for the other burners when full steam is again required, and the lever *F* moves the valve *E*. The position of this burner under the carriage is shown in Fig. 17. In the first-mentioned Serpollet carriage,* shown in section, a coke fire is used, fed automatically by the descent of the coke which is in the bunker between the boiler G and the water tank E, and it will be observed that with large or small fire the tubes were subject to its heat almost as much when the carriage was standing as when it was running. The petroleum burned is thus a great improvement. In the same carriage it will be seen that a small double cylinder horizontal engine was used, the pistons of which were 2½-inch diameter with 2¼-inch stroke, and which were connected to two cranks in the usual way on a crank shaft, which by means of one pinion actuates a second motion shaft by a spur wheel on a hollow shaft, one end of which carries the outer ring of a neat form of spur wheel compensating motion. On the ends of this second motion shaft are pinions having 10 teeth gearing into pitch chains, by which the road wheels are driven. In the newer vehicles (three-wheeled) the engines have inclined cylinders and give motion to the driving wheels by means of spur gearing of about five to one. The pinions on the ends of the crank-shafts gearing direct with wheels on the drivers. In both carriages the steam passes into the space above the top tubes of the boiler, and from it into a downward chimney or escape pipe in a superheated condition, so that it is generally imperceptible. I have said that much concerning the Serpollet system, because whether precisely in accordance with the designs of M. Serpollet or not, there appears to be good reason for belief that the instantaneous steam generator, or an analogous generator, may for the smaller vehicles, at least, be an important element in the future success of steam carriages. Of the engine used by M. Serpollet, it is not necessary to say more.

The Count de Dion and M. Bouton have been very energetic and persevering in their attempts to make a successful steam carriage. At present they have achieved most success with the steam tractor already mentioned in connection with the Monte Carlo and Marseilles race. The boiler used in these tractors is of the water-chamber and tubular class (Fig. 19), with what might be called a central pot. This form was adopted after trials with the form which was illustrated in the author's Cantor Lectures. It consists of a circular water casing, made up of the outer shell and cylindrical fire-box; in the centre of the fire-box space, about a foot from the bars, and extending about 9 inches above the top of the boiler shell, is a central chamber or pot, the upper part of which forms a steam dome. This central chamber and the outer water shell are connected by short, straight, radial, upwardly-inclined tubes in considerable number, the upper rows being superheating tubes. Very good results appear to be obtained by this boiler, but of course its water-level has to be watched as with an ordinary boiler, and when the carriage is stopped the production of steam for a considerable time continues, and much care would have to be exercised in this country to prevent the noisy escape of steam. It is, however, a type of boiler which is of considerable interest, although in all probability the future will lie with more completely tubulous or water-tube boilers. The Dion engine is horizontal, and, with the second motion shaft driven by it, is carried in one frame, the engine being compound with overhanging crank-pins, a main pinion in the centre of the shaft driving the exterior of the differential motion. The slide-valves are worked by eccentrics on a separate shaft driven by pinions, one on each side of the main pinion.

Exceptional lightness for most vehicles will be aimed at, and the steam-engine will have to compete with the oil motor, for in spite of its undisputed advantages, the steam-engine and boiler together are of more weight, and in some cases more trouble, than its mineral-spirit competitor. The very small coil boiler made some years ago by Mr. Blackburn, patented by him in 1877, is said to have had great evaporative power; it was heated by a Bunsen methylated spirit burner, and was, it seems, merely a close coil of tubes about ½ inch diameter or less. It provided steam for a small Brotherhood engine fitted to a three-wheeled dogcart, the subject of his patent, but it does not appear that anything like a severe test to prove its capacity for ordinary road travelling was ever made.

In this country, of recent date, the Thornycroft Steam Van and Wagon Company have made steam vans, in which a Thornycroft water-tube boiler has been employed with a small vertical compound engine. This van (Fig. 20) and its parts I have fully described before,* and it is only necessary to say that for a van capable of carrying a maximum load of one ton, and weighing itself, ready for the road, 30 cwt., the boiler and its casings weigh, I believe, about 9 cwt., and contains 50 square feet of heating surface and 2½ square feet of grate.

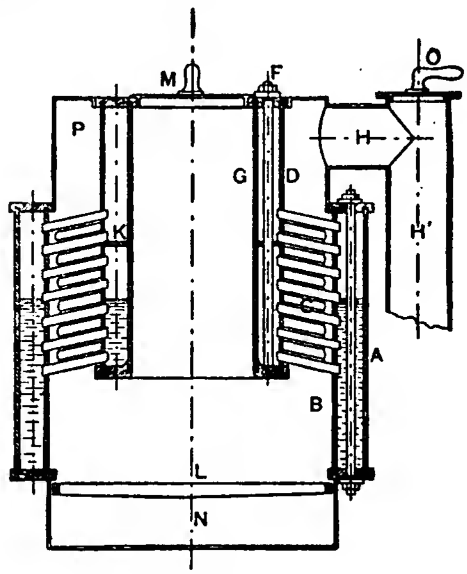

Fig. 19.—Dion Boiler.

Now, the weight of this boiler is at least as much as the weight would be of an oil motor of equal engine power, and this leads me to consider the relative merits of the steam and oil or spirit motors.

With the steam-engine we have greater range and ease of manipulation, within the limits of no power and full power, than with any other motor; for short periods it may be made to give more than its proper maximum, it may be stopped and started with more freedom, certainty, and smoothness than any other motor, with the exception of the electrical; it may be employed for travelling any distances with fuel available everywhere, is easily fitted with reversing gear, and is easily understood.

Now, for long-distance work the only competitor at present with this is the oil or the spirit motor, the disadvantages of which are small range of power within the maximum, no excess of power for short periods, difficulty of starting, and consequent necessity for keeping the engine running when the carriage is stopped for short periods; vibration due to explosive impulse on the piston, and necessity for running the motor at nearly full speed before starting the vehicle, most of the change of speed having to be made by frictional or other gearing. The motor and vehicle cannot be started together, and hence whenever the vehicle is started the motor is called upon to attempt to impart

* *Engineering*, October 18th and 25th, 1895

* For illustration see the December number of The Automotor and Horseless Vehicle Journal, page 90.

to it a speed equal to that proper to the lowest ratio of the speed gear. A frictional gear means loss of power and loss of time in overcoming the inertia of the vehicle, and unless the frictional clutch is connected to the motor through very low speed positive gear, the starting is almost certain to be effected more or less jerkily. To avoid the difficulties attending the use of all variable speed gears in which the gear not in use is running, whether at work or not, the author devised the "antinertia" power gear and clutch, by means of which any driven thing may be put into motion by positive gear at a low speed, and in which the gear for the time being doing the work is the only part in motion.

Having described the disadvantages of the oil or spirit motor, it is necessary to describe their merits as compared with the steam-engine. The first is that the oil-engine requires no steam generator and no condenser. It uses fuel of a high calorific value, easily carried, and no trouble to apply, and it uses it more economically than the same fuel, oil, can be used for the generation of steam. As it needs no apparatus for the generation of the working fluid there is no such apparatus to attend to and no space required by it. Hence the motor and gear can be much more conveniently arranged than the steam-engine. This it is that gives it all its advantages over the steam-engine, even assuming all the little troubles connected with boilers and condensers to be entirely overcome. The motor will, however, weigh a little more than the steam-motor of equal power, running at equal speed, and this may, perhaps, be put at 25 per cent. The weight, moreover, of a boiler and condenser is not all in excess of the oil-motor, for jacket water arrangements and exhaust silencer have to be included. The oil-motor cannot, however, use the cheapest fuel, such as coal or coke, or even crude or the partly-refined petroleums, and this is an objection to it for the larger powers and for vans and vehicles, which must in any case have a paid driver and attendant to whom the work of stoking would be part of his duty. It is, moreover, an objection to oil-engines for such purposes that they in some respects depend upon more delicate adjustment as to air, vapour, and oil supply, admission and ignition, and it is not always that even those well acquainted with oil-engines can say precisely and at once why an oil-motor will not start, or being started will not continue to work. The cause may be one of a dozen things which are not obvious, and which may take a good many minutes to find out. In a corresponding sense, the steam-engine is not at all delicate, and this is an advantage it will probably offer for a considerable time, but with decreasing force as the motors become more definite or fixed in points which are now subject to adjustment and are more generally understood. In the oil-motor, either the main or the supplementary air supplies may be too much or too little, the oil supply may be too much or too little or may stop, the exhaust or the air valve may either of them leak or be made temporarily to leak, by dirt under the seat or part of it, or by corrosion or erosion, and in any of these cases it is difficult to say what is happening. The ignition tube may not be hot enough; this may be seen, or it may be stopped or partly so, which cannot be seen, and this must be guessed, or, like any of the other numerous things, must be diagnosed. To sum the matter up, it may be said that the steam-engine would be in every way the best were it not for its boiler and condenser or escaping steam; and that the oil-motor is best where the boiler and condensor are both inadmissible, and where the vibration it causes and its occasional freaks (which are diminishing in frequency) are not sufficient reasons for rejecting the advantages of motor-carriages.

We are thus led to the conclusion that steam propulsion is mainly a question of steam generator, for, although a condenser is very desirable, the passage of the exhaust steam into the uptake, as was done by Gurney, Hancock, Holt, and Mackenzie, might be considered sufficient means of disposal for many kinds of vehicles. A condenser is not, however, an impossibility, and a combination of the air and evaporative condenser systems will probably lead to the solution of the problem. The construction of a suitable very light generator is not, however, very easy, and it would seem that, in spite of the high efficiency of a boiler made up on Hancock's system, with numerous flat thin chambers with thin passages between them for the heated gases, the weight of the enclosing plates and buck-stays cannot be brought below a minimum which is too great. Other methods of supporting the pressure of the sides of the envelopes might be devised, but increase in the number of joints is undesirable. A generator of the instantaneous kind, although those of Serpollet are heavy, seems to offer itself as the best means at present available. The objection as to want of heat storage is one which would have to be overcome by means of a furnace or other heat supply which can be made to respond rapidly to a call for a maximum quantity of steam for some little time. Heat accumulation in the form of heated water cannot be obtained with this class of generator, and the specific heat of iron being very low, storage by thick or cast-iron coated tubes is a very inefficient addition to weight. The generator question, therefore, resolves itself into one of the construction of a suitable rapidly responsive furnace for ordinary fuel, or of burners for liquid fuel, acting in concert with the steam demand from an instantaneous generator, or one in which the weight of the water-containing space is not materially greater than that of a mere tank for carrying the same quantity of water. With a good condenser even this qualification need not be conceded; but, ignoring the value of pure water, the economic question is one of selection as between (1) the boiler containing a quantity of water, accompanied by a water-tank; (2) the lighter, instantaneous generator with no water contents, and demanding no care as to water level but by a larger water-tank; or (3) an instantaneous generator and a condenser and a water-tank of merely nominal capacity. The weight of the condenser seems to be the determining quantity for this. Such generators as that used by H. S. Maxim for his flying machine suggest another line of development. This boiler* contained a very large number of thin $\frac{3}{8}$ copper tubes connected to larger trunk tubes, none of them containing much water, and a steam receiver of small diameter. Most of the tubes were only $\frac{1}{50}$-inch thick, and with four of these in a white-hot furnace Maxim found he could evaporate $26\frac{1}{2}$ lbs. of water per hour per square foot of surface. His boiler was heated by gasified naphtha, and contained 800 feet of heating surface, and weighed 1,000 lbs. with feed heater. Inventions and patents for light steam generators are numerous enough, but none are yet, or not more than one or two are being used, even experimentally.

I have said nothing as to the smell of the oil or spirit motor—firstly, because it is not or need not be really serious, it is only a different stink from that or those to which we are accustomed, either with horses or steam-engines, and will be lessened by experience.

With regard to the vibration caused by them I think there is little doubt that this will soon be overcome. The piston and connecting rod of an oil-motor and cylinder are like a shot in a gun, action and reaction being only equalised by different amounts of imparted motion or of inertia of different masses overcome at different velocities. A vertical motor operated by explosions at irregular intervals, and mounted on a springy base is not likely to stand very steady, and as few motors are properly balanced the occasional explosion merely aggravates a vibratory movement of smaller range set up by the continuous rotation of unbalanced parts. The difficulty is one which should be surmountable, but there is no doubt it is less a difficulty with the horizontal engine and for obvious reasons.

It is unnecessary that I should again describe either the French spirit motor-carriages of the leading makers, or those of Benz, of Mannheim, or of Lutzmann. They are represented in this country by the Great Horseless Carriage Company, London and Coventry; by the Anglo-French Motor-Carriage Company, Birmingham; by Arnold's Motor-Carriage Company, East Peckham; by Julius Harvey and Company, 11, Queen Victoria Street; by Mr. J. A. Koosens, Southsea; and many of them were illustrated in the Cantor Lectures previously referred to, and in the paper by me read before the Society of Arts in November last.

I may, however, by means of a few views on the screen,

* *Journal of the Society of Arts*, November 30th, 1894.

recall some of them to your memory, including those above mentioned and some of those of English make. All these Continental vehicles, with the exception of the Serpollet and the Dion, are propelled by mineral-spirit motors, several of them by the Daimler motor, which is the only one with which no carburetter is employed. It is a vertical of simple design and works exceedingly well. Ignition is effected by heated ignition tubes. Several of the foreign makers, including the Lutzmann, the Benz, the Delahaye, and others, are propelled by horizontal motors, and ignition is effected by electric sparks. No noteworthy improvements have been made in recent months. The gearing used by the best-known makers, such as MM. Panhard and Levassor (Fig. 21), remains much the same as when described at the end of 1895. It usually consists of

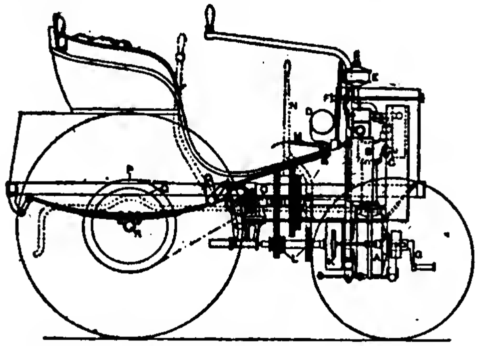

Fig. 21.—Panhard and Levassor's Daimler Motor-Carriage (1894).

three or four pairs of spur-wheels of different sizes on the engine shaft, driving by one or other of three or four corresponding wheels, a second motion shaft which gives mo ion to the driving wheels by chains or by belts. It has two cylinders, set at an angle of about 15°, and coupled to a crank partly formed by a pair of fly-wheel discs. This motor is entirely enclosed in a box, which also contains the carburetter, B, and an exhaust box, C. The reservoir for carrying the benzoline is seen at D. At E is the regulator for controlling the supply of benzoline to burners for heating the ignition tubes. At H is a small centrifugal pump driven by a belt on the pulley, J, for circulating the water round the cylinder jackets. Gearing

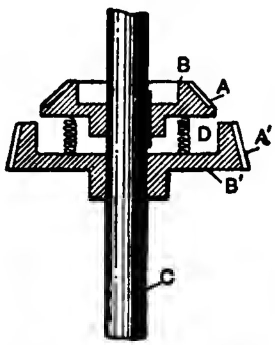

Fig. 22.—Panhard and Levassor's Friction Clutch.

is arranged for three different speeds, the cog-wheels, L, being made of gun-metal, and movable, so that they may either of them be made to engage with the three wheels above them, they are made tight or loose upon the crank-shaft by means of friction clutches at K. The intermediate shaft driven by this gear conveys motion by another intermediate shaft, placed transversely across the carriage, and carrying a pair of pitch chain pinions which drive the road wheels by a pitch chain on sprocket wheels attached to their spokes. A differential or compensating motion is fitted to the transverse intermediate shaft. To alter the speed while the engine is running, the pedal, M, is depressed, and the gearing then brought to rest by means of the lever, N. The change in the position of the gear wheels is then made, the cogs all being rounded at their corners to enable them to find their way into the corresponding teeth of the upper wheels.

A pulley, Q, is placed upon the driving wheels, and used for carrying a brake instead of putting a brake on the tyres of the road wheels.

The clutch already referred to is shown by Fig. 22. The shaft, C, is the crank-shaft, upon which is fixed the coned disc, B. In front of this and sliding upon a feather is another friction cone, the face of which has a greater angle. When the containing or interior cone disc which encircles these is pushed against these inner cones, the smaller one retires into the larger one against the resistance of the springs, D, and when the frictional contact due to the resistance is reached, the further frictional contact and more powerful grip of the disc, B', is obtained, the object being, as far as frictional cone clutches makes it possible, to put the carriage gradually into motion; the faces of the cones B and B' are coated with leather at A and A'.

Most of the makers who use gear transmission between the engine and second motion shaft employ the three or four speeds, but those who use belts avail themselves of the slip of the belts more or less controlled to vary speed between the two which are mostly used. Belts are not, however, to be commended for vehicles, because the belts must be short, some must be crossed, and all of them may often have to run in bad, wet weather. For light work the shortness of the belts when on pulleys of no great difference in size may not make great tightness necessary, but for variable work the objections to tightness can only be escaped by using jockey pulleys. In some cases where these are used the belt which for the time being is doing no work is nevertheless running idle on one of the pulleys, or loose on both, and this is objectionable. The use of belts as friction brakes, or in place of better variable speed arrangements, is also objectionable, even if for no other reason than that it polishes the pulleys and makes greater tightness, necessary for a given amount of frictional adhesion. We can only say of it that it is not a bad makeshift.

In Great Britain there are now numerous manufacturers who are making or preparing to make oil or spirit motor vehicles, but for the next two or three months it does not seem that we shall see their vehicles on the road. Some of these makers use the Daimler motor, the construction of the main features of which is so well known as to need no description here.* Mineral spirit is used for its operation.

Several makers will use what is known as the Pennington motor, which is a small light high-speed mineral-spirit motor, the cylinders of which are made of thin steel tubes, as used by Mr. Hiram S. Maxim in his steam-engines for his aerial machine, and from which Maxim got over 360 horse-power† from engines which he could support on his lap, weighing 640 lbs., or less than 1·8 lbs. per horse-power actual. The pressure used was 325 lbs. Mr. Maxim is now at work, not only on a gas-engine which will run fast or slow like a steam-engine, and reverse, but on a light steam-engine and boiler or generator of high capacity, a 12 horse-power generator being only 9 inches thick, and in the shape of a book.

American inventors are at work on the subject, and the Duryea carriage, fitted with the Duryea mineral-spirit motor,‡ is running in this country, and is in the hands of Messrs. Maberley and Thrupp, of Oxford Street, London. Compressed air is much favoured in America, but less progress seems to be made in the United States than in this country.

Messrs. Petter, Hill, and Boll, Yeovil, are also making motor-carriages run with Petter's mineral-spirit motors.§

Messrs. Atkinson, Phillipson, and Toward have made a steam carriage, a photograph of which appeared in the last issue of

§ *Society of Arts Journal*, November 27th, 1896, and Automotor and Horseless Vehicle Journal, December, 1896. Paper by the author.

THE AUTOMOTOR AND HORSELESS VEHICLE JOURNAL, which has reached the stage of experimenting on the road, and with promising results.

As far as I am aware, the only motor-carriage which is at present being propelled with a motor using ordinary lamp oil, is that made by Messrs. Roots and Venables, of the Westminster Bridge Road, the motor being a horizontal one on the Roots system. I have fully described this motor-carriage recently,* but I may here mention that the motor is constructed on the vaporised system without any spray-making apparatus,† and is fitted with a governor which controls by acting both on the oil feed and on the exhaust, so that the objectionable smell resulting from the exhaust of imperfect combustion is avoided.

There appears to be a general opinion in England that the use of mineral spirit is likely to be attended with more risk of accidental ignition and explosion than ordinary lamp petroleum. There is no doubt that more care is necessary, but very little more. Very few accidents have happened with motor-carriages as a result of the use of the mineral spirit, while lamp accidents with ordinary lamp oils happen every day and often with fatal results. The extra care required in handling mineral spirit is, however, attended with much greater simplicity in the construction of a motor worked by it, and some minutes less time are required in starting than when the heavier oil is used. Hence the fact that all the Continental and American so-called oil-motors use mineral spirit. In contrast with the well-made economical English oil-engine, with good governing arrangements, any tin toy maker could make a spirit motor which would work, though a great deal of ability and ingenuity has been expended in producing a really useful spirit motor for carriage work. There is still much remaining to be done, not only with reference to complete combustion under the varying loads, and more or less frequent stoppages of motor-car work, but particularly in the construction of an oil or spirit-motor, which in daily ordinary use will work well throughout a considerable range of power, from light load to its maximum. There is also a great field for the inventor of a satisfactory self-starting oil or spirit motor. We seem to be some distance from it at present, but it is not impossible that the combination of a self-starter and existing engine might produce a motor which would start by turning on the oil or vapour supply and igniter, and thus avoid the necessity for keeping the motor running while the carriage stands during short stops.

Concerning electrically-propelled vehicles, there is still not much that can be said with respect to those intended for more than the short runs in towns. The electrical motor possesses all the attributes of a perfect motor for any power within its maximum when used with suitable speed-gear to get over the difficulty of starting the vehicle and climbing steep hills. The one practical difficulty is the great weight of the accumulators required for a few horse-power for a few hours. At present there is no good battery which weighs less than about 500 lbs. per horse-power hour, and this weight far exceeds that of the whole motor machinery required for an oil or spirit motor-car.

Compressed air for motor purposes is again occupying attention. In this connection it would do little good to base any calculations on the foot lbs. of work represented by the expansion of a given quantity of air at a given pressure down to atmospheric pressure, the losses being numerous, variable, and considerable. We can best arrive at an estimate of the comparative cost of compressed air for the purpose by two different methods from practical experiments with engines worked by compressed air. At the well-known air compressing establishments of M. Victor Popp, of Paris, engines have been run on the brake with compressed air. At a pressure of 80 lbs., and with the air raised to a temperature of 300° F., as it might be on motor-cars, a 70 horse-power engine consumed an average of 34 lbs., and a smaller engine giving two horse-power on the brake consumed 55 lbs of air per brake horse-power. Now, if we take 50 lbs. of air and allow one-fifth for the air which must be left in the receivers, and make the usual estimate of ten times the weight of the air as the weight of receivers, we get a weight of 600 lbs. per horse-power hour actual. One horse-power is, however, of very little use for a vehicle to carry, say, four persons, and we must reckon upon two horse-power actual at least as the mean power required on most roads, and giving the compressed air the benefit of any advantage that may arise from a lessened draught on particularly good roads it will be seen that at least 1,000 lbs. weight of air and receivers will be required, and this 1,000 lbs. weight will itself require another horse-power to move it; so that for a stage of, say, 10 miles between charging stations the total weight of air and receivers at pressures which it would be advisable to use would be considerably more than half the weight of vehicle and load.

As another method of arriving at some estimate of the value of compressed air for the purpose, we may take the cost of air compression on a large scale in Paris, but allow 20*s.* per ton as the cost of steam coal instead of 25*s.* per ton, the cost in Paris. As the result of a year's working it was found that the coal consumption to compress air to 120 lbs. per square inch reached 1 lb. for every 13·8 lbs. of air. At 20*s.* per ton this costs 0·017*d.*, so that, taking 60 lbs. of air as being required for small motors per horse-power hour, it will be seen that we get, as the actual cost of coal alone for compressing, 0·465*d.* per horse-power hour. The numerous other charges in a compressing establishment will easily run this up to considerably over 1*d.* without any charge for distribution. It is thus pretty clear that compressed air is out of the running except for very short town service, but it is quite possible that it may be cheaper and less troublesome to deal with than the secondary batteries of electrical motor-cars.

Comparing this with compressed gas for motor-car use, we see how great is the advantage attending its use. Instead of requiring receivers for 60 lbs. of air per horse-power hour, and a capacity of say 50 to 70 cubic feet according to pressure adopted, we should only require receivers for about 1 lb. of gas per horse-power hour, but with receivers weighing rather more than those for air. Instead of being limited as in the case of air to short stages of say eight miles, long stages of say 50 to 70 miles could be run, and the two horse-power previously referred to could be used throughout the whole of this distance. If the good roads mentioned with respect to the air-motor were met with the distance would, of course, have been correspondingly increased. Thus by using compressed gas instead of air we may have from 50 to 100 per cent. more power, and from six to seven times the number of hours stored in the same space. The one disadvantage of the gas-motor as compared with the air is the difficulty of starting it, and as at present made, the necessity of keeping it running light while the vehicle makes short stops. There is, however, little objection to this in the case of tradesmen's vans and many other vehicles, and it does not cause any trouble with the gas-driven tramcars as used so successfully and economically on the Blackpool, Lytham, and St. Anne's Tramway on the Gas Traction Company's system, and as equally successfully at work on the Dessau and other Dresden Tramways. The system has the advantage that the motor can get its working fluid in almost every town and every village of any size, and the motor vehicle could be provided with a pump by which it could fill its own receivers while the users go to lunch or dinner.

During this year there are to be numerous public exhibitions and trials of motor vehicles of various kinds, commencing with the exhibition at the Royal Aquarium in May, and including the trials of the Royal Agricultural Society at Manchester, those which presumably will be made for the competitive prizes offered by the proprietors of *The Engineer* and by the British Motor Syndicate. The conditions of competition for the Royal and for *The Engineer* prizes have been widely published, and the latter include runs of not less than 200 miles, as well as the preliminary trials, but routes and arrangements for the long runs have not yet been made known.

Disappointment is often expressed at the non-appearance of British-made motor vehicles at present, and in this connection it must be remembered that it was not until November last that British makers were permitted to run their vehicles,

U

* *Society of Arts Journal*, November 27th, 1896, and AUTOMOTOR AND HORSELESS VEHICLE JOURNAL, December, 1896. Paper by the author.

† *See* the author's articles on "Oil-Engines," in *The Engineer*, June and July, 1894.

even for trial purposes, on our roads. Until the Act was actually passed last August, engineers and manufacturers would not turn their serious attention to the construction of vehicles and motors, the use of which Parliament might, after all, not sanction. Now that they are free to make and try their vehicles, they have to start in quite a new industry, and even those who propose to manufacture vehicles very much on Continental lines have to get their factories and plant built in order to manufacture on a paying scale. Many makers have been misled by unqualified irresponsible condemnation of Continental vehicles to attempt to start on radically different lines, instead of devoting their attention to such modifications as would remove substantial defects, and this will cause much waste of time, for the French vehicle makers have accomplished a great deal which should not be ignored. In England many are prone to reject a thing as a failure which is not a success, and to deny themselves the advantages of a partial success or a good makeshift. In America this is much less the case. There the tendency is to use whatever at the time is best, if it secures any advance, until something which is better is achieved, and this policy often leads to rapid development.

As compared with the men of 60 years ago, we have advantages which in many respects are of the greatest importance, and which ought to enable us to accomplish with ease and certainty that which they left unfinished. In particular, we have the advantage of the materials and tools which make it possible to run engines continuously at three times the number of revolutions they could use, and at double the piston-speed. We have, moreover, materials at our disposal which enable us to reduce the weight of our motor machinery by probably 70 per cent. as compared with theirs. We have steel sheet tubes of all sizes and splendid quality, steel castings, drop forgings, and many other such things; we have ball bearings and rubber tyres, and we have aluminium alloys, which place in our hands materials for motor parts and frames, water and oil tubes, connecting pieces, and many other things of half the weight of anything then or at present made of either cast iron, bronze, or gun-metal. Aluminium alloys for castings are now made of specific gravity very slightly over 3·0 and therefore of considerably less than half that of cast iron, and of much higher strength. Tests made at the Durham College of Science, Newcastle, of aluminium alloy castings from Mills's Atlas Works, Sunderland, of 3·05 specific gravity, have given a tensile strength of as much as 20 tons per square inch with an elongation of 1·25 per cent., and another alloy used for castings of bed-plates and standards for engines and dynamos, brackets, gear-wheels, and other parts, has a tensile strength of 15 tons per square inch, and with a specific gravity of only 2·98. The immense advantages such a material offers in the construction of motor-carriages and motor-cycles will be readily seen, and should help to remove considerable difficulties.

"THE ENGINEER" HORSELESS CARRIAGE COMPETITION.

The entries for this competition finally closed on the 31st ultimo, and we trust that no intending competitor neglected the chance of being able to secure one of the prizes by being a day too late. For many reasons the decision of the proprietors of *The Engineer* not to publish the list of entries until the date fixed for delivery of the vehicles at the Crystal Palace is an excellent one. In the meantime, it is interesting to note that the number of entries received is 71, distributed as follows:—In Class A 25 entries, in Class B 21, in Class C 15, in Class D 2, and in the "Supplemental" Class 8.

NOTES OF THE MONTH.

Birmingham just now is so full of orders for cycles, &c., that it is difficult to place any new business at all. Several firms, however, are finding time to push on in the motor-car line, and we think those who are getting well forward in this branch of engineering will find themselves shortly in a position to double and treble their connection, as any good work in this line turned out quickly will ensure repeat orders from a large number of dealers all over the country who are anxious to be supplied with motor-carriages. Amongst others we may mention Accles (Limited), who are putting forth every effort to get out the first delivery of a thousand De Dion tricycles. These are being built on an entirely new pattern, and are at the order of the British Motor Syndicate. We believe that the first complete machine will be shortly ready, probably about the same time as the publication of this month's issue of the Automotor Journal, and we hope in the next number to give a photograph of some of this firm's excellent work. We noticed upon a recent visit to their premises that very extensive enlargement is going on, which to a very great extent will be utilised for building motor-cars. Mr. G. Accles is personally much interested in the new industry, and he already has on the way from America a special motor-vehicle of his own, in the advantages of which we understand he has the very greatest confidence.

The Wolseley Sheep-Shearing and Machine Company, of Alma Street, Birmingham, are also determined to be in the front rank for motor-car building, and so as to be able to meet the likely demand upon their establishment, are erecting a new building especially for this purpose. We also hear of a new motor which is likely to be exploited shortly by Messrs. Wilkinson and Son, of Birmingham.

We give herewith a brief description of a horseless fire engine. It is the invention of Mr. Reuben Plass, of 508, Lafayette Avenue, Brooklyn. On either side of the machine is a footboard, while on the body are arranged the ladders and hooks, at the back of which sits the person in charge of the steering gear. Above the front axle and directly beneath the driver's seat is placed the gas-engine, from which the power is transmitted by a series of cog wheels. These are directly in front of the engine and just below the footboard of the driver's seat. Through the footboard extend two levers a little higher than the driver's seat. By one of these the speed of the engine is controlled, and the other is used in steering the machine and as a brake. By drawing the left-hand lever toward himself the driver puts the machine in motion. On the lever is a set of cogs which, when the former is pulled, act upon another set of cogs directly connected with the engine. In order to stop the machine it is not necessary to stop the engine. Pressure on one of the levers throws the cogs out of gear, and the other lever controls the compressed-air brakes, by which the machine is stopped. The engine can also be reversed by another set of cogs. As the motive power is always under control, it can be used successfully in elevating an extension ladder, which is a great advantage in that much time can be saved over the ordinary method.

Evidently Mr. William Georgeson, ex-technical teacher in coachbuilding in Gordon's College, Aberdeen, is a strong advocate of coachbuilders working in harmony with engineers to produce perfect motor-vehicles. This gentleman recently lectured before the members of the Aberdeen Coachmakers' Mutual Improvement Association in Silver Street Hall, on "The Rise and Progress of Carriage Building," Mr. James Clark presiding. In the course of his remarks, he said that motor-cars were not such a recent invention as many people imagined, motors being used in London in 1781. A steam omnibus capable of going from 10 to 15 miles an hour was in use in the metropolis in 1833, and plied between the Bank and Paddington, the fare being 6*d*. With the introduction of the electric motors of the present day, coachmakers, he maintained, would have to prepare themselves for the new innovation in locomotion. It was possible that motor-carriages would to a certain extent solve the problem of agricultural depression, as they could go long distances and collect cottage and farm produce very expeditiously, and bring it to centres of distribution.

To a physician in Youngstown, Ohio, is due the distinction of being the first medical man in the United States to make use of a motor-carriage for the purpose of working his practice. Dr. Carlos Booth terms his vehicle a motor-cab, has used it for several months, finds it an excellent substitute for one drawn by a horse, and prefers it in most respects to that animal as a motive power. In this carriage Dr. Booth has attained a speed on the level of 10 miles per hour, and climbed an incline of from 10 to 15 per cent. grade at the rate of 5 miles per hour.

Motor-carriages should prove especially useful to the general practitioner in Great Britain, and particularly to the country one, on whose shoulders the burden of maintaining the two or three horses, with their attendant expenses, necessary for a large and scattered practice falls very heavily. The initial cost is the worst part, but, on the other hand, the cost of working horseless carriages is small, and the country roads of England, unlike those of America, are peculiarly well adapted to their use. Cripples, paralytics, and those who retain the use of their arms but have no control over their lower limbs should also find these vehicles of the greatest service; they would not only be able to travel by means of them without assistance, but also be able to amuse themselves with corresponding benefit to their health.

As a result of the recent report of the Aberdeen Parks and Links Committee Mr. John T. Clark, the well-known carriage builder of Aberdeen, is working two experimental vehicles propelled by electric motors. He is also engaged in constructing, for private owners, a vehicle to seat six persons, in which Mitchell's Electric Motors will be employed.

Application has been made to the Watch Committee of the Brighton Town Council for permission to run an electric char-a-banc from Brighton to places of interest in the surrounding districts. The committee have resolved that they will be willing to grant licenses for electric motor char-a-bancs after each vehicle has been inspected and approved by the committee.

The lock-out in the engineering trade has necessarily been a further check to the development of the Johnston-Arrol oil motor. Since the blow it received from Glasgow's municipal dignitaries little has been heard of its progress, but we understand that the working drawings of the motor have been completed, and the patterns are on the point of being put in hand. But as Messrs. Arrol, the engineers, and Messrs. Fullarton, Hodgart, and Barclay, the founders, are members of the Engineering Employers' Federation, it is feared the motor needs must wait until things in the engineering industry have resumed their normal condition.

It is to be hoped that by the time the Paris Exhibition of 1900 is open, a goodly show will be made in the British section of English-made motor-cars. At present the majority to be seen in England are of Continental manufacture, but we think there is little doubt that long before the Exhibition the tables will have been turned and the leading makes will be from the works of British engineers.

In Belgium the manufacture of motor-vehicles is increasing rapidly. A number of well-known firms are already putting down special plant for this purpose, the movement for the moment being centred at Brussels and Malines.

In Ireland they are not slow to press any new idea into service for coercive purposes; and the motor-car has not had to wait long before finding its place. At a meeting held a few days back in Belfast regarding a direct tramcar service from York Street to Antrim Road, the conveners, who included several of the leading Belfast citizens, were determined that the Corporation should provide them with what they demanded, or they would start an opposition service of motor-cars to the tramcars. Mr. James Hogg, in reading the circular convening the meeting, said: "It is not our intention to promote a rival carrying company to the tramway, provided our requirements are granted, but in view of the unsatisfactory replies referred to, we have put ourselves in communication with the Motor-Car Company, and have obtained prices for suitable cars, and are promised a trial on most favourable conditions. But before going further in this direction we think it only right that the representatives for our ward should have an expression of opinion from the ratepayers, so that they may do what in them lies to endeavour to secure for us what is admittedly a long-felt grievance." There was, he (Mr. Hogg) urged, great necessity for the tram service, and he said the principal ratepayers in the ward were prepared to adopt the motor-car system if they did not get the tram service. For the running of the motor-cars a company would be formed, and it was intended to run those cars from Chichester Park to Messrs. Robinson and Cleaver's and to the Northern Counties Railway terminus. Mr. John M'Cormick thought the only practical suggestion was the formation of a Company for running the motor-cars. That Company would be a great benefit not only to that district but to the city, and it would let Mr. Nance see that they were not dependent on the Tramway Company, which had abused the power given to it. Ultimately, before starting motor-cars, it was resolved to send a deputation to the Corporation giving them the alternative of motor-cars or a direct service as desired.

The following personal experience of a motor-car by the special correspondent of the *Weekly Sun* is interesting. Writing from Paris, the correspondent, who is presumably one of the fair sex, says:—"I have had my heart's desire—a drive on a motor-car. Mrs. Crawford, of the *Daily News*, said, 'If the weather is good we will come for you at half-past two o'clock.' It has been a long time since my anxiety was so keen for a fine day. And great was my relief when Marie opened the blinds the next morning, and the sunlight streamed in. The air was absolutely intoxicating in its freshness, the sun as warm as in May. Promptly at the hour my hostess appeared, and after a few minutes of a rather trying, trembling condition, we started bravely off. So far, the motor-car has the right of way—mothers and nurses gathered up their children and rushed for the pavement; tramcars and omnibuses stood still to allow our trundling by; carriages and cabs fairly fled from our rumbling approach.

"The horses in Paris are now somewhat accustomed to the car, but a few were made unhappy by it. But we soon left them in the rear, as our car was almost twice as quick as horse locomotion. After we started, the odour of oil was not perceptible, and the motion was easy and smooth. Being able to go, however, at a very smart pace, and knowing there were no fagged animals to consider, was a comfort. It seemed but a moment after leaving Paris that we passed Buzenval, the place where the French made their last sortie during the Franco-Prussian War. It looked peaceful and happy with its fields of short new grass. La Manche, the racecourse, is beautifully kept. A few horses were being exercised there. We were so quick that I scarcely caught a glimpse of Vaucresson, where a number of pretty new villas are going up.

"When we reached Versailles, which I thought never looked more picturesque nor full of colour than with the brilliant spring sunshine striking down upon it, we had not the inconvenience of waiting for the horses to rest, and, as one of our party was hurried, we at once turned our fore-shortened carriage, and whistled along at great speed back to Paris. And, what with the perfection of the day, the rapid motion, and Mrs. Crawford's brilliant descriptions of the East, where she has been lately travelling, it was but a moment from Versailles to the Avenue de l'Opéra. Everything went well, from the start to the finish, and I can only speak of the motor-car as one hears one woman apologetically speak of another who has the reputation of being disagreeable, 'She was very nice to me.' And so with the motor-car—he was very nice to me."

An amusing but realistic sketch of a journey by diligence in Spain appeared in the *Daily Mail* a short time back. The writer in describing it as the laziest travelling in Europe, says that "even in these progressive days of electric railways and motor-cars there are to be found people conservative enough to affect a yearning for the return of what they are pleased to call 'the good old coaching days.' In the most acute cases a radical cure might be effected by a night journey in one of the old-fashioned diligences which to this day form the chief means of communication between the lesser towns and villages of Spain. The diligence is a lumbering vehicle that bears a far-away resemblance to a London 'bus, to which has been added a railway coupé and the platform of a tram, whilst its speed may be compared to that of a hearse." The rest of the article describes graphically the many discomforts experienced through a night journey, and may well bring home to sceptics the advantages in store for mankind from the advent of the motor-car.

The Nuneaton Urban Council intends to get as much value as possible for the ratepayors' money. At a recent meeting the question of purchasing horses, and the Council carrying on its own haulage instead of contracting for it, was considered, and in the course of the discussion Mr. J. F. Johnson thought the Council should consider whether they might not effect a great saving by having motor-traction carts, which were being made, and which would do away with the keeping of horses. The question was referred back to the committee, the clerk being instructed to write to the Local Government Board asking if it would allow the Council to obtain a loan for the purchase of either horses or motor-cars.

The Automobile Club of France has now nearly 1,000 members, which number embraces 139 owners of motor-vehicles. The list of members is of a very cosmopolitan order, and we notice that amongst some of the more recent elections are Mr. Radcliffe Ward, Sir Edward Blount, Mr. Thomas Myring, and Mr. William Ingersoll. The present premises of the club now being too small for its increasing membership, additional buildings have been secured in the Bois de Boulogne.

Mr. Ernest M. Bowden, writing in a contemporary, in suggesting that in the course of another month or two the Local Government Board authorities will have to consider the question whether any change shall be made in regard to the speed that is legally permitted, for the limit (or rather limits, since they vary with different classes of vehicle) were imposed, to commence with, for a period of six months from November 14th, hopes the authorities will see fit to raise the limits of speed above what they are at present, for although it is all very well for irresponsible drivers to disregard the law on unfrequented roads, it is much better that the law should not attempt to restrict freedom any more than is necessary. We hardly agree with his statement that the limits for the heavier vehicles are a serious difficulty in the way of successfully introducing motor-omnibus traffic. Of course, nothing short of an Act of Parliament can legalise a higher speed than 14 miles an hour, but the limit for the lighter vehicles might very well be brought up to this speed.

Mr. Bowden, speaking as a leading authority upon cycling matters, truly says that it seems to be forgotten by many people that no attempt is made to impose a hard and fast limit on such machines as triplets and quads and quints, which are capable of developing tremendous speed, and are by no means as manageable as a well-designed motor-car. Yet we do not find that these machines are a formidable danger to the public, for the simple reason that riders are not usually such idiots as to get up a high speed unless the road is seen to be clear.

Messrs. G. Kynoch and Co. have during the last month incorporated themselves under the Limited Liability Act with a capital of half a million sterling, a significant feature of the articles of the new Company being the power which they take to build motor-cars. Their extensive premises at Witton, Birmingham, are particularly adaptable for this business, and the recognition of motor-cars as an accomplished fact by this eminent firm should turn the scale with any firms who are wavering as to the wiseness of embarking in the new industry.

A remarkable article appears in the *English Illustrated Magazine*, in which Mr. G. P. Lathrop has thrown into the form of a story the notes which he made of suggestions and hints received from Mr. Edison as to inventions and changed conditions which may possibly be accomplished in the future. For narrative purposes Mr. Lathrop gives particulars of a Society of Futurity whose members have discovered the secret of preserving life in a state of suspended animation. The hero is chloroformed and is subjected to an elaborate process, whereby he becomes inanimate, and at the end of 300 years is restored to existence at the exact point he had quitted it when chloroformed. Amongst the many wonderful things he finds (which are supposed to represent Mr. Edison's views of the future) the great features are electric motors and air ships. Mars can be reached in eight hours, trams travel at 150 miles an hour, and special paths are available for electric bicycles, tricycles, and carriages, with power supplied from stations at regular intervals, and at all hotels. Horses are but little used for travel, and exist mainly as a form of preserved life, like deer in parks, or for racing purposes, although, even in racing, their speed is so greatly surpassed by that of flotation, sails, and rubber-oared boats, and various mechanical four-legged machines for running, that they are not much more than domestic pets, like cats and dogs. A motor "walking balloon" is described and a marvellously ingenious motor-driven "air ship" is minutely worked out. The article is an extremely interesting feature of Messrs. Macmillan's magazine, and conveys the impression that Edison is distinctly in favour of motor-vehicles as the coming form of locomotion.

With a view to meeting certain defects in the existing Patent Laws of America, the United States Congress has recently passed a Patent Law Amendment Act, which is not without importance to English inventors. This new Act will come into force after January 1st, 1898. In the present state of the law, if an invention is patented in America, subsequently to its being patented in other countries, the American patent becomes void on the first date that a corresponding foreign patent expires, no matter for how short a time it may up to then have run. As not infrequently a very long period elapses in America between the application for, and granting of, a patent, it is evident that a patent might actually be rendered void before it was granted, by the expiration of a corresponding foreign patent. At the same time it will be observed that a patentee might insist upon payment of royalties in respect of the use of an invention patented in some other country, although, perhaps, for many years well known in the United States, or might even restrain its use immediately after the grant of an American patent for it.

To remove these defects, from the beginning of next year it will be a law that a valid patent cannot be granted in the United States for an invention which has been published in any way in that country two years prior to the American application. And also that no patent can be granted for an invention that has originally been patented in a foreign country after seven months from the date of application for the earliest foreign patent, but that if application be made within the prescribed time, the patent shall be granted for the full term of 17 years.

These enactments will, of course, not apply to patents granted before January, 1898, nor to applications filed prior to that date or to patents granted on such applications. It follows from these amendments that to obtain a United States patent it will be necessary to file the application within the present year for foreign patents applied for before the 1st of June of this year, or for inventions which have been made public in the United States prior to January 1st, 1896. The new measure also provides for a six years' period of limitation in actions for infringement of patents.

The accompanying sketch is the latest idea for a horseless carriage emanating from America. It has been built on the lines of patents secured by Gotthold Langer, of St. Louis, Mo., and is an odd-looking contrivance, but it is claimed for it that it is the only practicable automobile vehicle that has yet been invented, inasmuch as it is superior to irregular road conditions, and is not limited in its usefulness to boulevards or perfected pavements, and is the only motor-carriage designed for pneumatic tyres. These are to be of special construction, and will be made self-inflating by means of an automatic pump connection with the motor—a principle, it is stated, that has recently been utilised in the construction of an English bicycle. The entrances to the carriage are on either side, through the centre of the main wheels, which are of a maximum diameter of 8 feet. The inner wheel or rim, which is a wheel within a wheel, furnishes the bearings for the body of the vehicle. The motor, which may be of steam, gasoline, or electric power, is stored beneath the driver's box and is geared to two drive wheels, which revolve in the inner rim of the large wheels in front of the centre. The motor is double geared, so that the power can be applied by the driver or motorman to both wheels simultaneously, or to either wheel alternately, or in steering the carriage, the front supporting wheel being pivoted to the under forepart of the wagon in front of the centre. The front wheels are the rudder and the large driving wheels are operated like the paddle-wheels of a side-wheel steamer. There is at present a big outcry for a new design for horseless carriages. This "latest" may fairly claim to "fill the bill" just to go on with.

No wonder the untravelled Yankee thinks the Britisher a "krank" when he reads the trash served up to him by papers which have the reputation of being at the head of American journalism. We have before us an article in a leading Pittsburg paper seriously dealing with the English Motor-Car Club and its doings, in a way to bring ridicule upon all concerned. The article is headed with a sketch showing a bevy of frivolous-looking girls taking an airing upon what appears to be a Pennington motor-carriage, the legend under the picture being:—

"Feminine Members of the London Motor-Car Club ont for a Spin. (Drawn from a Photograph.)"

The article deals freely with the doings of the Motor-Car Club, bnt we hardly think the statements of fact (!) therein put forth are likely to be either corroborated or relished by Mr. Harrington Moore, the Honorary Secretary of the Clnb. Such articles are not calculated to add to the dignity of anybody concerned.

Councillor West, of the Coventry Electric Light Committee, is urging the Council to supply the current for charging the storage batteries of motor-cars. The transformer plant for this purpose wonld be fixed in the switch room which it is proposed to have in the centre of the city, so as to be easily accessible.

The motor-car seems likely to enter very largely into the service of the Continental restanratenrs and hotel proprietors. Some mechanical vehicles are already running between the Riviera Palace Hotel at Nice and Cimiez, while other services are to be run by the Compagnie Internationale des Grands Hotels to Cannes and Monte Carlo.

The prejudice is still so great amongst the ignorant and bigoted inhabitants of these Isles, that it behoves all those interested in the fntnre of motor vehicles to exercise the greatest care to avoid any transgression of the rules and regulations laid down for the time being by the authorities that be. This more especially relates to an excess of speed beyond the maximnm of 12 miles an honr prescribed by the Board of Trade. Any violation of this vital rule gives only too readily a peg npon which to hang a complaint by the enemy, and in view of probable revision of the present rules it cannot be too strongly impressed npon users of motor vehicles rather to travel nnder the 12 miles than over. Like other innovations, the diffienlties and prejudices now existing will be broken down in time, but it will take all the longer if, at the outset, those who are now the most interested financially, and shonld, therefore, be all the more in a position to grasp this fact, are themselves the greatest offenders.

Referring to this very point the *Coventry Standard*, which is published at what is termed by a certain set the "home of the motor-car industry," last week thonght fit to sonnd a note of warning in the following leaderette:—

"It may do no harm to draw attention, through the medium of a local print, to the fact that the pace at which motor-cars are in some cases being propelled is, ontside Coventry, becoming a matter of criticism and complaint. Coventry being the home of the motor-car, mention of the matter in these columns may help to bring it under the notice of those principally concerned. Our sympathies, together with those of every well-wisher of the industries of Coventry, are with the motor-car as a promising source of industrial activity, and when the question of restrictive legislation as to speed, &c., has been under the consideration of governing bodies, we have supported the landable disinclination which has been shown to hamper and hinder the development of the new industry by surronnding it with too stringent conditions. Bnt the fact that this possibility exists makes it all the more imperative on the part of those who have the control of the motor-cars already in use to be extremely carefnl, for their own sake, how they risk creating a hostile spirit by running their cars at a higher speed than wonld seem to be consistent with the safe use of the roads by the ordinary public. A word to the wise is sufficient."

As an illnstration of how far the above-mentioned prejudices can go, the following paragraphs, which we reproduce from the current issue of our excellent contemporary, *The Road*, is worthy to rank with the records in which we read of some of the effects of the first introduction of steam locomotives:—

"A correspondent at Leamington sends me an amnsing description of a visit paid to that town a few days ago by a conple of motor-cars, which had rather a bad time of it. Leamington is a town whose associations and surroundings are eminently sporting, not to say horsey, and anything that does not in some form or other appertain to the friend of man can rely upon but a cool reception. How much more so, then, in the case of a stinking, snorting machine, which is so entirely opposed to the very existence of the horse? The advent of a motor-car in the streets of Leamington acts in pretty much the same way as a red rag does to a bnll. Hence the fnn which ensued when two particularly nasty specimens of the new road terror made their appearance there nnexpectedly.

"Snuffling, snorting, and quivering, the motor-cars pulled up—or rather waddled np—to the hospitable door of Mr. McGregor's well-known Bath Hotel—hospitable, that is to say, to all genuine users of the road. It is not necessary to dilate npon the ready welcome and pleasant reception awaiting travellers as a rule at the Bath hostelry; bnt a line mnst be drawn somewhere, and Mr. McGregor apparently draws it at motor-cars. The fact remains that he refused to accommodate these fearsome things anywhere near his premises, and, in view of the presence of people with sensitive nostrils, to say nothing of several horses not used to such things as motor-cars, the landlord cannot be held to blame.

"The motor-car passengers were furious, of course; but that fact weighed but little with Mr. McGregor, who keeps his livery stables *as* livery stables, and does not let them out as goods and locomotive sheds. So persistent were his unwelcome visitors, however, that the good services of the law in the person of a local policeman had, I am told, to be called in. By the time that the custodian of the peace arrived upon the scene the two motor-cars had moved on, much to the relief of the Bath Hotel proprietor, and to the intense amusement of a number of interested spectators, who had, by sound and smell—especially the latter—been attracted to the scene. If this sort of thing becomes common, special hotel and stable accommodation will have to be provided for motor-cars and motor-car passengers."

This all reads very prettily, but somehow we think should the story be true and the conduct of Mr. publican McGregor be brought before the licensing magistrates at the next Sessions this licensed victualler might find it difficult to explain the correctness of his views as to his obligations under the public-house license which he holds. Possibly the travellers, whoever they may be, will make themselves heard under the circumstances when the renewal of Mr. McGregor's license comes on. Licenses *have* been recently refused renewal for less offences than this, and it should be fully worth the aggrieved individuals' while bringing it home to persons of this sort that to continue to participate in the big profits obtained from being one in a monopoly is subject to the due performance of certain decent obligations to the public set forth under the license when granted to the publican. This type of person is growing so rich now by reason of this participation in a monopoly that some of them are apt to forget that they are still amenable to the law which imposes certain obligations and regulates the supply of refreshments, liquid and otherwise, to Her Majesty's subjects whilst travelling in her realm.

MR. KNIGHT ON MOTOR-CARS.

Mr. John Henry Knight, of Barfield, Farnham, recently gave a most interesting lecture on Motor-Cars, at Tongham (Surrey). Mr. Knight, while admitting that France had taken the lead in the matter of motor-cars, clearly showed that this was due to the silly prejudices of English landowners, &c., who stifled the invention of such motor carriages by making prohibitive road tolls for such. Just as railways were fiercely opposed, so were motor-cars, but with this difference in result—whereas the railway companies had large capital to back them up, and often had to bribe, the inventors of motor-cars had no such means of pushing their schemes. He had twice been fined for running his machine on the road. By means of a lantern, fitted with the new acetylene gas, Mr. Knight showed photographs of the various steam and petroleum gas motor-cars lately invented. He had himself been to France, and tested the various machines. The Serpollet steam carriage, which he described, was, he said, a most ingenious and safe invention. Petroleum gas, however, had proved superior to steam as a motive power, and many of the most satisfactory motor-cars were those worked by this gas. Several inventions were described and illustrated, and loud cheering was evoked when a photograph of Mr. Knight on his own petroleum gas tricycle, which he invented, was thrown on the screen. To conclude, Mr. Knight referred to the value which such motor-cars would prove to tradesmen, professional men, and others, when the expense of their construction became smaller.

A 300-MILE RUN ON A PEUGEOT PHAETON.

The illustration on this page is the Peugeot phaeton referred to by Mr. Wellington in his letter on page 284, taken immediately after the run of 300 miles.

Writing of this performance, a correspondent says that "some sensation was caused in Colchester by its sudden appearance, when Mr. Wellington took several gentlemen short trips, who pronounced the sensation agreeable as well as novel, and in giving general information stated that orders had already been placed for 500 cars, and that no fresh cars, therefore, could be undertaken for several months to come. One gentleman was driven to his home on the car, covering the distance—13 miles—including 20 minutes for stoppages, in five minutes under the hour, which, considering the state of the roads, was good. During this run two or three brewers' carts and coal wagons, that usually can never by any threat or persuasion be made to get out of the way of other vehicles, gave the occupants their blessing (?), and made a more rapid departure from the centre of the road towards the ditch or fence, as the case might be, than they had ever done before in their lives. The effect on the cottagers as the car passed along was curious. Some flew in precipitous haste to the interior of their dwellings and, clutching hold of the door-posts, looked on in wonder and fear. Others advanced with a broad grin, and looked as though they wanted to run behind. Boys invariably broke into loud laughter, and hurried after. So, altogether, the ride was pleasant, and made one ponder over the thought that perhaps by-and-by motor-cars will be as common as carriages are now, when roads would be like pavement, and everybody racing—no horses, no oats, no stables—and nothing to cloud the agricultural horizon but perhaps a few balloons in the sky!"

The Glew Tyre.—The necessity of having a special tyre for motor vehicles is already being realised by inventors, and Mr. Glew, of 40, Chancery Lane, is, we understand, about to place upon the market one of an improved cushion or noiseless type, especially applicable to road vehicles. On the score of economy, the rubber being covered by a steel shield, it is claimed that the durability far exceeds that of the ordinary plain rubber tyre, the saving in repairs being estimated at quite £6 per annum for each pair of wheels. The rubber being protected by the steel covering, a more virgin material can be used, thus securing a smoother movement, and to an extent reducing the vibration. These tyres are easily removed and replaced without having to call in a skilled wheelwright; they are free from suction in damp weather (which is a great consideration when an increase of draught power is difficult to obtain), are smart in appearance, and by Mr. Glew's arrangement the tyre is practically as noiseless as an ordinary plain rubber tyre.

NOTICES.

Contributions and articles likely to prove of interest to our readers will receive due attention, but in all cases the name and address of the writer must be given, not necessarily for publication.

All matter intended for publication should reach us not later than the 10th of each month. Stamped envelope must be sent if the manuscript is required to be returned. The Journal is published the middle of each month.

All Advertisements should be sent to the Advertising Department, F. King and Co., Limited, 62, *St. Martin's Lane, London, W.C., where Advertising Rates may be had on application.*

The Annual Subscription is 7s., including prepaid postage to any part of the world. Single copy 7d., post free.

Cheques and Post Office Orders should be made payable to F. King and Co., Limited, *and crossed London and County Bank; otherwise no responsibility will be accepted.*

SPECIAL NOTICE.

The Automotor and Horseless Vehicle Journal *can be obtained from all* Messrs. W. H. Smith and Son's *bookstalls, and the following Agents:—*

London: Pottle and Sons, 14 and 15, Royal Exchange, E.C.
Wholesale: Brett and Co., 5, Pilgrim Street, Ludgate Hill, E.C.
Birmingham: J. McCann, 87, Union Street.
Manchester: John Heywood, Deansgate.
Newcastle-on-Tyne: C. C. Ross, 35, Side.
Paris: Homère Moreau, 97, Rue Nollet.
Victoria (Australia): Phillips, Ormonde, and Co., 169, Queen Street, Melbourne.

When any difficulty is experienced in procuring the Journal from local newsvendors, intending subscribers can obtain each issue direct from the Publishing Office, by forwarding remittance of 7s. for 12 months' subscription, post free (or at the rate of 7d. per copy).

The Automotor and Horseless Vehicle Journal.

A RECORD AND REVIEW OF APPLIED AUTOMATIC LOCOMOTION.

APRIL 14th, 1897.

ANSWERS TO CORRESPONDENTS.

H. M. Bramall (Eastbourne).—(1) There are several books already published dealing with the subject you mention: "Autocars," published by Messrs. Whitaker and Co.; "Horseless Road Locomotion," by the same publishers; "Carriages Without Horses Shall Go," and "Power Locomotion on the Highway," publisher Wm. Gate (Limited). There are also several other publishers getting works ready upon the subject, including "Motor-Cars," to be shortly published by Crosby Lockwood and Son. (2) We are afraid there will not be many new types of motor-vehicles where you mention.

E. A. Walton (Derby).—Many thanks for your good wishes. Our endeavours are to maintain our success by absolute independence.

E. Hozier (Co. Wicklow).—We are not personally interested as owners of any motor-car patents. You will find plenty of names in the current and previous issues of our Journal, both in the text and advertising columns, to enable you to arrange agencies for New Zealand, &c.

D. F. D. (Liverpool).—It is perfectly correct that the British Motor Syndicate will very shortly have a good stock of motor-vehicles on hand. We refer you to the current issue of our JOURNAL for further information upon this point.

SHEADU (Tunbridge Wells).—(1) The address of the Wolseley Company is Alma Street, Birmingham. (2) We note your remarks, and our columns are always open to fair criticism. (3) Shall be glad to hear from you as suggested. (4) The address of the Roots' Petrocar is 100, Westminster Bridge Road, London.

R. F. HALL AND Co. (Manchester).—We are always glad to notice any real novelty, but make it a rule to examine personally first. Evidently your novelty is hardly as important as your letter implies, or you should have spared time to allow our special representative to inspect the article at your works when he called. You do not even supply section as asked. Under the circumstances your communication savours somewhat of endeavouring to obtain, with scant justification, a free advertisement.

POSTING (Norwich).—(1) Solicitors dealing with the matter can only tell you what the arrangement is. As you have shares and cannot obtain the return of your money, possibly it is best to hold in hopes of a better price; but the concern is hopelessly over-capitalised at the premium price. (2) This Company appears to be a *bonâ fide* concern, and is preparing to do considerable business, we believe. They have a really good motor, and we would recommend waiting before selling.

WM. SCHEU (Leeds).—(1) Our JOURNAL is published about the 15th of each month, and should be procurable not later than the next day by you. If ordered at W. H. Smith and Son's railway bookstall, you will always get it immediately. (2) Your query is too vague *re* French axles, as there are so many in use. In the present issue we illustrate Ackermann's very old steering system, which is probably what you refer to.

W. HUGGINS (Dundee).—The address of Mons. Serpollet is 13, Boulevard Malesherbes, Paris.

W. E. (Dewsbury).—Medhurst's gunpowder engine is described and illustrated in his Patent Specification, No. 2,431, A.D. 1800, which we are afraid is out of print, but may be inspected at the Patent Office Library, as well as at a good many other libraries throughout the country. The idea of using gunpowder for motive power engines is a very old one. The suggestions or schemes of Sir Samuel Morland, Jean de Hautfeuille, and others, all made in the seventeenth century, are described in some of the steam-engine text-books. The Patent Records contain a great number of inventions in this direction, but we do not know of any books dealing with the subject.

M. G. McCONNELL (Manorcunningham). — Mons. Serpollet's address is given above. For England you had better apply to Mr. G. Hopkins, 30, Parliament Street, London, S.W.

ALAN FARIE (Lanark, N.B.).—The address of the Wolseley Company is Alma Street, Aston, Birmingham.

RACROTOM (Tunbridge Wells).—We appreciate the points in your letter, but we prefer letters for publication couched in milder terms. We are not desirous of unnecessarily bringing ourselves within the Libel Act.

"STEAM-FOR-EVER" (Chipping Norton).—(1) The consumption is not actually known, but would be about 50 per cent. to 100 per cent. more than the oil used in the internal combustion engine of the ordinary oil motor. (2) Compound engines are not used.

EBOR (Liverpool).—(1) We do not know anyone making the Serpollet Section in this country, but you can obtain solid-drawn boiler-tube, other than Serpollet Section, from the Credenda Company, Spencer's, or Lloyd's, &c. (2) We would suggest your applying to Mr. Shrapnell Smith, 35, Botanic Road, Wavertree Park, Liverpool, who will be able to put you in the way of what you want.

W. H. WYBORN (Walmer).—The address of Messrs. New and Mayne is Palace Chambers, Bridge Street, Westminster, S.W.

ACETYLENE.

THE proverbial idiot who searches for a leak in a gas pipe with a naked light and generally succeeds in locating the leak and eternity at about one and the same moment of time would be well advised if he left acetylene severely alone.

Handled with ordinary intelligence and care acetylene is as safe as coal gas, but being an endothermic compound, that is one in the formation of which heat has been absorbed instead of, as is usually the case in the formation of chemical compounds, liberated, it is evident that its stored heat must be again set free when the gas undergoes decomposition, thereby adding considerably to the violence of its action, and as it only requires 2·7 per cent. of acetylene as against 8 per cent. of coal gas to render its admixture with air explosive, it follows that the "p. i." should rather depend upon his nasal organs than upon a lucifer when searching for a leak of acetylene.

Notwithstanding its being an endothermic compound the gas at any pressure up to two atmospheres, roughly 30 lbs. per square inch, is perfectly safe from any explosive action *per se*, as at these low pressures a high temperature, even up to that caused by the detonation of a charge of mercuric fulminate in the gas, simply causes a purely local decomposition, and any explosion so caused would not travel more than a few inches from the point of origin; but given the gas under higher pressures, such as obtains when compressed in the liquid state in cylinders, and the application of a red heat will cause an explosion of the whole volume of the gas, the moral of which is that experimenters should not store cylinders of the gas in close proximity to a stove or try to forcibly unscrew the cap of a supposed empty cylinder with a 4-foot lever, as the assistant to a well-known professor did, or they may find in their flight through space that v^2 by m, where m equals a 9-inch brick wall, is a quantity the value of which will interest them no more.

On the other hand, and with rational treatment, cylinders of liquid acetylene are, for all practical purposes, perfectly safe, as spontaneous decomposition and its attendant explosion will not occur until a temperature of close on 1,400° Fahr. has been reached, a temperature surely sufficiently high in itself, but which the timid layman can still further augment by 100° Fahr. for every 10 per cent. of coal gas with which he dilutes his acetylene.

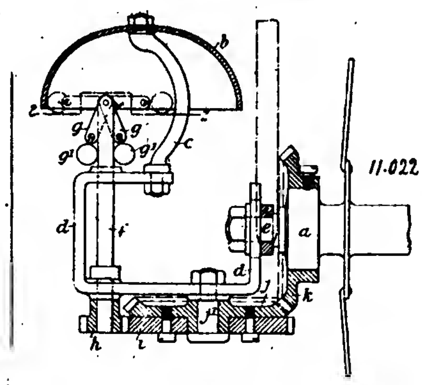
It having recently been proved that the gas will not form those explosive combinations with copper and the copper alloys with which it was at first credited, and that its noxious properties are not any more dangerous than are those of ordinary coal gas, it only remains to warn those of our readers who may contemplate going in for acetylene that the calcic carbide made in England is much purer than that which is imported, and though the British product is a trifle dearer to buy the yield of gas per unit of weight is higher.

Regarding the use of acetylene for motor purposes we have, unfortunately, very little available data, but the following comparative figures may be of service to those interested in the subject. It attains its maximum explosive force when the volume per cent. of acetylene in the air is 7·8. The ignition temperature of the gas is 896° Fahr., or just 20 per cent. lower than that of coal gas, while its heat value in calorics is about two and a half times that of the latter gas. Tested in a two horse-power gas engine, with double-acting cylinder, it was found that 28·4 cubic feet of acetylene per hour gave 2·48 indicated horse-power, the same engine requiring 85·3 cubic feet, or almost exactly three times the quantity, of coal gas to produce the same amount of power. Used as an illuminant it is about 20 times more powerful than coal gas; one cubic foot of the liquid gas sufficing to supply a 16 candle-power burner for no less than 800 hours.

Messrs. Cohendet and Co., 166, Quai Jemmapes, Paris, are building an acetylene motor to the design of M. Raoul Pictet. The motor will have three cylinders, and will be 10 horse-power.

SPEED INDICATOR.

A novel arrangement for giving an audible indication that the speed limit has been attained is shown herewith. The action of the apparatus is of course due to the fact that the arms, g, g, are caused to fly out centrifugally when the speed of the spindle, f, reaches the predetermined point. This causes the hammer, g', g', to strike the gong, b, so warning all concerned of



the speed at which the vehicle is moving. The other details are sufficiently clear, a being the hub of the wheel to which the apparatus is attached, the gong, b, being mounted on an arm, c, rigidly bolted to a bracket, d, secured to the axle, e, on which the hub rotates. Mr. John Clements, of 360, Coldharbour Lane, Brixton, is the inventor of this signalling apparatus.

LAW REPORTS.

The Dublin Pneumatic Tyre Deal—Dunlop v. Maccabe—Judgment for the Plaintiff.

Judgment was given on the 18th ultimo in Dublin, by the Vice-Chancellor, in the case of Dunlop *v.* Maccabe, which involved a sum of £10,500, and which was at hearing for nearly a week. The plaintiff, who is the inventor of the Dunlop tyre, sought a re-transfer by the defendant, Dr. Maccabe, to himself, of any of 2,000 shares in the Pneumatic Tyre Company undisposed of, which the plaintiff charges that the defendant obtained to make sale of and re-transfer as his agent. The plaintiff further charges that the defendant obtained the execution of the transfer and legal ownership of the shares by fraudulent representations and fraudulent concealment. An account of defendant's dealings with the shares was sought, and also damages. In giving judgment in favour of the plaintiff, the Vice-Chancellor went carefully over all the facts deposed to in the evidence. Regarding the interview between plaintiff and defendant, his Lordship said there was, of course, a direct conflict of testimony as to what passed between them then; but, in weighing their evidence, he could not give the same credit to the men who formed the deliberate purpose of what he must designate as defrauding the plaintiff out of his shares, as he did to the plaintiff, who appeared to have acted honestly in this transaction. The defendant had difficulties to contend with in proposing to the plaintiff the purchase of 2,000 shares. He dared not tell the plaintiff that it was by the advice of Du Cros that he was offering to purchase, or that Du Cros was to lend him the money for the purchase; for the plaintiff would have at once seen that there was more in the matter than an ordinary purchase. He now came to a very grave portion of the case, namely, the transaction about the letter of Du Cros to the defendant, written on the morning of 29th March. That a letter was written by Du Cros to the defendant, which was produced by the defendant to the plaintiff on the Sunday morning, was undisputed; but there was a very great controversy as to its contents. The letter was not forthcoming, and it was the only document that was not forthcoming. The defendant said he kept this letter in his pocket for about a week and destroyed it, as he considered it of no value. He could not credit this statement. He knew well he had produced it to the plaintiff for the purpose of inducing him to sell his shares. He gave it to him to take upstairs to show his wife, in order to overcome her advice to her husband not to sell. This was not a letter which a person like the defendant would be likely to keep for a week in his pocket, and then destroy as of no value. But that was not all. The defendant must have known it would have been of great importance to his case to have something more than a mere verbal statement from memory of the contents of such a letter, and accordingly a document was prepared by Du Cros, at the instance of defendant, and described as a memorandum of the letter. It appeared that it was prepared in the month of September, which was after this action was brought. There was a very serious contradiction between the parties as to the true contents of the letter, and it was important for the decision as to which version was the true one to bear in mind the relative positions of the parties when it was written. He could not account for the great haste of Du Cros in writing a letter merely for that purpose on Sunday morning, and sending it by his servant on horseback to the defendant. But that letter was not so compiled, no matter which version was the true one. There was evidently something more to be communicated, and so the letter showed. It seemed an extraordinary coincidence that a letter should be despatched in haste by Du Cros to the defendant unsolicited, which should come to the defendant's hands exactly at the time he wanted it in order to work on the plaintiff. It was difficult to believe that some communication did not pass between the defendant and Du Cros which led to the writing of that letter. As soon as the defendant got the letter he took it with him to the plaintiff's house and showed it to him. The plaintiff took it up to his wife, who was unwell and in her room, and the result was that the bargain between the plaintiff and defendant was closed. He had no doubt that it was the production of this letter that induced plaintiff to sell. He was satisfied the letter produced to the plaintiff, and shown by him to his wife, was understood by both of them as showing the opinion of Du Cros that as a matter of prudence it would be well to sell the shares at £7, and that it produced the intended effect, and induced the plaintiff to agree to sell them to the defendant. This established the second case of fraud relied on by the plaintiff. After going fully into the other matters in the case, his Lordship, in conclusion, held that the defendant had been guilty of fraud and misrepresentation, and declared that the sale by the plaintiff to the defendant of 2,000 shares in the Pneumatic Tyre Company was procured by the fraud of the defendant, and adjudged him to pay to the plaintiff all profits realised by him by resale or other dealings in the shares, and directed an account of such profits, with interest at 4 per cent. He should adjudge the defendant to pay all costs. A stay was put on the order, pending an appeal, the defendant to lodge £5,000 within a fortnight, and a further sum of £2,500 within an additional week, the defendant to speed the appeal.

Cycle Components as a Monopoly.

In the Court of Appeal, on the 31st ultimo, before Lords Justices Lindley, A. L. Smith, and Rigby, Mr. Fletcher Moulton, Q.C., with whom was Mr. Walter, appeared on behalf of the Cycle Components Manufacturing Company (Limited) in support of an appeal from a decision of Mr. Justice Kekewich, refusing to grant an injunction restraining the Standard Weldless Tube and Cycle Components (Limited) from trading under their present title, or from in any way using the term cycle components as a part of their title, or in a way calculated to deceive the public into believing that the defendants were connected with the plaintiff company. The defendants relied upon affidavits, showing that the words objected to were used by many firms; and Mr. Justice Kekewich, without calling upon the other side, gave judgment in their favour, remarking that the case illustrated the anxious desire of many people to appropiate a bit of the English language. There seemed to be no reason why the defendant company or any other company should not manufacture cycle components, and why, if they did so, they should not state so. Their Lordships now upheld the decision in the Court below, and dismissed the appeal, with costs.

Company Promotion.

On the 1st inst., before Mr. Justice Bruce and a special jury, the case of Evans *v.* Hart was an action brought by Mr. Edward Jones Evans, a member of the Bristol Stock Exchange, against Mr. William Hart, to recover £787 10*s.* alleged to be due to plaintiff on a letter signed by defendant on June 9th last. Defendant admitted the letter, but said it did not contain the true contract.

Lord Coleridge, Q.C., and Mr. Ernest Pollock appeared for the plaintiff; while Mr. Dickens, Q.C., and Mr. A. J. David represented the defendant.

Lord Coleridge said in June last a Company was to be floated called the New Beeston Cycle Company, with a capital of £1,000,000, and the chief promoter was Mr. H. J. Lawson, who, being anxious to introduce the matter in as large and wide a manner as possible, selected the plaintiff to act for him in the West of England. Mr. Lawson consulted with the plaintiff as to engaging a broker to act for him in London, and the plaintiff selected the defendant, whom he had known as a broker on the London Stock Exchange for many years. Mr. Lawson engaged the defendant, and agreed that in consideration of the defendant permitting his name to be used in connection with the prospectus of the Company as the London broker, and pushing the business amongst his clients, to pay him, within one month of the Company going to allotment, a fee of 2,000 guineas, together with the usual commission of 5*s.* per share in all shares allotted to his clients. On the same day the defendant handed the plaintiff a letter agreeing to pay him 750 guineas out of his fee as soon as he received it. The defendant, being unable to get the amount of his claim, issued a writ against Mr. Lawson, and the case was settled, the defendant receiving 1,500 guineas and £500 in shares. The defendant, in a letter to his solicitor, asked if he should pay the plaintiff 25 per cent. on the first half of the 1,500 guineas, 50 per cent. on the second half, and his proportion of the shares, and these sums, when totalled up, came within a shilling of the sum now claimed. The plaintiff would be quite content to take this sum, and would make the defendant a present of the shilling. (Laughter.)

Mr. David: Such generosity overpowers me. (Renewed laughter.)

The plaintiff was then called, and bore out the opening statement of counsel.

Mr. David, on behalf of the defendant, submitted that under the agreement the plaintiff was only entitled to recover a proportion of the compromised sum, seeing that it was a reasonable and proper thing to compromise the action, and that he had been offered £525 as his proportion.

The jury found for plaintiff for the amount claimed. Judgment accordingly.

Underwriting Motor Shares.

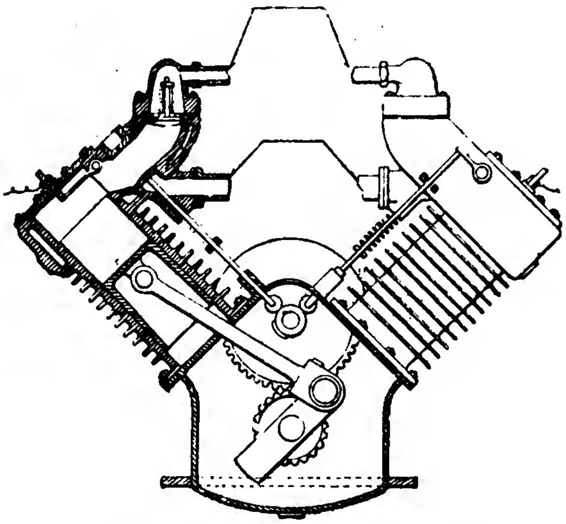
On the 1st inst., in the London Lord Mayor's Court, before the Common Serjeant (Sir Forrest Fulton, Q.C.) and a jury, the case of Gamage *v.* Marshall was disposed of. The plaintiff, Mr. A. M. Gamage, athletic outfitter, sued the defendant, Mr. Marshall, to recover the sum of £20, and damages, for breach of an underwriting contract in the London Electric Omnibus Company. According to counsel's statement, early in last year the defendant was bringing out the London Electric Omnibus Company (Limited), and an arrangement was made with the plaintiff by which, in consideration of his underwriting 400 of the shares, he was to receive 5 per cent. in cash and 10 per cent. in fully paid up shares. Under this contract the plaintiff had had to take up 160 shares. There was at the time a boom in this class of shares, and if the plaintiff had had delivery he could have sold those due to him for commission at a premium, as he had done those taken up by him. At the present time the shares were practically unsaleable. After hearing counsel for the defendant, the learned Common Serjeant said the case was practically undefended, and the only question was that of damages. Eventually the jury returned a verdict for the plaintiff for £66 5*s.*, including a sum of £20 paid into Court by the defendant.

A lecturer at Dover College, who appears to be a humorist, has amused his audience considerably by the conjugation of a new verb. It is worth recording, especially as the spirit of the joke is equally applicable to the acquisition by a novice of a fresh young horse and cart, or a timid learner of the bicycle. Life was too short, he said, for such sentences as "I am going to ride my motor-car this morning." There had long been the verb to "bike"; there must now be the verb to "mote." The active voice, present tense, ran somewhat thus: "I mote, thou stokest, he looks out for the police, we're getting on, you run us into a lamp post, they pay the damages." The imperative ran: "Mote me by moonlight alone," and "Mote ye, or perish in the attempt." The present subjunctive was: "I may mote, thou mayest buy me a motor, he may think better of it."

THE MORS MOTOR-CAR.

One of the most conscientious French engineers endeavouring to produce a perfect motor-vehicle is M. Emile Mors, of 48, Rue du Théatre, Paris. In a recent interview with the representative of *The Engineer* he gave some interesting particulars of his latest type, which we illustrate, as being of value to workers for an ideal car in this country. M. Mors's present carriage is fitted with a water reservoir under the fore part of the carriage, the water circulating through a coil of ribbed cooling pipes.

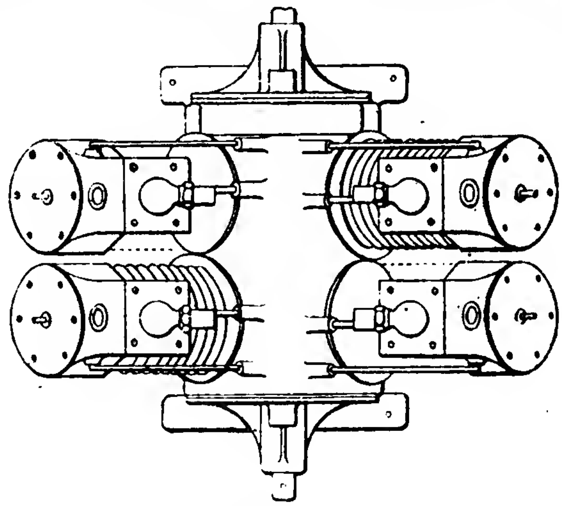
The motor is composed of four cylinders inclined in pairs at an angle of 45 degrees, the pistons working on a single crank. While one pair of pistons is compressing the gas mixture the other pair is performing its active stroke, so that the crank receives two thrusts at each revolution. By this arrangement the motor is able to run very steadily, and there is said to be an almost entire absence of vibration when the transmission mechanism is thrown out of gear. Above the crank is a distributing shaft geared down to half the speed by pinions, and this shaft carries cams for actuating the valves, which are enclosed in the upper part of the ribbed cylinders, and the electrical igniters. Each cylinder has an inlet valve opened by simple pressure; the exhaust valve is operated by a rod, one end of which presses on a cam on the distributing shaft. As the piston makes its downward stroke a volume of air, which has been carburated in a special apparatus, is drawn through the



valve, and is compressed by the piston making its upward stroke, and then exploded by electricity. The piston is thus driven forward again, and at the moment of returning the cam on the distributor opens the exhaust valve and allows the piston to expel the burnt gases. The electricity is provided by a small dynamo driven by friction by the fly-wheel and generating enough current to explode the mixture and keep the accumulator permanently charged. The accumulator is only employed for starting the vehicle. The current from the dynamo passes through an extra-current bobbin, and is conveyed inside each cylinder where a "breaking spark" is produced by means of a couple of pallets and an insulated rod, the pallets being operated by cams on the distributing shaft. This spark is certain and instantaneous in its action, and all danger of erratic explosions is said to be avoided.

The carburator is of a special type invented by M. Mors, and is intended to provide a perfectly regular supply of gas mixture for the engine, so as to prevent the dangers incidental to such appliances where the supply of mixture is liable to be in excess of the needs. The spirit flows by a pipe into a receptacle in which there is a float. When the spirit reaches a certain level, the float rises and shuts a valve, thus cutting off further supplies until the level of the spirit in the receptacle again drops, when the valve is of course opened. From this receptacle the spirit flows up through a pipe into an atomiser in the shape of an inverted cone, and a quantity of air equal to that represented by the downward stroke of the piston enters through a pipe and mixes with the spirit. The quantity of air admitted and the density of the mixture may be regulated with the greatest nicety by means of screws.

The crank of the motor is geared on to the countershaft by bevel pinions, one of which serves for the forward movement and the other for reversing. Leather belting transmits the power from the countershaft to the driving axle, and the speed



is varied by moving the belting on to one or other of the pulleys. The mechanism is thrown out of gear by a pedal, and another acts on the brake with such force as to stop it almost instantly. The carriage complete weighs only 570 kilos., and, running at from 300 to 1,600 revolutions a minute according to needs, the motor will, it is stated, give nearly 6 horse-power on the brake.

The vehicle will attain speeds of 19 miles an hour on the level, and will climb gradients of 12 per cent. at 6·5 miles an hour. It is claimed that once the carriage is started it will run for 10 hours without its being necessary to renew supplies of water or petroleum, or to pay any attention to the machinery. The oiling is done automatically; in fact, the whole carriage has been designed to avoid the necessity of any attention being given to it once the engine is started. M. Mors is about to carry out extensions to his works so as to be able to build his new vehicles on a large scale, and he hopes in a month's time to be able to start delivering them, having already taken orders for 240 carriages.

BUSINESS NOTES.

The British Motor Syndicate have taken the ground floor premises at 40, Holborn Viaduct, which have hitherto been occupied by the Daimler Motor Company, and purpose using them as a show room for their carriages. The Daimler Company have removed their head offices to Nos. 219 to 229, Shaftesbury Avenue, W.C.

Messrs. Conze and Simon have taken into partnership Mr. Herbert Berry, who lately represented Messrs. Siemens Bros. and Co. (Limited). The name of the Company has been altered to Simon, Berry, and Co., and all debts due to Conze and Simon will be taken over by the firm under the new style, and likewise all liabilities will be paid by the new partners. It is their intention to conduct the business upon the same lines as heretofore.

We regret to hear that, a few days after going to press with our last number, a serious fire occurred at the works of Messrs. Peugeot of Lille (France). We understand this will not interfere with the business of the firm, and that fortunately practically no serious injury was done so far as the Motor-Car Department is concerned.

The Secretary of the I.E S. Accumulator Company (Limited), notifies that the head offices of the Company have been removed to 78 and 79, Palace Chambers, Bridge Street, Westminster, London.

The London Electric Omnibus Company (Limited) intimates that Mr. F. S. Tomkins has been appointed the Secretary of the Company, and that the registered office of the company is now No. 6, Northumberland Avenue, Charing Cross, London, W.C.

The Tubeless Pneumatic Tyre and Capon Heaton (Limited) has, we understand, served the Trench Tubeless Tyre Company (Limited) with writs for infringements of its patents.

Messrs. J. and C. Stirling, of the Hamilton Carriage Works, Hamilton, N.B., are now prepared to accept orders for their motor dogcarts, stanhopes, victorias, wagonettes, and vans, for delivery in April, May, and June, and will shortly issue a catalogue. They use the Daimler motor.

A new motor-car wheel and special puncture-proof tyre for light and heavy weights under any pressure of inflation is about to be placed on the market by the Aquinas Cycle and Motor Company, Aquinas Street, London, S.E. The actual patentee is Mr. J. D. Stidder, and from the special designs which we have had the pleasure of inspecting we gather that the invention consists of new ball hubs with self-containing oil chambers, which can easily be taken off and on the axles, it being rendered practically impossible for any dirt or grit to pass on the inside. There is also a provision for oiling and for regulating the oil to a given height in the chamber, with a waste draw-off when it has done its duty. The driving wheel hub and ball box are of a rather novel construction, and are easily taken apart or refitted, and in order to avoid vibration are worked in slides. The wheels can be made of iron or wood, and the fellies are secured by being pressed to the tongue of the spokes and by having a spring socket with a screw dowel, the end of the tongue expanding so that it cannot disconnect itself from the felly; for repairs you simply unscrew the expanding block and the fellies can be taken off without damage. The tyres, Mr. Stidder claims, are inflated with a new mode of action, and are specially adapted for carrying heavy weights, being unpuncturable. Mr. Stidder also has another solid form of tyre, which is attached on short lengths of steel bands of a particular section, and in case of any damage to one part it can be set right by removing one connection and replacing it by a new section of tyre of any length required.

REVIEWS OF BOOKS.

"Horseless Carriages." By J. E. Tuke, Burleigh Villa, Harrogate. Price 6*d.*

This is a carefully put together little pamphlet, written by the author with the idea that it might prove useful in giving some information about horseless vehicles to those whose curiosity is large and whose practical knowledge is small. In about 24 pages Mr. Tuke has given well condensed particulars of the ancient history of Self-propelled Vehicles, the present position of steam, oil, and electricity, whilst the text of the new Act, and hints on the management and use of oil motors, brings the booklet to a close.

The British Motor Syndicate have issued what they call their "Monthly Trade Circular," which appears to be made up of a review of the present position of the Company. From a trade point of view the title of this latest production of the "B.M.S." is a misnomer, as for all practical purposes there is nothing of interest to the trade. The document chiefly deals with the financial position, prospective dividends, and price of shares, &c., and we think it would be more to the point, if the intention of publishing this document regularly is adhered to, if there were a little less detail emanating from the finance department, and a little more information likely to be useful to members of the trade, who are desirous of assisting in securing part of the coming motor-car business.

We are in receipt of the current number of the "Coachbuilders' Art Journal," from Messrs. J. and C. Cooper, of 64 Long Acre. We are glad to notice that this excellently got up journal is taking the motor-car building seriously in hand from the coachbuilder's point of view. There is no doubt a big scope for the practical coachbuilder to join hands with the engineer in turning out a perfect vehicle, and we trust that the leaders in the trade will in every way assist to that end, setting aside all prejudice. It certainly will not be the fault of our contemporary if this does not come about, and amongst several well-produced plates given with the issue is a charming design for an elegant park motor-car.

A motor-omnibus, constructed to carry about six persons, was placed on the streets of Birmingham last week by the Birmingham Motor-Omnibus Company. Several journeys between Colmore Row and Five Ways, and between New Street and Five Ways, were made; but as the vehicle had not received its formal license from the Watch Committee, the driver was unable to pick up the crowd of would-be fares who crowded up to take their places.

THE NEW-MAYNE ELECTRIC RUDDER-MOTOR.

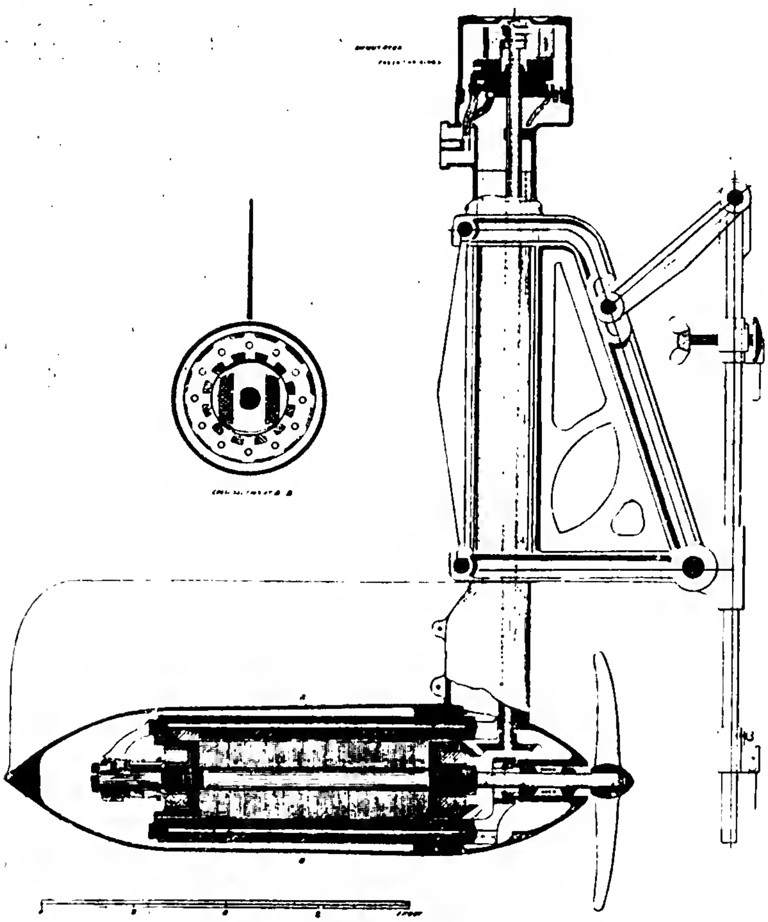
An ingenious method of adapting an electric motor to the propulsion of a boat, without in any way interfering with the structural arrangements of the same, is shown in the accompanying illustrations.

The New-Mayne rudder-motor is not by any means an innovation, but the 1897 model contains so many improvements as to render it now practically perfect. In the new type the efficiency of the machine has not only been greatly increased, but the weight of each size has been considerably reduced, while at the same time the insulating properties have been enhanced by a special patented process, so much so that no breakdown takes place, even though water should leak into the motor case as the result of any collision or careless handling. Further additional improvements allow of the commutator and brushes being inspected while the motor is running, which, as now arranged, it will do for long periods without lubrication.

As will be seen from the part sectional elevation the motor rudder is fitted to an adjustable frame, and this is attached to the stern of the boat in the ordinary manner, and all the bearing surfaces being ample there is no vibration, the frame being held perfectly rigid by two small pads pressed against the stern of the boat by thumbscrews. The propeller moving as it does away from the keel line of the boat, adds greatly to the steering qualities, but as the rudder area is made sufficient by means of the fin above the motor case, the rudder answers in the ordinary way when sailing or rowing. Electrically the motor is peculiar, in that the field magnet revolves within the armature, and drives, by means of bevel gearing, a vertical shaft, by which commutation is effected in the manner shown, the connections from the sections of the armature being taken up the interior of the supporting tube to the segments of the commutator, which is fixed near the top of the vertical shaft. The commutator is stationary and the brushes revolve. This arrangement does not prevent a fairly high electrical efficiency being attained. The necessary current is supplied from secondary cells, the motor being controlled by a regulating and reversing switch. Electrical connection between the switch and motor is made by means of the rudder lines, which terminate with metal plugs, and these fit into sockets provided on the switch.

The motors are listed from half horse-power to two horse-power, but can be made to four horse-power, the weight of a one horse-power motor rudder, exclusive of batteries and switching gear, being 110 lbs.

Ordinary Boat Fitted with New-Mayne Rudder-Motor.



Sectional Elevation of Rudder and Motor.

A New Lubricant.—A serious difficulty which arises in the use of motor-cars is the necessity of having a first-class lubricant, it being essential that the body should be just sufficient to keep the rubbing surfaces apart and prevent abrasion of the metal, whilst the flashing point should be very high in consequence of the heat, and in the case of acid being present, corrosion of the metal must necessarily follow. We understand there are several firms at the present moment who are endeavouring to meet these special requirements, and we have just received from the Britannia Supply Company, of 49, Lime Street, E.C., a sample of a special oil which they are about to place on the market, for which they claim that the flashing point is from about 350° to 400°, and that, in regard to the body and its freedom from acid, they are prepared to guarantee their commodity as fully meeting the requirements in both cases. They also appear to have got over the difficulty of the residue which remains in the cylinder, thereby clogging the engines, as the Britannia Motor Oil is a pure petroleum product instead of the usual made-up oil.

A PRESTON MOTOR-CAR FACTORY.

Striking evidence of the commencement of the new era in locomotion is afforded by a visit to the works of Messrs. T. Coulthard and Co., Preston.

This well-known firm of engineers has taken up in earnest the construction of automotors, having erected large works, well supplied with special tools for this purpose.

Messrs. Coulthard have in hand several vehicles fitted with "Pennington" motors. One of these, shown in the adjoining illustration, is a motor-car built, we understand, to carry eight or nine passengers and a ton of luggage. The car is fitted with a 16 horse-power Pennington motor and carries two tanks of 50 gallons capacity for supplying the motor with oil and water. Messrs. Coulthard are building several of these cars for the West Australian Freight and Express Company, of Southport, for use on the goldfields of Western Australia. An interesting feature in this vehicle is the dispensing entirely with carriage springs by the use of wheels built upon cycle lines with ball bearings, and fitted with 9-inch pneumatic non-puncturable tyres. These tyres, attached to one of the above-named cars, have been very thoroughly tested by Messrs. Coulthard over very rough ground, and have been found to give entire satisfaction.

Another type of carriage, and one which has apparently an important future before it, is the "*Lancashire*" autocar, shown by the annexed illustration, the design of which has been registered by Messrs. Coulthard.

This car has been specially designed to meet the requirements of those who desire a light, compact, yet strong and durable vehicle for ordinary use. The "Lancashire" is fitted with a powerful Pennington motor, having two different speeds, as well as a reversing motion.

The body is hung on springs, rendering it quite independent of the frame which carries the motor and gearing. In consequence of this, the vibration of the motor is taken up by the special arrangement of springs, instead of being communicated to the carriage body and its occupants.

A very different kind of vehicle, also built by the firm, in striking contrast to the last-named, is a large freight wagon, to carry a load of 10 tons, and fitted with a motor of 25 horse-power.

We gather from Messrs. Coulthard that they have some difficulty in satisfying the demands of customers for quick delivery, as the latter do not sufficiently recognise what a variety of points in this new industry have to be carefully considered, tested, and approved before being carried out in the construction of the vehicles to ensure their giving entire satisfaction.

The majority of the public, which does not understand the practical side of motor-car building, expected to see thousands of these vehicles overrunning the country within a week of the passing of the new Act, imagining that they could be turned out at a moment's notice. Hence the mistaken idea amongst the ignorant that the motor-car boom is a thing of the past. It will not be long now, we think, before they have a sharp awakening, and it is as well for the future of the industry that the new vehicles have not been "rushed" in manufacture, but have been delayed by the various makers like Messrs. Coulthard and Co., who, having a reputation to lose, are determined that what they do deliver shall not impair it.

The Motor Mills, Coventry.—The confusion as to the ownership of the Motor Mills, Coventry, is, to a certain extent, explained by a letter addressed by Mr. E. T. Pennington to the Dublin Press. In it he states that these mills are the property of the Great Horseless Carriage Company, and they at present occupy the first story, recently used by the Humber Company, and the third story; while they rent the second story to him at £400 per annum, for the manufacture of the Pennington motors, and the fourth story to the Beeston Tyre Company. Then, on the ground floor, brick extensions have been erected which are used for the works of the Daimler Company. The Motor Mills have a 300 horse-power steam engine, which is arranged to drive the shafting on the different floors, by means of rope transmission. While this power can be utilised, Mr. Pennington at present does not use it, as he prefers to drive his works by means of his own engines. We understand the prospectus of the new Irish Company to carry on Mr. Pennington's works in Dublin will be issued in a few days.

Self-Propelled Traffic Association.

(Incorporated by Special Licence of the Board of Trade, under the Companies Acts, 1862 to 1890.)

Some of the objects for which the Association is established are:—

To originate and promote improvement in the Law from time to time directly or indirectly affecting self-propelled locomotive road traffic, and to support or oppose such Law, and for the purposes aforesaid to take proceedings as the Association may deem expedient.

To popularise and assist the development of self-propelled vehicular and locomotive road traffic, and for this purpose to take such steps and proceedings as the Association may deem expedient.

To take or defend any proceedings on behalf or against the Association or its members, which in the interests of the Association or the members thereof may seem to the Association expedient to take or defend. Provided that no such proceedings shall be taken or defended on the part of the members of the Association except in the *bona fide* furtherance of some object of the Association of a public or *quasi* public nature.

To promote the scientific knowledge of the construction and propelling of all kinds of self-propelled vehicles or locomotives, by means of competitions, exhibitions, by giving of prizes, or in such manner and on such conditions as may be found desirable.

Subscription ... ... £1 1s. per annum.

President	SIR DAVID SALOMONS, Bart.
Secretary	ANDREW W. BARR, Esq.
President of the Liverpool Centre	The EARL OF DERBY, G.C.B.
Hon. Local Secretary	E. SHRAPNELL SMITH, Esq.
Semi-Official Journal of the Association	THE AUTOMOTOR AND HORSELESS VEHICLE JOURNAL.

THE Honorary Secretary of the Self-Propelled Traffic Association (Liverpool and district centre), Mr. E. Shrapnell Smith, has been elected a member of the special light railway committee of the Liverpool Incorporated Chamber of Commerce. This body is making an exhaustive inquiry into the question of improved means of transit for goods between Liverpool and the manufacturing towns, and it is satisfactory to know that so energetic a gentleman as Mr. Shrapnell Smith is a member of the Committee, as the claims of motor-wagons, &c., on the road can be safely left in his hands.

AN EARLY MOTOR-CAR.

By J. H. KNIGHT.

THE steam-carriage shown in the illustration was made in the years 1868-1870. Originally it was fitted with a single cylinder, 5 inches by 7 inches, driving the road wheel, or rather one wheel only, by a pitch chain geared as 1 to 6. With the single cylinder it was found very difficult to start on rising ground, and after running some months was altered; two cylinders, 5 inches by 7 inches, were put in, but the gearing reduced to 1 to 4. This was a great improvement, but after some time the boiler, a vertical multi-tubular, gave trouble; there was great difficulty in keeping the tubes tight, and it also gave trouble through priming, therefore it was altered to a Field boiler.

The steering wheels, 2 feet 8 inches diameter, were only about 2 feet gauge. Steering was done by a tiller, but the arc through which the tiller moved was twice that of the steering wheels; this gave the steersman good control over the steering.

The weight empty was about 32 cwt., three passengers sat on the seat side by side, a fourth (making a fifth with the stoker) was sometimes carried on the firing platform. On fair roads about eight miles an hour was maintained. The engines were far from economical, and used more fuel and water than they should have done. Water for about six or seven miles was carried in a tank under the engines. Coal for about 18 miles was carried in a bunker at the back.

Looking back after 25 years, it is easy to see what mistakes were made in construction. The slide valves and pistons were not easily accessible, and, after a short time, became leaky and wasted steam. The boiler was unnecessarily heavy; it would have been improved by a fire-brick baffle in the fire-box; a feed-water heater would have been a considerable help. If the boiler had been stoked carefully and with a thin fire, doubtless better results would have been obtained. A very sharp blast was required, and it was impossible to burn coke so a soft coal was used and, consequently, there was a great quantity of smoke at times. If the boiler primed (and the original boiler would sometimes suddenly prime for a few minutes), the passengers were covered with a black rain. Many of these difficulties were overcome, and in 1870 and 1871 some very good runs were made. A hill about three quarters of a mile in length, with one sharp rise of 1 in 11, was ascended on three or four occasions. After using the steamer for three or four years it was sold and converted by the purchaser into a small traction-engine.

In the early seventies, although the red flag Act was in force, the writer was only once stopped by the police, and then only name and address demanded. This caused a rather amusing rumour. Some passer-by who had seen the police inspector stop the carriage reported that the passengers had all been arrested, handcuffed, and walked off to prison; a few miles further on a breakdown occurred which delayed the return of the steamer till late at night, and this report was in some instances really credited.

On one occasion what might have been a very serious accident was avoided; a pin came out of one of the levers in the steering gear, the carriage turned sharp round and ran through the hedge; if it had turned to the right instead of the left it would have gone down a steep bank some 5 or 6 feet high into a pond, and most probably would have turned over on the slope.

An Early Motor-Car.

Another time the chain broke and the carriage ran away down a long hill, and was only stopped by running it into the bank, with no further damage than smashing the steering handle and carrying off a few yards of fencing.

The pressure at first carried was 110 lbs. and to get up any fair incline at least 100 lbs. was required; if a stop were made on the slope to allow a restive horse to pass the safety valve would immediately commence blowing. Once, on meeting a regiment of cavalry, after a few of the horses had passed by the valves began to roar, so the stoker was compelled to hold them down till all had gone by. But when the two cylinders were put in the pressure on the road was kept at 80 lbs., so there was a large margin left before the valves lifted.

Justice Romer last week sanctioned a petition by the Burnley and District Tramway Company (Limited) for the confirmation of special resolutions enabling the Company to add to its memorandum of association power to run motor-cars and omnibuses as well as tramcars.

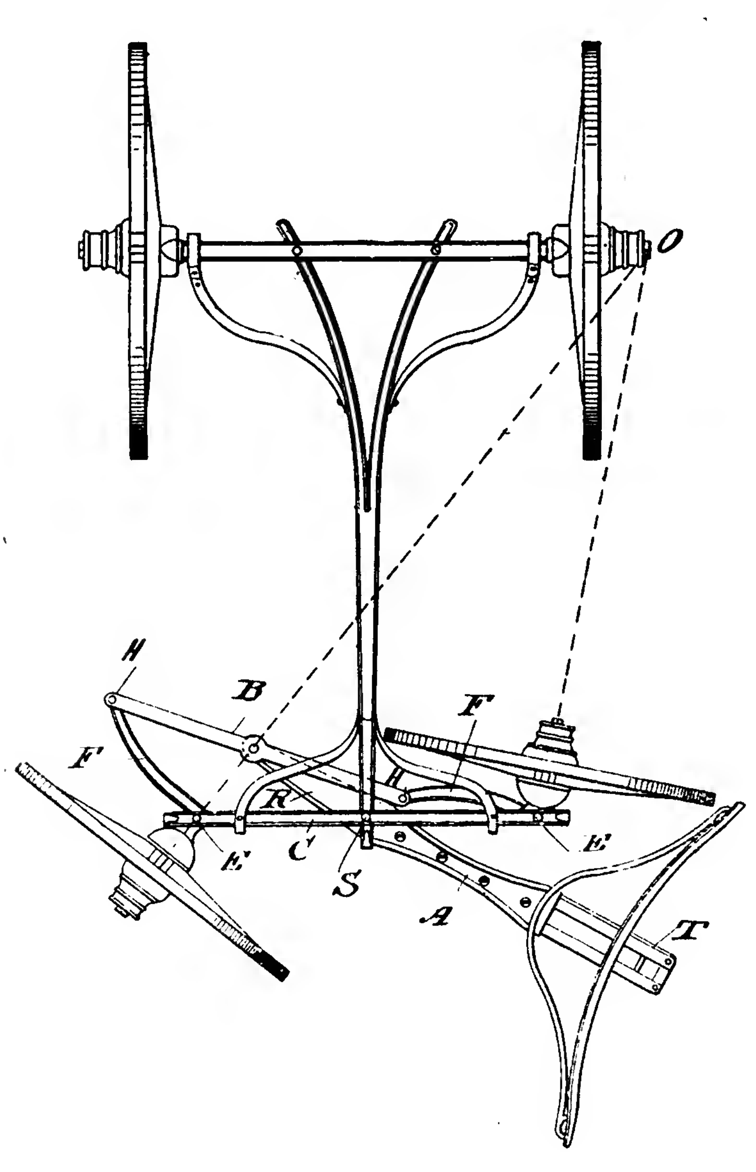
MR. BRUFORD ON AUTOMOTORS.

At Hinckley, on March 27th, the subject of Horseless Carriages was dealt with by Mr. G. J. Bruford in an illustrated lecture. The Rev. D. Stephens, before introducing the lecturer, called attention to the enormous strides and changes during the Victorian age that had come over our methods of locomotion. Sixty years ago, people who could not afford to maintain a large establishment and keep horses and carriages had to walk, as nature originally intended they should, but such an important development had since taken place with regard to locomotion that nowadays nearly everybody rode cycles, and probably in the near future motor-cars would come into general use. The commencement of the Victorian era was marked by a period of carriageless horses; to-day we had horseless carriages. Mr. Bruford said he claimed that in time the autocar would prove the greatest benefactor to the overworked quadruped, which was more often treated as the poor slave of man. He pointed out that one of the most prominent and practical horseless carriages now produced was made in Coventry, where large factories had been acquired for the manufacture of this latest form of conveyance. Electricity was what they had to look to as the ideal power for propelling these vehicles, but the chief difficulty at present was the storing of the electricity. The lecturer also pointed out that nearly every autocar which had been running in this country up to the present time was made abroad, with the result that English money had gone elsewhere. Now, however, large factories in Coventry and other places were as busy as they could be in bringing out these vehicles, so that they would see more and more of them every week.

Before the Sheffield Society of Engineers and Metallurgists, at the Technical School, on Monday evening, the President, Mr. T. W. Sorby, in the chair, Mr. Wm. Cleland, M.I. Mech. E., gave a lecture on "Motor-Cars, or Horseless Carriages." The lecturer gave a short historical account of the motor-car, described in detail the different kinds of motive power and motor employed, the different methods of transmission of the power to the driving wheels, &c., concluding with an account of the present position of the motor-car industry, and stated that the industry was being seriously injured by the company promoter. The Chairman, in moving a vote of thanks to the lecturer, proposed that a separate evening be set apart for the discussion of this most interesting subject, and this was agreed to.

ACKERMANN'S STEERING GEAR.

We have had so many applications from our readers in reference to Ackermann's Steering Gear, of which we now give an illustration, and to which a short reference was made in one of our early numbers, that we now have pleasure in giving fuller details of this interesting invention. The original patent was taken out on June 13th, 1818, and was numbered 4,212, it being



the patent of Mr. Rudolph Ackermann, Strand, London, the communication of same to our Patent Office being made through George Lenkensperger, of Munich, Germany. At the time of the sealing of the patent a good deal of interest was created by its novelty, and in the Patent Library, in a work entitled "Observations on Ackermann's Patent Movable Axles, &c.," published by J. Diggens, St. Ann's Lane, in 1819, a number of comments are passed upon it and the principles involved, the book embracing a large amount of well-merited praise from well-known coachbuilders of the day, although at the same time there is full evidence of determined opposition being made against the system by those most interested in its adoption. In this respect Ackermann's invention shared the same fate as nearly all other innovations which have subsequently been great successes. Its practical utility was afterwards demonstrated by means of an extended tour through Germany of a carriage furnished on its system.

From a very careful search made since Ackermann's patent was granted, we find practically the same principle has subsequently been the subject of at least 50 patents, one and all of which there is little doubt are clearly based upon this original. We hardly think we can improve upon the original wording of Mr. Ackermann's claim, which is as follows:—

Improvements on Axletrees Applicable to Four-wheeled Carriages.

At or near the ends of the fore transome, *C*, are holes which form the sockets wherein the vertical axles, *E*, *E*, are inserted, and they are secured by nuts, &c., in the manner of linch pins in order that the vertical axles, *E*, *E*, may turn in their sockets and form the centres round which the axle-arms have their horizontal rotary motion for the purpose of placing the fore wheels in an oblique position when the carriage is to be turned. *F*, *F*, are levers or stays projecting backward from the elbow or bend where the vertical axles and the axle-arms unite; these stays are connected together by the controlling bar, *B*, which is united to the extremities of both stays by knuckle-joints, *H*, *H*, and therefore if any motion is given to one vertical axle and axle-arm the other must partake of it. The futchel, *A*, passes through a bow or crook underneath the fore transome with which it is united by the perch-bolt, *S*, making the centre of motion for the pole, and the futchel projecting behind the fore transome forms a lever, *R*, whose centre of motion is at *S*. The controlling bar is connected with the end, *R*, of the futchel by a pin. The splinter bar, *T*, is bolted to the futchel as usual and braised by iron stays; it must be fixed at such a distance from the perch-bolt as to allow full play for the fore wheels at their greatest obliquity. In turning, the futchel moves on the perch-bolt and moves the controlling, bar, *H*, *B*, *H*, end-ways; this communicates motion to both stays, *F*, *F*, and consequently to both the axle arms and fore wheels so as to put them into an oblique direction in respect of the hind wheels and then the carriage is prepared for turning. If the distance between the two vertical axles, *E*, *E*, be made more than the distance between the joints, *H*, *H*, at the ends of the controlling bar, *B*, it will occasion that fore wheel which is on the side to which the carriage is intended to turn to have a greater degree of obliquity than the opposite wheel. This is conducive to quick turning because the axles of all the four wheels of the carriage become directed to one point, *O*, as shown by dotted lines, but if the length of the controlling bar, *B*, be made equal to the distance between the two vertical axles, then the fore wheels will always stand parallel to each other.

A limit of speed is to be imposed on motor-cars in France, but it will be less restrictive than in this country. It is proposed to restrict the speed of the lighter vehicles to 20 kilometres an hour in towns and 30 kilometres in the country; while other regulations are also to be enforced in relation to reckless driving.

A Horseless Vehicle.—A ship's gig.

DOINGS OF PUBLIC COMPANIES.

The British Motor Syndicate.—Progress of the Action by Subscribers.

MR. HAYDEN COFFIN A VICTIM.—HOW HE GOT HIS MONEY BACK.—HIS SOLICITOR STILL A USEFUL SHAREHOLDER.

THE action by the subscribers to the British Motor Syndicate, to which we have already referred in previous issues, is progressing as rapidly as legal procedure will permit. The actual plaintiff is Mr. Malcolm Wagner, the defendants being the British Motor Syndicate, Messrs. Harry J. Lawson, Thomas Humber, H. H. Mulliner, Prince Ranjitsinghi, Lord Norreys, and Thomas Robinson, all these gentlemen being directors of the first-named Syndicate. The writ, which was issued on February 17th, will be supported by Sir Edward Clarke as leader. The plaintiff claims to have his name struck off the register of shareholders, and also asks for damages and the return of moneys which he was induced to subscribe through alleged misstatements in the prospectus. Mr. Wagner is nominally the only plaintiff, but in fact, we understand, his expenses will be divided amongst a number of subscribers who are in the same unfortunate position as himself, this being practically a test action which will govern the rest of the sub scribers' rights.

ON previous occasions, says the *Financial Times*, when recording the progress made by the agitation amongst the shareholders of the British Motor Syndicate (Limited) for the return of their subscriptions, we have hinted that a similar movement was likely to develop in regard to the Great Horseless Carriage Company (Limited), which is a baby of the former concern. We now learn that this movement is drawing to a head, and that the shareholders are combining, under the same leadership as the British Motor Syndicate shareholders, the counsel who is settling the pleadings in the former case having advised that the shareholders of the Great Horseless Carriage Company would have good grounds for bringing a similar action. Mr. Harry J. Lawson appears to be having a very lively spring.

IN reference to the rumoured resignation of the Earl of Winchilsea as a director of the Great Horseless Carriage Company, the noble lord has, through Messrs. Ashurst, Morris, Crisp, and Co., his solicitors, addressed the following letter to a contemporary :—

"My attention has been drawn to a statement that I have resigned the chair of the Great Horseless Carriage Company, and to the fact that this statement has been reiterated, in spite of an official letter from the Board stating that it was incorrect.

"As such an impression appears to me likely to prejudice the interests of the shareholders, I think it my duty to remove it by stating that I have taken no such step. The fact is that I have for the past two months been so unwell that I have not been allowed to see, much less to answer, my correspondence; but I am better, and hope soon to be in a position to do business again.—Your obedient servant, WINCHILSEA."

As a supplement to the articles published by the *Pall Mall Gazette* regarding the British Motor Syndicate, the following thrice interesting communication received from Mr. Munton, of Munton and Morris, the solicitors of 95A, Queen Victoria Street, is worth reading :—

"Early in January last you allowed me to take part in a correspondence in your columns as to this Syndicate. Numerous persons had written to you on the subject, and you became acquainted with the fact that my firm were solicitors for a certain shareholder whose name and my own I withheld from the public, as I neither had the consent of my client to mention his, nor did it then seem expedient that I should mention mine. It was sufficient that my client held 40 shares in the Company, and that having paid the allotment he was hesitating as to complying with the demand for calls, looking to the allegations which were appearing in your columns and elsewhere.

"I limited my personal statement to the fact that I had commenced legal proceedings to recover back the amount paid on allotment, and these being actually pending there was greater reason why I should be reticent. Circumstances have, however, since altered, and as my client sees no reason why the steps he and I have taken should not appear in chronological order in your columns, I will shortly summarise what has happened, it being no part of my province to do more than record facts.

"A GENEROUS ALLOTMENT.

"You went a very long way in one of your leaderettes to identify my client, when you were good enough to dub him as a famous light-opera singer, and I now complete the identity by saying that he is Mr. C. Hayden Coffin. It is not necessary for me to state that he is closely occupied in his profession. He has, however, a taste for investigating mechanical coutrivances, and seeing it extensively advertised that the original £1 shares in this Syndicate were so much sought after that they had been freely sold at £3 (a preliminary to issuing to the public a fresh lot of £1 shares at £2 premium), and being desirous of obtaining 20 shares by way of a toy holding, he thought he would apply for 40, seriously believing that he might not get more than half. He, however, at once received a notificatiou that the whole 40 shares for which he had applied had been allotted to him.

"He soon saw reason to think that he had better not have applied for premium shares, so much so that he wrote a letter to the secretary suggesting that his application should be vacated. His request, of course, was not acceded to, and he paid the allotment of £20, in due time receiving a demand for the first call of £50 followed by an application for the second call of like amount; and these documents tumbling in one after the other brought him to me.

"Having carefully perused the statements contained in your journal I advised Mr. Hayden Coffin not to pay the calls, and on January 6th I wrote a formal letter to the Company stating that I should be glad to know when and where the £1 shares had been dealt with at £3 and upwards as alleged. I gave a reasonable time for a reply, and no answer having arrived I resolved, looking to the smallness of the amount, to take a short cut by bringing a simple action in the Mayor's Court, London, for the return of the £20 allotment money.

"This process was served upon the Company on January 9th. On the 11th of that month I received a communication from the secretary to the effect that the Company would hand the process to their solicitors. They eventually did hand same to a well-known firm—not, however, the firm whose name appeared in all the papers as the Company's solicitors—and I was told that my measures would be resisted in every possible way. This was followed by a formal notice of appearance with an intimation that an application would be made to remove the case from the Mayor's Court to the High Court.

"AN IMPORTANT POSTSCRIPT.

"The secretary's letter emphasising the intended resistance contained, however, a footnote, which (like the lady's postscript) formed the more important part of the communication, intimating that the Company frequently had applications for £1 shares at prices varying from £2 15*s*. to £2 17*s*. 6*d*., and that if my client really desired to sell, business could be done on such terms.

"I had noticed in your columns that these identical shares were nominally quoted at less than half the price which the Company were offering me, and being anxious to test the market I walked across to the Stock Exchange and asked my broker in a casual way whether he could buy 20 shares at anything like the then public quotation. He ascertained that he could buy 20 shares at the rate of 22*s*. 6*d*. per share. I accordingly instructed him to purchase them at that price, at the same moment telegraphing the Company that I should recommend my client to sell his 40 shares at the middle price of their quotation—namely, £2 16*s.* 3*d.*

"This seemed to be a very easy way of getting what Mr. Hayden Coffin wanted, practically achieving the object of the Mayor's Court action, and my wire being followed by a firm offer from the secretary I notified to my professional adversaries that as by the course taken by their own clients the action had been reduced to vanishing point, it might remain where it was. My client accepted the offer, and in due course the case was settled on these lines.

"But now comes a point. My client can sing to the thousands, but he has not practised the art of making himself heard at company meetings, and he asked me to be trustee of his Stock Exchange purchase of 20 shares at 22*s.* 6*d.* per share. I heard that the articles of association were astoundingly rigid as to selecting shareholders—indeed, quite hampering sales—but my brokers applied that my name should be placed upon the register in respect of such newly acquired 20 shares, and after seven weeks' interval the usual certificate has come to hand.

"I have promised the numerous gentlemen who applied to my client for information and assistance that if and when occasion arises I shall be found in my place among the rank and file of the shareholders whether the meetings be held in Coventry or elsewhere, and here I take leave of the matter for the present. Indeed, I personally am just leaving for the south of Europe on business."

Hastings and St. Leonard's Cycle and Motor-Car Co.

A statutory meeting in connection with the Hastings and St. Leonard's Cycle and Motor-Car Company was held at the offices and works, Marina recently, when Councillor L. O. Glenister (chairman of directors) occupied the chair, others present being Councillors Coxeter and Slade, Messrs. H. F. Cheshire, Wingfield (manager), Gaby, J. C. Miller, Newman Chennells (managing director), G. Jenkins (secretary), and Salter.

The Secretary having read the notice convening the meeting, the directors' report was read as follows :—

"In presenting their first report, your directors congratulate the shareholders upon the bright prospects of the Company. We have a plant which will compare with any on the South Coast, and are now in fair working order, and can turn out a bicycle within fourteen days from booking order. After pointing out several excellent pieces of business which the directors had in hand, the report referred to the motor-car part of the business which so far the directors had not been able to touch, as the wholesale houses at present would not accept orders on account of the great demand for motor vehicles, but we have the promise of three orders as soon as these can be taken. In conclusion, the directors solicit the recommendation of shareholders, and no trouble will be spared to give all customers the best article at a reasonable price with prompt delivery."

Midland Cycle and Motor-Car Exhibition Co.

The first ordinary general meeting of the Midland Cycle and Motor-Car Exhibition Company (Limited) was held in Birmingham on the 31st ultimo, Mr. J. B. Burman presiding. The report stated that the first exhibition held by the Company, in Bingley Hall, in January last, was a complete success. The profits, after payment of all expenses in connection with the formation of the Company, &c., amounted to £1,052, out of which the directors recommended the payment of a dividend of 80 per cent., and to carry forward the balance to reserve.

The Chairman, in moving the adoption of the report, remarked upon the satisfactory character of the balance-sheet and the success of the first show. With the exception of 20 per cent. carried to reserve, the whole of the capital had been returned to the shareholders during the first year, and it was complimentary to know that similar companies had been formed in Manchester, Sheffield, and Leeds, and also in Melbourne. The Company had cleared off the formation expenses, and might have paid 100 per cent. and still have carried 5 per cent. to reserve, but the directors thought it wiser to pay only 80 per cent. The exhibition had been so successful that the directors' fees had come to a good deal more than was expected. The report was then adopted.

Wednesday, March 31st, was the day appointed by the Stock Exchange Committee for a special settling day in the shares of the London Electrical Cab Company, Nos. 1 to 62,768.

We notice that our enterprising contemporary, *The Scottish Wheel and Motor News*, has formed itself into a limited liability company with a capital of £2,000 in 2,000 shares of £1 each. The first subscribers are :—David R. Stavert, accountant, 10, St. Andrew Street, Edinburgh, 100 shares ; Richard W. Hawk, insurance secretary, 32, Gayfield Square, Edinburgh, 50 shares ; Henry Brown, insurance manager, 24, York Place, Edinburgh, 100 shares ; A. F. Bainbridge, printer, Tanfield, Edinburgh, 100 shares ; George Inglis, S.S.C., 19a, Hill Street, Edinburgh, 100 shares ; and R. L. Orr, advocate, 38, Great King Street, Edinburgh, 50 shares.

The Esson Motor (Limited) statutory return has been filed, showing 14 shares taken up out of a capital of £20,000 in £200 shares ; £120 per share has been called, and £1,440 has been paid, leaving £240 unpaid.

Applications have been made to the Stock Exchange Committee to appoint a special settling day in :—

Clement Gladiator and Humber (France) (Limited)—20,000 ordinary shares and 10,000 six per cent. cumulative preference shares. (Special application.)

Great Horseless Carriage Company (Limited)—36,507 shares, Nos. 1 to 36,472, and 61,473 to 61,507.

Starley Brothers and Westwood Manufacturing Company (Limited)—78,000 shares, Nos. 32,001 to 110,000.

New Issues.

For the Month ending April 12th.

Hanman's Cycle and Needle Company.

Share capital £100,000, the present issue being 85,000 £1 ordinary shares, there being offered in addition £25,000 in 6 per cent. mortgage debentures of £100 each, repayable on January 1st, 1918, and redeemable at any time at £105 per cent. on six months' notice. The prospectus states that the Company has been formed to acquire the businesses of the Hanman Cycle Company (Limited), of Sparkbrook ; Messrs. S. Thomas and Sons, of the British Needle and Fish-hook Mills, Redditch ; and the Radiant Cycle Company (Limited), also known as the A B C Cycle Company, Redditch. It is proposed to make cycle component parts and motor-cars. The purchase price is £105,000, leaving £5,000 available from the present issue for working capital.

Hearl and Tonks (1897).

Share capital £160,000, in £1 shares, divided into 50,000 7 per cent. cumulative preference and 110,000 ordinary. The Company has been formed to acquire the whole undertaking and assets of the cycle manufacturing business of Hearl and Tonks (Limited), carried on at their leasehold premises, Imperial Works, Bordesley, the Victoria and Albert Works, and the Britannia Works, all at Birmingham. The works are complete in themselves, and may be worked either jointly or independently, and are equipped with the latest machinery. The purchase price is £160,000, the vendor taking in part payment £25,000 in shares, and provides £20,000 in cash as working capital.

THE TRENCH TUBELESS TYRE COMPANY (LIMITED).

SHARE capital £200,000, in £1 shares, the present issue being 170,000 shares. The Company has been formed to acquire the patent rights of John Townsend Trench and others in an improved form of tubeless pneumatic tyre, and to manufacture and sell the same. The purchase price is £150,000. Thirty thousand shares are reserved for future issue as required to develop the business of the Company.

BRITISH "ZENITH" ADJUSTABLE CYCLE COMPANY.

SHARE capital £80,000, in £1 shares. Present issue 53,500 shares. The Company is formed to acquire, work, and exploit the British patent rights in the inventions for improvements in cycle handle bars, cranks, and pedals, the right to apply for Colonial patents, and to acquire the Tabard Works, London, S.E. Among the improvements claimed for the patents are that the handle bar can be turned so as to line with the machine, and that the cranks allow the pedals to be folded inwards. These adjustable parts can be fitted to any modern machine at a small cost. The purchase consideration is £65,000, payable as to £26,500 in shares, £10,000 in cash, and the balance in cash and shares, or either, leaving £15,000 available for working capital.

THE DIAMOND CYCLE COMPONENTS AND ENGINEERING COMPANY (LIMITED).

SHARE capital £65,000, divided into 15,000 7 per cent. cumulative preference shares and 50,000 ordinary shares of £1 each. Present issue 5,000 preference and 40,000 ordinary shares. Formed for the purpose of acquiring the New Hudson Cycle Company (Limited). The purchase money is £50,000.

BRETT'S (LIMITED).

SHARE capital £100,000, in £1 shares. Formed to acquire the business of general stampers and manufacturers of stampings in steel, iron, aluminium, and other metals for all kinds of cycle, motor-car, and general engineering work, now carried on by Brett's Stamping Company (Limited), at Coventry, and also certain patents taken out and in course of being taken out by Mr. Edward Samuel Brett. The present issue includes £20,000 of 5 per cent. mortgage debentures. The prospectus does not state what is the purchase price of the business.

MORGAN'S CHAINS AND PEDALS (LIMITED).

CAPITAL of £50,000, in ordinary shares of £1 each. The present issue is 30,000 shares. Formed to acquire the business of manufacturers of cycle and motor chains and pedals, now carried on by Morgan Brothers, at Floodgate Street, Birmingham. Messrs. Henry and J. W. Morgan (who are largely interested in the vendor company) guarantee that the minimum profit for the next two years shall not be less than £4,500 per annum. The purchase price is £20,000. This will leave £10,000 available for working capital.

WELDLESS TUBES (LIMITED).

CAPITAL £1,000,000, in preference and ordinary shares. Formed to manufacture weldless steel tubes, which are used in the construction of marine and other boilers, shafting, heating apparatus, condensers, super-heaters, boring and mining apparatus, axles, gun-carriages, cycles, &c., and to acquire, with their liabilities, the following undertakings:—Climax Weldless Tubes (Limited); the New Credenda Tube Company (Limited); the Star Tube Company (Limited); and the St. Helens Tube and Metal Company (Limited). The total purchase moneys of the four undertakings as going concerns amount to £981,000, and the capital to be provided by the present issue of shares and debentures will leave a sum of upwards of £100,000 for extensions. Present issue 475,000 6 per cent. preference shares, and 475,000 ordinary shares of £1 each, and also £150,000 of mortgage debentures.

NEW FOWLER-LANCASTER (LIMITED).

SHARE capital £100,000, in £1 shares. Formed to acquire, as a going concern, the business, property, and assets generally of Fowler, Lancaster, and Co. (Limited), electrical and mechanical engineers, autocar builders, &c., of Birmingham. The purchase price is £51,500, leaving £23,500 available for the purchase of additional plant and machinery and working capital.

PNEUMATIC TUBE MACHINE COMPANY (LIMITED) (BRAINARD'S PATENT).

CAPITAL £300,000, in £1 shares. Formed to purchase and work the British letters patent granted to Austin Brainard, of Hartford, Connecticut, U.S.A., for machines to manufacture pneumatic tubes, hose-pipe, and other similar articles. The machine can also be used for making pneumatic tube tyres for carriages and autocars, vacuum brake connecting tubes for railway carriages, &c. The purchase price is £230,000, payable as to £100,000 in fully-paid shares, and as to the balance in cash. The present issue is of 200,000 shares, of which 70,000 will be set apart for working capital.

CHAMPION WELDLESS TUBES (LIMITED).

Capital £35,000, in £1 shares. Formed to carry on business as manufacturers of weldless steel tubes used in the construction of cycles, locomotive, marine, and other boilers, motor-cars, &c. Purchase-money, £25,000.

New Companies Registered.

[Under this heading we give a full list of new Companies registered which take power to make, deal, or become interested in any manner in automotor vehicles. We shall be pleased to reply with detailed particulars to inquiries through the "Answers to Correspondents" column. All communications should be addressed to the Editor. The only stipulation which we make is that where the inquiry involves a search of the records at Somerset House—as in the case of information on the subject of the holdings of shareholders—a postal order must be enclosed to cover the Government stamp of one shilling which is charged before a search is allowed to be made.]

	Capital. £
Adjustable Handle Co. (Limited)	10,000
A. King and Co. (Limited), Peterborough	4,000
Alpe Manufacturing Syndicate (Limited)	15,000
Auster (Limited), Birmingham	25,000
Barton and Devoil (Limited)	15,000
Bath Cycle Co. (Limited)	2,000
Blumfield Manufacturing Co. (Limited), Birmingham	5,000
Brazeless and General Cycle Fittings Co. (Limited), Birmingham	60,000
Brett's (Limited), Coventry	100,000
Brierley Hill Cycle and Manufacturing Co. (Limited)	5,000
British Electrical Cycle and Motor Engineering Co. (Limited)	40,000
British Steel Ball Syndicate (Limited), Birmingham	10,000
Briton Cycle Co. (Limited), Chelmsford	2,000
Cambria Cycles (Limited), Swansea	15,000
Cameo Cycle Co. (Limited)	10,000
Challiner Carriage Tyre Syndicate (Limited)	10,000
Circular Chain Syndicate (Limited)	12,000
Clipper Pneumatic Tyre Co. (Limited)	150,000
Coventry Gear-Case and Belting Co. (Limited)	25,000

Tyre Development Syndicate (Limited)	100
Weldless Tubes (Limited)	1,000,000
William T. Smith and Co. (Limited), Bolton	20,000
Winchurch Bros. (Limited), Birmingham	2,000
Yarrow and Co. (Limited)	160,000

"PEERLESS" METAL.

This new metallic alloy, in consequence of its strength and brilliancy of colour, is particularly suitable for the framework and other parts of motor-cars, &c. "Peerless" is a white metal, closely resembling old silver in colour, and does not tarnish or oxidise by exposure to atmospheric influence, nor is it affected by salt water, while, being a solid metal of uniform quality throughout, its appearance and polished surface are improved by ordinary wear.

As the result of some extensive tests carried out by Messrs. David Kirkaldy and Son we notice that this metal, in the form of 12 B.W.G. wire, stood an ultimate stress of 87,757 lbs. per square inch with an extension in a 10-inch length of 26·3 per cent., while a 5-inch length took 19·04 twists. These figures are the means of 10 tests. Tests were also made with castings, and the mean of these showed that when cast "Peerless" had an ultimate strength of 32,567 lbs., and an elastic limit of 20,350 lbs., giving the very favourable ratio of 62·6 per cent. The ultimate extension in a 10-inch length was 7·4 per cent., while the contraction of area at the fracture amounted to 17·5 per cent. Good as these results are they were equalled, if not surpassed, by the behaviour, in Messrs. Kirkaldy's hands, of rolled strips of "Peerless," the means of which show an ultimate breaking stress of 71,402 lbs. per square inch, with an extension of 7·2 per cent. in 10 inches. The specific gravity of the alloy when cast ranges at about 8·5.

The Peerless Metal Company (Limited), of 38, Parliament Street, S.W., will furnish any further information.

CONTINENTAL NOTES.

The Automobile Club of France.

This Club, which is maintaining its premier position on the Continent in promoting the best interests of "Automobilism," has announced a contest for automobile hackney carriages, to be held in April, 1898. The Committee have forwarded us the rules and conditions to be observed at the contest, and for the information of British "motorers" we now have pleasure in giving these in full:—

COMPETITION FOR AUTOMOBILE HACKNEY CARRIAGES, APRIL, 1898.

PROGRAMME.

Art. 1.—Under the patronage and direction of the Automobile Club of France an International Competition has been arranged for mechanical motor vehicles with regard to their use in the streets of towns.

Art. 2.—The meeting will be held in Paris on April 4th, 1898, and the following days.

Art. 3.—The meeting will have reference to—

(*a.*) The net cost for the day of an automobile hackney coach in general use in Paris, which shall accomplish a course of at least 60 kilometres in the space of 16 hours. To facilitate the trial, the 60 kilometres will be accomplished in a single journey, according to the route of the road.

(*b.*) The ease and management of the carriage.

(*c.*) The frequency of recharging; the extent of repairs needed, and the ease with which these were effected.

Art. 4.—Being accepted for the competition, all vehicles furnished with a mechanical motor, whatever the system, shall be classed in one of the following categories:—

I.—(*a.*) Closed carriages with two places.
(*b.*) Open carriages with two places, with hood.
(*c.*) Mixed carriages, with two places, able to shut or open instantly.

II.—(*a.*) Closed carriages with four places, with place for luggage (30 kilos. each traveller).
(*b.*) Open carriages with four places, with hood.

III.—Closed carriages with six places, with place for luggage (30 kilos. each traveller).

Art. 5.—The vehicles must be constructed so that the number of travellers indicated can be comfortably seated. They must be furnished with a kilometrique meter, with two brakes, one progressive and the other instantaneous. They must be capable of moving backwards. The position of the driver will be such that, having the steering and the levers beneath his hand, he is yet able to conveniently see the road in front of the carriage.

Art. 6.—The number of vehicles to be entered by each competitor is not limited, but a constructor cannot enter several vehicles of the same type and similar dimensions.

Art. 7.—For every vehicle engaged there will be paid an entrance fee of 200 francs up till February 28th, 1898, and a double fee after that date. The list of entries will be closed on March 15th, 1898, at midnight. Every application for entry should be accompanied by the fee for entry, which will remain in every case at the office of the Automobile Club of France.

Art. 8.—At least three days before the meeting each constructor will send to the Committee a note accompanied by:—

1. The description of the vehicle and its motor.
2. The distribution of weights on the axletrees.
3. A specification of the motive power operating the motor, and the quantity necessary for the day's work; indicating further if the charging of the carriage should be renewed during the prescribed course, which will comprise a duration of 10 hours.

Art. 9.—The competitors must send, at convenient times, to the localities designated by the Committee the supplies for motive power necessary to effect the whole of the competitive trials. Under the direction of the Committee there will be delivered to each driver :—

1. A printed book.
2. A sheet of the daily route.

On one of the leaves of the book the driver will give a receipt for oil, fuel, or the motive power which will be delivered to him on departing from the depôt, or in the course of the service, if he requires to renew his supply. The quantity of water necessary for the working of the motors will be entered in the book under the supervision of the manager or the Club's agents; if this water should be renewed in the course of the route it is also to be entered in the book. The daily route sheet is to be returned in the eveuing to the Coutroller's office, signed by one of the managers or by the Club's agent, who will have accompanied the carriage during the day. It will relate any iucidents which may have arisen during the day. Any excess of supplies will be deducted each evening upon the return of the vehicle.

Art. 10.—The trial will be composed of a service of 15 consecutive days. Fifteeu different routes will be selected, and each one of the vehicles engaged should accomplish these routes in the order indicated to them on the daily route sheet. The route sheets will be arranged upon the basis of ordinary horse vehicles, so as to approach as nearly as possible the practical daily routine of a hackney carriage. The speed in Paris should not exceed 20 kilometres an hour. The speed on certain inclines indicated on the route sheet to be noted. A special commissary, chosen among the members of the Automobile Club of France, will accompany each of the carriages during the time of these trials. The vehicles should accomplish the number of journeys and carry the weight of baggage indicated, or the corresponding weight (whether 70 kilos. by passengers and 30 kilos. of baggage) in dead weight.

Art. 11.—In the special localities approved by the Automobile Club, and where all the carriages should be housed, properly commissioned agents will be stationed with full control. These agents will deliver the supplies to the competitors, and will collect every day for the Committee the route sheets of the day before and the receipts of the drivers. They will superiutend the repairs which are to be made to the carriages or to the motors, pointing out the nature of the repairs. The repairs should be made before putting the carriage into the coach-house. These repairs should be recorded in the book.

Art. 12.—The recharging of the accumulators of the electric carriages will be made uuder the supervisiou of the controlling agents, but the responsibility will rest with the representative of the competitor, who should assist at it. The current will be furnished either by the means of a special installation, or by the nearest street sector. A special electric metre, of a type to be agreed upon by the Committee for each carriage, will iudicate the quantity of electricity absorbed, and the duration of each recharge. The expenses sustained by the electric charging will be borne by the competitors in the proportion of the energy which will be furnished to them.

N.B.—The Electric Sector of the Place Clichy has offered the *Kilowatt*, from midnight to 5 o'clock in the evening, at a price of 30 c. It is at this price that the cost of recharging an electric carriage will be calculated, in whatever way the recharge is accomplished.

Art. 13.—A jury composed of 12 members, taken from among the members of the Automobile Club of France, will be elected; six members by the Committee and six by the competitors. The competitors cannot form part of the jury. This jury will draw up a report, giving the net daily cost of the traction of each carriage and the regularity of the service. It should record its judgment on the elegance of the appearance, the noise of the vehicle, and the convenience for passengers. This report will be communicated to the Society of Civil Engineers of France and to different societies, and an extract from it will be addressed to all the Mayors of the chief towns of the department and district.

Art. 14.—Medals and diplomas will be given to the vehicles which are recognised as presenting the required conditions for the service of hackney coaches in towns. If prizes are offered for the competition, the conditions of acceptance will be regulated by the Commission, and the awards will be made by the jury.

Art. 15.—The competitors must conform to the decisions of the Committee of the competitions, particularly in the details of organisation and tests.

Art. 16.—The ordinary civil and penal responsibilities attaching to road locomotion will rest with the competitors, it being well understood that the Automobile Club of France declines all responsibility of any nature whatever. The competitors should conform to all the ordinary regulations and decisions of the police in force for hackney carriages and automobiles.

Motor-Cycle Race (Criterium des Motocycles).

This annual race, originated by our excellent contemporary, the Paris *Velo*, took place on Sunday, April 4th, in terrible weather. The event was open to all kinds of motor-cycles, so long as their weight did not exceed 200 kilos. (about 450 lbs.). Prizes of £40, £20, £12, and £8 were given to the first four. Distance, 100 kilometres (62½ miles), on the road.

A start was made from Moutgeron at 10.3 a.m., there being 14 competitors only out of an entry of 85. These were M.M. Thevin (No. 1), Honry (No. 2), Giradot (No. 5), Charron (No. 7), Mouter (No. 8), Maubo-sin (No. 16), Bouton (No. 32), Comte de Chasseloup Laubat (No. 33), Pietri (No. 40), Chesnay (No. 54), Feray (No. 58), Bertrand (No. 59), Feron (No. 60), Viet (No. 62).

All these geutlemen drove Dion-Bouton petroleum motor-tricycles.

The order of arrival at Melun was :—

No. 7 at 10 h. 40 m.	No. 40 at 10 h. 47 m.
No. 8 at 10 h. 41 m.	No. 51 at 10 h. 47 m. 15 s.
No. 58 at 10 h. 42 m.	No. 16 at 10 h. 48 m.
No. 62 at 10 h. 42 m. 30 s.	No. 32 at 10 h. 52 m. 45 s.
No. 5 at 10 h. 44 m.	Nos. 1 and 2 at 10 h. 57 m.
No. 38 at 10 h. 44 m. 20 s.	No. 60 at 10 h. 57 m. 30 s.

At Ozoir-la-Ferrière, Charron (No. 7) arrived first at 11 h. 35 m. 40 s., Mouter (No. 8), second, at 11 h. 36 m. 37 s., being followed by Nos. 58, 62, &c. At Melun, on the return journey, Charron still retained the lead at 12 h. 24 m., with Mouter almost neck and neck. The finish at Moutgeron was No. 62 first, the time being 3 h. 9 m. 5⅘ s.; the rest of the survivors coming in as follows:—Nos. 7, 8, 5, 58, 40, 16, 33, 54, 60, the last arrival's time being 4 h. 37 m. M. Charron, the second in, was only beaten by about 2 feet. M. Charron had a good lead all the way, but on nearing home the motor would not run properly owing to the lubricating oil becoming exhausted, and M. Viet secured the victory solely because he was using an automatic lubricator. From a technical point of view the race had little or no interest.

ALCOLITE.

We have been shown specimens of a new aluminium alloy which, while it possesses all the beauty of appearance of the lightest of metals, is endowed with many considerable mechanical advantages over it.

Alcolite in weight compares with steel in the ratio of 2·89 to 8, while its breaking point, in teusion, is equal to 43,300 lbs., or 19·38 tons, per square inch when cast, these figures increasing to 22 tons per square inch in a finished tube. As is well known a steel tube loses one-third and upwards of its strength at a brazed joint; with alcolite, on the contrary, the joint forms the strongest part of the tube. The new metal welds easily and perfectly, and as it successfully resists the attacks of all acids, excepting hydrochlorine, it is practically incorrodible, and particularly adapted for the construction of motor and cycle frames and other parts which it is desired shall be light and strong and yet remain of a dull silvery white untarnished colour.

CORRESPONDENCE

A MOTOR-CAR RUN OF 300 MILES.

To the Editor of THE AUTOMOTOR AND HORSELESS VEHICLE JOURNAL.

DEAR SIR,—It may interest your readers to know that I have just completed a ride of 300 miles on a Peugeot autocar fitted with Daimler motor.

An average speed of 12 miles per hour was maintained without any breakdown or stoppage other than required for changing water. The consumption of oil did not exceed one gallon for 25 miles, and I may say that no autocar could give better satisfaction. It can be handled with ease, and is under perfect control; it will climb a hill 1 in 8, with four passengers, at the rate of four miles per hour.

The horse power is 3½ brake. I will send you next week photo of this car after the 300 mile journey.—I am, dear Sir, yours truly, F. J. WELLINGTON.

The Indestructible Ignition Tube Syndicate (Ltd.),
100c, Queen Victoria Street, London, E.C., *April 2nd*, 1897.

[The photograph referred to by Mr. Wellington is reproduced on page 267. We think we recognise the car as the same which we illustrated in our December issue (page 117), in which case it is the British Motor Syndicate *v.* Hon. C. S. Rolls's car, now famous by means of red ink and other advertisements. —EDITOR.]

IMPERIAL VICTORIAN EXHIBITION, CRYSTAL PALACE, MAY, 1897.

To the Editor of THE AUTOMOTOR AND HORSELESS VEHICLE JOURNAL.

SIR,—Having been appointed by the Crystal Palace Company with Mr. R. Applegarth, the Commissioner for the above exhibition, to organise a Motor Section, I should be obliged if you would kindly allow me space to bring the matter before your readers.

It is intended to allow carriages to run in various parts of the grounds, and if possible to organise a service between the Low Level Station and the main building of the Palace on the one hand, and the cycle track, cricket ground, and lower lakes on the other.

With such a plan as this it is thought that the carriages would be of practical use, and there would be every opportunity of showing their regular working and reliability.

One of the chief objects I had in view in taking up this matter was to be in a position to afford facilities to all interested in the motor-car movement to show their carriages to best advantage and increase business thereby.

In order to make the terms as easy as possible, there will be no entrance fee, and all that the owners of the motor-carriages will have to do will be to provide the carriage and driver with fuel required for running, while storage with every possible facility will be afforded by the Crystal Palace.

Favourable arrangements will be made with regard to the takings, so that it is quite possible that a first-class advertisement may be obtained free of cost to the owners.

I wish to remind autocarists that *The Engineer* competition takes place at the end of May, and the owners of vehicles running in the grounds prior to that date would gain valuable information of the gradients, roads, &c., to be passed over.

The owners of some vehicles have already signified their intention of sending carriages, and I hope the opportunity will be taken by the leading makers to show some of their latest manufactures to the many thousands who will be visiting the exhibition. I shall be pleased to afford any further information, and apologising for the length of this letter,

I remain, yours faithfully,
24, Budge Row, Cannon Street, H. J. DOWSING.
London, E.C., *April 2nd*, 1897.

EASTER TOUR. ALTERATION OF ARRANGEMENTS

To the Editor of THE AUTOMOTOR AND HORSELESS VEHICLE JOURNAL.

DEAR SIR,—I beg to inform you that it has been found necessary to modify the published arrangements regarding the above.

The Tour will take place on Tuesday, April 27th. In order to afford a more lengthy and satisfactory test, the ride will take place from Coventry to Birmingham, a distance of twenty miles.

Below I give a synopsis of the programme:—

Mid-day, April 27th. Light Luncheon at Coventry.
Procession to Birmingham. (The Birmingham cyclists will be invited to meet us.)
Parade of all motor-cars and motor cycles in Birmingham.
Dinner at the Grand Hotel at 6 o'clock, at which the Lord Mayor of Birmingham has been asked to preside.
Demonstrations will take place, and explanatory lectures will be given, with addresses on the present position of the motor-car industry.

In all other respects the original programme will be adhered to. I regret, however, that it will be impossible to guarantee seats for members unless they have already applied. Brakes, however, will be provided for members to accompany the cars, and arrangements are being made to enable members to change places from time to time, in order to give each one an opportunity of testing the cars, if for only a short distance.—I am, dear Sir, yours obediently, C. HARRINGTON MOORE,
The Motor-Car Club. Hon. Sec.

Electric Light for Vehicles.—A new invention for lighting vehicles with electricity, generated by the motion of the vehicle itself, was exhibited last week. It is the old idea again of fixing a gearing to the hinder axle, and by an arrangement of cogs to either wheel of the vehicle sufficient power is transmitted to the dynamo to produce a light equal to upwards of 10 candle-power, according to the size and power of the dynamo. The apparatus and the lighting can be controlled either by the driver or occupant inside, and sufficient power can be stored to supply light for several hours.

THE English-speaking Americans call the man who drives a motor-car a motoneer or mutineer; the French nation calls him a wattman, or watthomme. We think a more appropriate name would be an Ohmer, or Homer, if the cockney prefers it. —*Electrical Review.*

*** IN consequence of the enormous pressure on our space this month we regret to say we have been compelled to hold over a large amount of interesting matter, including Mechanical Traction Notes, Correspondence, &c., &c.

RESULTS of all the Speed Trials hitherto held can be ascertained in full from the pages of THE AUTOMOTOR AND HORSELESS VEHICLE DIARY AND POCKET-BOOK for 1897, which contains over 100 pages of information. Price 6*d.*; post free, 7*d.*, of Messrs. F. King and Co., 62, St. Martin's Lane, W.C.

NEW INVENTIONS.

Claiming particularly to apply directly or indirectly to Motor Vehicles, &c.

Compiled for "THE AUTOMOTOR AND HORSELESS VEHICLE JOURNAL" by HERBERT HADDAN and Co., Registered Patent Agents, of 18, Buckingham Street, Strand, W.C., London.

*** *At the request of a number of subscribers we are pleased to announce that for the future we have arranged to more thoroughly cover the field of completed Patents referring to the Motor-Car Industry, by reproducing the latest Specifications and Diagrams.*

Specifications Published.

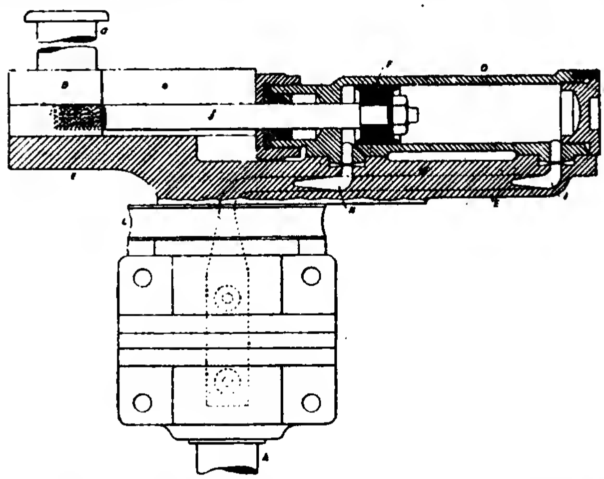
5,475. Locomotive Carriages. Ernest John Clubbe and Alfred William Southey, 16, Elm Street, Gray's Inn Road, Middlesex. March 11th, 1896.

This invention relates to the propulsion of locomotive carriages through the medium of a circulating column of fluid, whereby power is transmitted from a pump actuated by a motor to hydraulic engines coupled to the driving-wheel axles.

The invention relates, secondly, to the mode of suspending the hydraulic engines for propelling the vehicle, so as to combine lightness with freedom from prejudicial effects by vibration and jolting.

A is the shaft of the prime motor of any kind, running at a constant speed, and mounted in a bearing, B. C is the crank pin, coupled by a link to the piston of the hydraulic pump (not shown), the stroke of which is varied, for the purpose above stated, by varying the effective radius of the crank arm. For this purpose the crank pin is carried by a crosshead, D, fitted to slide between longitudinal gibs, *e*, on the crank arm, E, in one with the shaft, A, and it is attached to the rod, *f*, of the piston, F, of a double-acting hydraulic cylinder, G, mounted on the crank arm, E, and whose opposite ends are in connection with passages, H I, through the crank arms, E, and through the shaft, A. These passages, H I, respectively communicate through radial orifices with annular passages in the shaft bearing, to which are connected pipes which are controlled by a two-way hand operated valve, whereby the two ends of the cylinder, G, may be interchangeably connected with the flow and return circulation pipes connecting the delivery and admission of the pump with the admission and exhaust chambers common to two independent pairs of hydraulic engines actuating the independent driving-wheel axles. The area of the cylinder, G, must be larger than that of the cylinder of the pump, in order that the crank pin may be moved against the pressure of the pump. By suitably operating the valve the water pressure may be admitted to either end of the cylinder, G, to move the crank, C, for the purpose of altering its radius as required, and after being so adjusted the valve may be turned so as to lock the water in both ends of the cylinder, and so maintain the crank at whatever effective radius it is set. L is an eccentric on the motor shaft for working the pump valves.

Referring to the second part of the invention. In engines of the double-acting oscillating inclined cylinder type, the pistons of the two cylinders of a pair are coupled to the same crank, and in order to combine lightness and freedom from the prejudicial effect of vibration of the vehicle body and jolting of the wheel axle consequent on the play of the vehicle springs, each cylinder is mounted by trunnions at its outer end in a U-shaped sling frame formed of a pair of radius links, connected together at their outer ends by a



crosshead, and coupled at their inner ends to the crank shaft, the outer ends of these radius sling frames being suspended by spiral or other springs attached to the under-frame or body of the vehicle. The sling frames of the two engines of a pair are normally inclined at about 120° to each other, so that these frames, and the cylinders which they support, participate only in the vertical jolting motions of the axle by describing limited angular movements which do not materially affect the action of the engines, the fluid circulating pipes connected to the trunnions being of sufficient length to permit of this slight angular motion of the cylinder supporting frame.

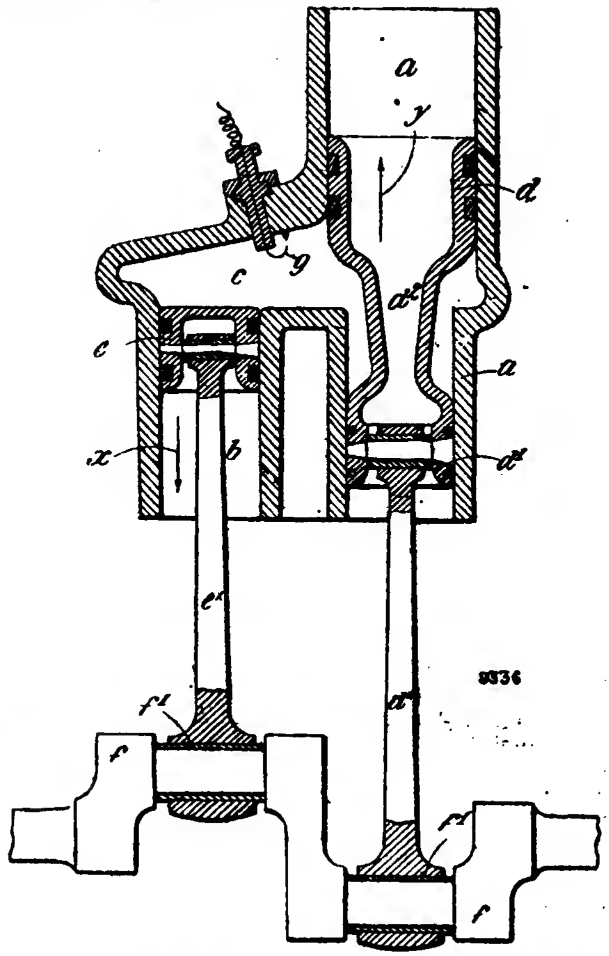
9,336. Explosion Motors. Count Albert de Dion and Georges Bouton, Puteaux (Seine), France. May 2nd, 1896.

This invention relates to improvements in explosion motors, and has for its object to obtain equilibrium of the forces exerted by the explosion of the gaseous mixture, thereby almost entirely doing away with vibrations or unsteady working.

a and *b* are the two cylinders which communicate with each other through a space or chamber, *c*, serving as the combustion chamber. The cylinder, *a*, consists of two portions, the lower of which is of the same sectional area as the cylinder, *b*, and is arranged parallel therewith, while the upper one is of larger sectional area; in this case double that of the lower portion, and is arranged axially in line with such lower portion. In the cylinder, *a*, is situated the double or differential piston, which consists of two parts, d, d^1, the former working in the upper and the latter in the lower portion of this cylinder. These parts are connected by a contracted portion or neck, d^2, and each of them is provided with suitable packing rings after the manner of an ordinary piston. In the cylinder, *b*, is arranged the ordinary or simple piston, *e*, corresponding to the part, d^1, of the differential piston.

The two pistons are respectively connected by rods, $d^\times$, $e^\times$, with the cranks, *f*, of the driving shaft, which are situated on opposite sides of the said shaft, so that the pistons travel in opposite directions. f^1 are bushes fitted in the connecting rod ends to give a proper bearing surface. *g* is an electric igniter, which is controlled, by any suitable means, whereby the explosions can be brought about at the required times.

The area of the upper part, *d*, of the differential piston exceeds that of the lower part, d^1, thereof by an amount equal to the area of the piston, *e*. In the present instance this is brought about by making the area of the upper part, *d*, double that of the lower part, d^1, since the latter is equal in area to the said piston, *e*. The effective areas upon which the explosion acts are, therefore, equal, and the weights of the respective pistons and their connecting rods are calculated so that the moving parts are properly balanced, thus more effectually minimising vibration.

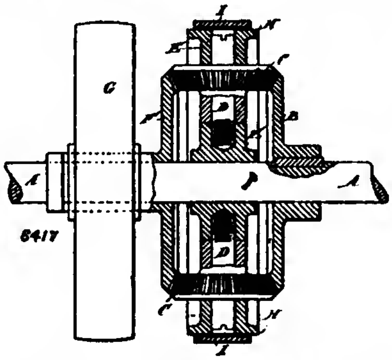


An explosive charge having been drawn or introduced into the combustion chamber, *c*, and ignited therein by the igniter, *g*, the piston, *e*, is propelled by the explosion in the direction shown by the arrow, *x*, while the differential piston is simultaneously propelled in the opposite direction indicated by the arrow, *y*.

6,417. Driving Gear for Motor Carriages. Herbert John Dowsing, 35, Queen Victoria Street, London, and Frederick Bremer, 1, Connaught Road, Walthamstow, Essex. March 23rd, 1896.

This invention relates to new or improved gear for transmitting motion from the steam, gas, oil, electric, or other motive-power engines of what are known as self-moving or motor carriages, to the axles and wheels of such carriages; and the chief objects of the invention are to provide means for applying the power gradually to the wheels, so as to enable the carriage to be started and stopped quietly and without shock; to arrange the gearing in a compact form, and obviate in some cases the use of intermediate shafting; and to combine with such gearing, when necessary or desirable, the usual balance gear to compensate for the unequal diameters, or the unequal number of revolutions of the wheels on opposite sides of the carriage.

Fixed on the wheel axle, A, is a toothed wheel, B, which gears one or more pinions, C, turning on suitable pivots or bearings, D, in a disc, E, arranged to run loosely on the said axle. Also running loosely on the said axle is another toothed wheel, F, which likewise gears with the pinion or pinions on the disc. Rotatory motion is imparted to the last-mentioned toothed-wheel, F, by means of a belt passing round a pulley, G, secured to or formed with the said wheel, F, or by means of any other suitable gearing, whenever the motive-power engine is in motion. The periphery, H, of the aforesaid disc is fitted with a frictional brake strap, I. It will now be understood that when the brake strap, I, is held free of the periphery, H, of the disc, E, the latter is free to rotate on the axle, and is so rotated, by the toothed wheel, F, causing the pinion or pinions, C, in the disc, E, to rotate so as to run planet-wise round the toothed wheel, B, which is fixed on the axle, without imparting motion to such wheel or to the axle. If now the brake strap, I, is applied to the periphery, H, of the disc, E, the latter is gradually brought to rest; but the continued rotation of its pinion or pinions, C, on its or their axes, D, causes the toothed wheel, B, fixed on the axle, and consequently the axle itself, to rotate. On again slackening the brake strap, I, on the disc, E, the latter is allowed to revolve, and its pinion or pinions



resume their planet-like motion round the wheel, B, fixed on the axle, and they then cease to drive such wheel, so that it and the axle are allowed to come to rest.

By making the wheel, F, smaller than the wheel, B, arranging the latter so that the planet pinions, C, do not come in contact with it, and providing other planet pinions connected with the pinions, C, and adapted to gear with the larger wheel, B, the wheel, F, may be caused to exert considerably greater turning power upon the axle, A, than when the two wheels, F and B, are of the same diameter, or by the reverse arrangement, namely, making the wheel, F, larger than the wheel, B, and arranging the planet pinions accordingly, increased speed of rotation of the axle, A, may be obtained at the expense of power. A modified form of gear is also described.

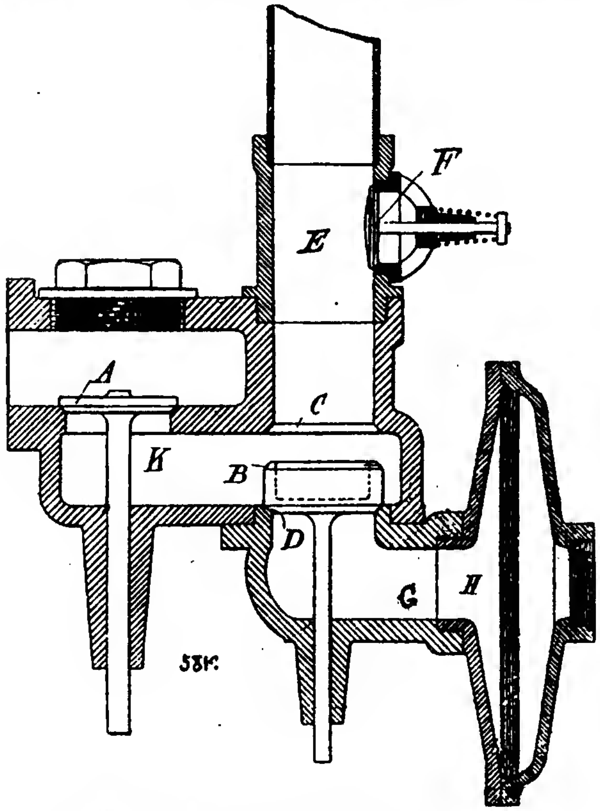
5,814. Gas and Oil Motors. Frederick William Lanchester, of Cobley Hill, Alvechurch, Worcester. March 16th, 1896.

Relates to improvements in the charging, exhausting, and governing arrangements of gas and oil motor engines.

Opening directly into or communicating with the cylinder is a main valve, A, of the ordinary lift type, this valve being operated at the proper moment from a cam on a side shaft and returned to its seat by a spring every alternate revolution of the engine. The under portion, or eduction side, of this valve leads to a short chamber, K, having two valve-seated openings, C and D, placed concentric with and opposite each other on either side of the chamber, K. These two valve-seated openings lead respectively, one, C, into the exhaust pipe, E, and the other, D, by a suitable port or passage to, G, the oil vapour and air supply. A double-seated lift valve, B, is placed between these openings, C and D, and it is made of a suitable depth, so that when it closes the opening leading to the air and vapour supply, that leading to the exhaust pipe is left clear, and *vice versâ*; a suitable lift brings it against and closes the exhaust opening, while leaving the passage free to the vapour and air supply. This double-seated valve is preferably operated by a governor of the usual gas-engine hit and miss type.

The operation is as follows:—The engine piston makes a forward or suction stroke, and during this time the main valve, A, is held open while the double-seated valve, B, is lifted so that the passage to the exhaust pipe is closed while that to the vapour and air supply is open, a charge of vapour and air being thus drawn into the cylinder by way of G and K; on the completion of the suction stroke the main valve, A, closes, and the double-seated valve, B, closes on to the vapour and air admission opening. The piston now makes its return stroke, and compresses the mixture, firing it when compression is complete, and then making a forward or working stroke. The main valve, A, now opens, and a return or exhausting stroke is made.

When the engine is working at full load the double-seated valve, D, now crosses over to close the exhaust aperture, and the piston draws in a new charge of combustible mixture to be in turn compressed and ignited. When a pre-arranged speed is exceeded, the governor gear causes the mechanism to miss operating the double-seated valve, B; and the motor piston then draws back a charge of exhaust gases from the exhaust pipe, E, and a missed impulse results. An automatic or other valve, as F, may be arranged on the exhaust

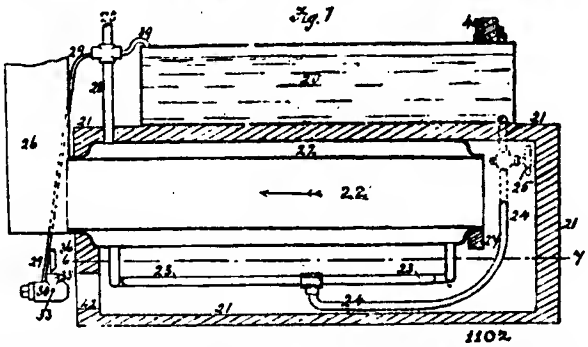


pipe, so that a certain amount of ventilation takes place at each cut out to prevent condensation of exhaust products within the motor cylinder.

To avoid back ignitions into the vapour and air supply pipe, in the port or passage, G, leading from the vaporiser, is placed a series of thick gauze copper, or other metal, screens, as H, through which the vapour and air is drawn, or it may also be drawn through granulated copper.

1,102. Road Vehicles. George Rose, Engineer, Gowanlea, Bishopbriggs, near Glasgow. January 16th, 1896.

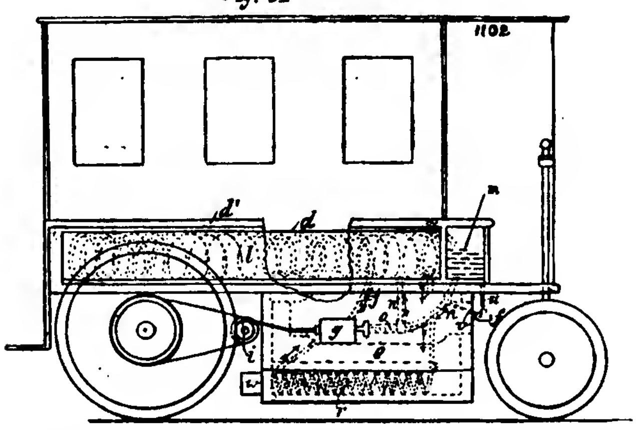
The invention especially consists in the arrangement and combination of parts of the steam generator, or the construction of same.



The generator comprises a closed metal tank, 20, for holding water to be converted into steam. It is mounted on a casing, lined with fire brick, or other suitable material. Into the casing, is fitted an annular chamber, 22, made of two metal tubes of different diameters welded together at ends, so as to constitute a strong closed main vessel, 22, for generating and superheating the steam. One end of vessel, 22, is fitted with metal chimney, 26, the other end being supported by a bridge, 27, in casing, the top being covered over by casing so that the flame shall pass along its bottom and then through its inside on way to chimney. To the underside of chamber 22, is connected the two upturned ends of a series of pipes, 23, formed on a level plane inside the combustion chamber of casing, 21, and connected at middle by a joint to the feed water inlet pipe, 24, which is led through the casing, 21, and provided outside with stop-cock, 25, and then connected to bottom of tank, 20. Fitted to top of generator, 22, is the steam main outlet pipe, 28, and connected thereto is a branch steam pipe, 29, also connected to an oil-spraying nozzle, 30.

As applied for driving a road vehicle which is mounted on two back driving-wheels and front steering wheels. A water tank, *d*, is fitted on the carriage frame under the seats, *d*[1], the steam generator

Fig. A



casing, *e*, being bolted to the underside of vehicle. Said generator may be constructed and worked by sprayed oil from a nozzle, *f*. A steam-engine or engines is mounted alongside casing, *e*, a cylinder, *g*, on both sides thereof driving the shaft, *i*, which is geared to revolve the driving-wheels in usual way. The exhaust steam is led by pipe, *j*, to a tube coil, *l*, fitted in the tank, *d*, through which the exhaust steam flows and is condensed. The condensed steam is allowed to trickle into a small tank, *m*, placed under the driver's seat, and is drawn therefrom through pipe, *n*, by a force pump, *o*, and forced into the water tank, *d*, by pipe, *n*[1]. By thus dealing with the exhaust steam noise therefrom is avoided. The two tanks, *d*, are connected together at bottom by a pipe, *p*, and at the top by a pipe, *g*, respectively, to allow the water and air to flow from each to each. A hand pump may be fitted into either tank to create pressure; the combustion products are led off by an outlet on bottom of casing into a branch flue, *w*, into which is fitted a coiled pipe, *r*, through which the water is led to bottom of steam generator in casing, *e*; oil is supplied from a tank under driver's seat by a pipe to spraying-nozzle, *f*, the steam being led thereto from the generator by pipe *v*.

2,569. Speed and Balance Gear for Motor Carriages. Ernest John Clubbe and Alfred William Southey, 16, Elm Street, Gray's Inn Road, London, W.C. February 4th, 1896.

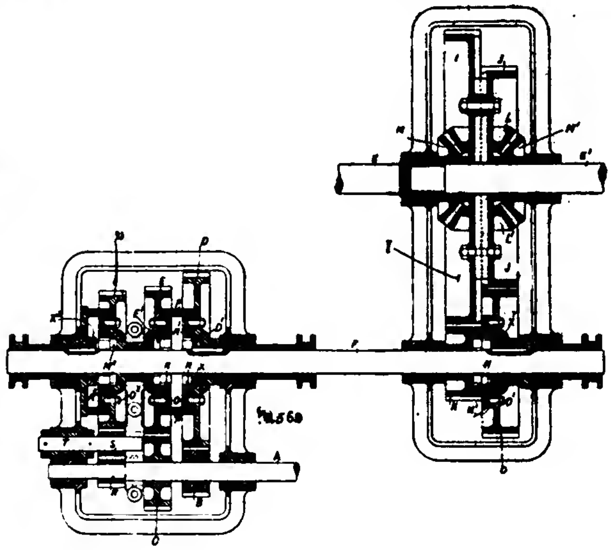
This invention relates to a combined multiple speed and balance gear for motor carriages, and it has for its object to enable the greatest number of different speeds and a balance motion to be obtained with the fewest number of parts constituting the change gear.

The first motion shaft, A, of the multiple speed gear is geared by two pinions, B, C, of different diameters keyed upon it, with two gear wheels, D, E, of correspondingly different diameters mounted loose on a second motion shaft, F, and capable of being put either the one or the other into driving connection with said shaft by a combined friction and dog-clutch of the kind described in the Specification of 2nd day of March, 1895, No. 4,518. Upon the said shaft, F, are loosely mounted two other pinions, G, H, of different diameters, which are also capable of being put into driving connection with said shaft by a similar clutch, and are in gear with spur rings, I, J, of correspondingly different diameters in one with each other, and forming the external member of a balance gear of the equational box or other form of epicyclic gear. This external member, I, J, of the balance gear rotates about the common axis of the two members, K, K[1], of the driving shafts of the vehicle, and upon radial axes carried by such external member are loosely mounted the pair of bevel pinions, L, L[1], which are in gear with a pair of bevel pinions, M, M[1], keyed on the two members, K, K[1], of the divided driving wheel axle.

By suitably adjusting the clutches on the second motion shaft, F, the following four combinations of trains of gearing may be obtained with differences of speed corresponding to the differences of ratio, viz.:—wheels B, D, G, J; C, E, H, I; B, D, H, I; C, E, G, J.

The clutch whereby either of the wheels, D, E, may be put into driving connection with shaft, F, consists of a male member, X, having peripheral dogs, and carried by a sleeve sliding upon and splined to the shaft, F, the male member engaging with corresponding dogs in a socket, D[1] or E[1], in the hub of the wheel, D or E, as the case may be. Each wheel carries a friction ring, N, also formed with dogs for engagement by the dogs of the male member, X, said ring being held friction-tight to its wheel by a spring-pressed clamping ring, N[1], secured by bolts, O, and springs as shown, the meeting faces of the friction and clamping rings being bevelled as shown so as to retain the movable friction ring, N, in concentric position and apply the pressure necessary to ensure the requisite amount of driving friction between the rings, N, N[1], so that before the male member, X, enters into, or after it passes out of, engagement with the dogs of the wheel-socket, the driving is effected during the transmission through the friction ring so as to prevent shocks. Between the friction rings of the two wheels, D, E, sufficient clearance is left in order that the male member, X, shall be free from both when in its mid position, so as to provide for the motor running free, if required.

This clutch gear is enclosed by a cylindrical casing, P, acting also as a distance-piece between the wheels, D, E.



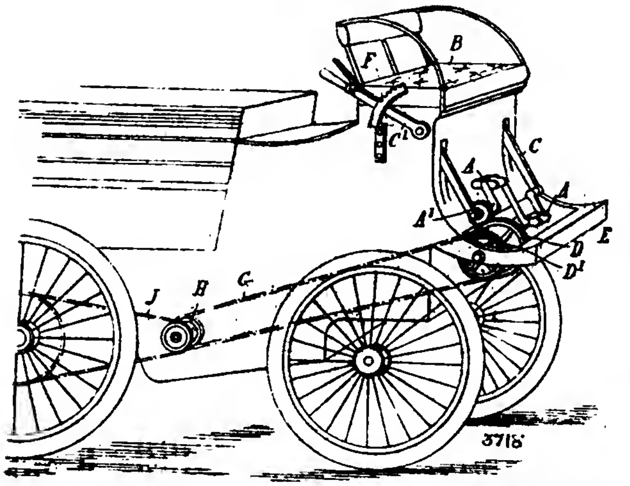
The clutch by which the one or other of the pinions, G, H, is connected with the shaft, F, is similar, except that only one friction ring, N, is employed, said ring being applied to the larger pinion, G, in the manner above described for engagement by the dogs of the male member, X[1], of the clutch which passes directly therefrom to the socket of the pinion, H, and conversely, there being in this case no need of an intermediate clearance space.

If it is required to provide for reversing the direction of running, the usual reversing device may be added, consisting of a third pinion, R, gearing through a pinion, S, on an intermediate shaft, T, with a third spur wheel, U, loose on the second motion shaft, F, and capable of being put into driving connection therewith by a clutch, X[2], M[2], similar to the one first described, except that in this case there is only one wheel to be geared with the shaft. It is essential that this clutch be not put in gear except when the clutch, X, is out of gear with both wheels, D, E.

3,718. Motor Vehicles or Traction Motors. Henry John Lawson, of 40, Holborn Viaduct, London. February 18th, 1896.

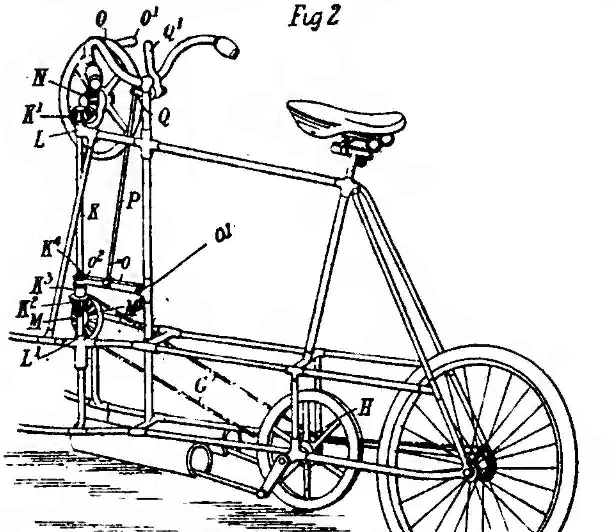
Relates to motor vehicles or traction motors, and the object is to enable the person in charge of the vehicle to back or move the vehicle for short distances so as to bring it to any required position, or to start the motor.

Fig 1



In the arrangement illustrated in Fig. 1, the pedals, A, are arranged to be put in or out of gear and operated by the driver seated on the box, B, of the vehicle. The pedals, A, together with a small pinion wheel, A^1, which is operated by them, are carried in bearings at the ends of the arms, C, of a U-shaped frame, which is pivoted beneath the seat, B, in such a manner that the frame, C, may be swung forward or back by the movement of a handle, C^1, connected thereto,

Fig 2



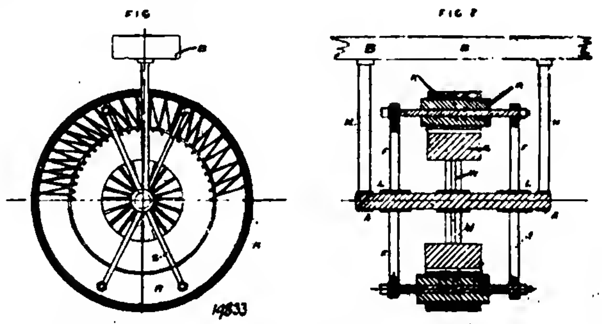
and arranged at the side of the seat. A toothed wheel, D, together with a chain-wheel, D^1, are carried by a short spindle in bearings in the footboard, E, the toothed wheel, D, being so arranged that on swinging the frame, C, forwards the pinion, A^1, may be caused to engage with the toothed wheel, D, the handle, C^1, being provided with a spring catch to engage with a toothed rack, F, in order to maintain the engagement of these wheels. A chain, G, passing over the chain-wheel, D^1, and over another chain-wheel, H, on the motor shaft, affords a connection by means of which the motor, and consequently the vehicle, the driving wheels of which are connected with the motor shaft by another chain, J, may be moved by operation of the pedals on the box. A ratchet and pawl, clutch or disconnecting gear may be used if desired.

The rear portion of the motor tricycle, illustrated in Fig. 2, is shown to be provided with an arrangement for starting or backing the same, this arrangement being adapted to be operated by hand. In this device a vertical shaft, K, carrying bevel-wheels, K^1 and K^2, is arranged to run in bearings, L and L^1, in the framing of the machine. The lower bevel-wheel, K^2, on this shaft engages with another bevel-wheel, M, carried by a spindle which also carries a chain-wheel, M^1, this spindle being arranged horizontally. A chain, G, connects the chain-wheel, M^1, with the chain-wheel, H, on the motor shaft. Engaging with the upper bevel-wheel, K^1, is a bevel-wheel, N, upon a spindle, which carries a band-wheel, O, provided with a handle, O^1. To enable this mechanism to be disengaged when desired, the lower bevel-wheel, K^2, is provided with a short sleeve, K^3, and is arranged to slide longitudinally upon the shaft, K, but caused to rotate therewith by means of a feather, K^4. A lever, O, pivoted to the framing at O^1, is provided at its free end with a fork, O^2, which engages with a groove in the sleeve, K^3, a rod, P, connects the lever, O, with a bent lever, Q, which has a handle, Q^1, by the manipulation of which it will be readily understood that the bevel-wheel, K^2, may be moved down or up the shaft, K, so as to be in or out of engagement with the bevel-wheel, M. It is obvious that other similar arrangements may be employed.

19,833. Electrical Propulsion of Vehicles. Anthony George New and Arthur James Mayne, of Palace Chambers, Westminster. October 22nd, 1895.

Relates particularly to cycles and other vehicles intended for use on roadways, and consists in arranging the rotating part of the motor or motors as the direct traction wheel of the vehicle.

The "stator," S, of this polyphase motor is shown inside the "rotor," R, the perforations for the windings alone being indicated, and is secured by the web, W, to the fixed axle of the vehicle, A. This axle, A, is secured by the standards, H, to the bottom board, B, or any other suitable portion of the vehicle. The "rotor," R, is bolted to the arms, F F, forming a second web and turning on the axle, A, in the bearings, L L.



The external rim, K, is the tyre of the wheel thus formed.

The same arrangement may be adopted with a direct current motor, S, being in that case the stationary part of the motor, while the rotating part (which would in that case be preferably the armature) is arranged as is R in the drawings, in which case it will have to be connected with a commutator in the ordinary manner.

25,210. Improvements relating to Axles and Axle-boxes. Ronald John Livingstone Hildyard, of Cue, Western Australia. November 10th, 1896.

A is the axle, provided with an internal chamber or reservoir, B, for lubricant; C is the axle-box (shown in section), enclosing the axle, A. The reservoir, B, is charged through the plug-hole, *b*, and the lubricant finds its way to the axle-box through the open end of the axle, and through holes, *a*, pierced in the axle. The axle-box, at its outer end, is closed, but it has the plug-hole, *c*, furnished with a screw plug, which plug-hole, when open, provides means for flushing out the reservoir and axle-box, when required, by hot water, kerosine, or other cleansing liquid, poured in at the hole, *b*.

"THE MOTOR TYRE."

Inventors:—JESSOP BROWNE & JAMES PREECE. *Provisional Protection.*

The Illustration represents the latest, and as the Inventors believe the very best and most reliable solid rubber Tyre on the Market for heavy vehicles, Omnibuses, Motor Car Vans, &c.
It is firmly secured with brass tube and eyelet bolts.

ITS ADVANTAGES ARE, VIZ:—

SECTION 1.

Coming off an impossibility.

Easily repaired by ordinary workmen.

Cheaper and Simpler than Pneumatics.

Once fixed holds firm until worn out.

Rubber not cut by rims when weighted.

TRIAL SOLICITED.

Can be made in sections.

Can be fixed to existing wheels.

As resilient as Pneumatics without danger of puncture.

Best workmanship.

Can be repaired on the roadside if required.

CORRESPONDENCE INVITED.

MANUFACTURED ONLY AT THE

CITY WHEEL WORKS, 104-107, Gt. Brunswick St.,
JESSOP BROWNE, Proprietor. **DUBLIN.**

INTERNATIONAL MOTOR CAR COMPANY,

369, EDGWARE ROAD, LONDON, W.

Sole Agents (Wholesale and Retail) for England and Colonies for the World-known

"PARISIAN" MOTOR CARS.

These beautifully made Carriages can be had in all styles. They are the leading Motor Carriages of the World, having had six years' nstant use on the roads of France and Germany. **THEY ARE NOT EXPERIMENTS,** but **PROVED SUCCESSES.** We hallenge any Maker in the World to produce a **more reliable** Motor for all round general purposes than ours. It is not likely to break down or "go wrong" at awkward moments. Our Carriages are extremely simple and reliable. They burn purified petroleum spirit which gives off practically no smell or steam. They make very little noise, and there is no vibration when the Carriage is running. They can be instantly stopped and restarted. The steering is extremely simple, and can be governed by a child. There is no flame, consequently no fear of fire. There is no limit to the distance which can be travelled. The car will run so long as it is supplied with petrol. They are very economical compared with horse-drawn carriages, and are much more pleasant to ride in. They are very handsome in appearance, nd moderate in price. **WE CAN DELIVER QUICKLY.** Those who are ired of the worries and troubles of horseflesh should take a trial trip on one of our ars, and we venture to say they will never ride behind a horse again.

EVERY CAR IS GUARANTEED.

The mere fact that over 1,000 of these Cars have been sold show

PRICES FROM £140. District Agents being appointed.

TANDEM ANTI-FRICTION METALS

Are manufactured entirely on scientific principles, and

Are claimed to be absolutely the Best Alloys for Anti-Friction purposes.

Anxious to remain

THE FOREMOST IN THE MARKET,

And to adopt any improvements, competition metals are constantly analysed by us. So far, however, we have found no reason to make any change in the composition of our Standard Alloys, which are now

The Result of Fifteen Years' Experience and Exhaustive Tests by Practical Men, and

OVER 3,000 CUSTOMERS ALL OVER THE WORLD.

TANDEM METALS fulfil better than any other their purpose, and are therefore—

The Most Economical,
The Least Wearing,
The Most Durable,
Friction Preventing,
Resistance Reducing,
Journal Preserving,
Power Increasing,
Lubricant Saving,

ANTI-FRICTION METALS.

BEWARE OF IMITATIONS OR ALLOYS SOLD AT DOUBLE OR TREBLE THEIR PRICE.

Apply for Illustrated Catalogue, Tests, Testimonials, &c., and Sample Ingots, which are forwarded free of charge.

CONTENTS.

MOTOR TRAFFIC.*

(CHIEFLY TECHNICAL.)

By SIR DAVID SALOMONS.

MY audience will probably think that it is presumptuous on my part to read another paper on the well-worn subject of self-propelled traffic on the highway. An excellent series of lectures was delivered in this room by Mr. Worby Beaumont, which dealt mainly with the history of the subject. Mr. Cunynghame also read a paper here of very considerable interest, while elsewhere a great deal has been written and said on the same question by others as well as myself, covering a sufficient amount of paper to light the fires of a large household through a long winter. Probably no lover of music would be bold enough to assert that because millions of melodious combinations have already been produced from a limited number of notes on the piano, that at no future time may we expect further combinations likely to produce a pleasant effect on the mind. May I therefore venture to think that, in dealing with the various points bearing upon the question of self-propelled traffic, there yet remain possible combinations which may prove of interest to an audience? If the proposition be true, you will possibly allow that, in addressing you on this subject once more, the presumption is not so great as it might at first sight appear. I do not propose on this occasion to discuss the pros and cons of motor traffic, as to where its uses and abuses lie, but to deal with the matter rather from a technical point of view, and to examine the patent law so far as it affects the question. The former has been already attempted, but not, to my mind, in a satisfactory manner. Too much history has been mixed up with the subject, as well as loading it with pure theory. The interest I have taken in the matter has led to the forming of a large collection of books, old and new, dealing with road traction, as well as prints and engravings illustrative of the same subject. Indeed, I doubt whether anyone has a more complete collection of the kind, and a careful perusal of the various volumes and plates is most instructive.

The two chief lessons to be learned by their study are the following:—

(1) How few patents taken out recently in connection with the subject are original.

(2) How the whole tendency of the construction of light vehicles gravitates to the better types of those in existence between the years 1820–30.

We, of course, possess an advantage over the constructors of that period, inasmuch as we have improved materials to deal with, and can therefore produce a better kind of engine and boiler, in the case of steam. Much surprise has been expressed by the uninitiated, not even excepting many engineers, as to the reason why the horse-power to be carried on the motor-propelled vehicle should be greater than when the living horse is employed. I will examine this question first. You will fully realise that if carriages had wheels no larger than the ordinary reel of cotton, the usual obstructions to be found on highways would generally be as high or higher than the diameter of the carriage-wheels; so that when the obstructions were met by the wheels, if the former were loose they would be pushed along, and if fast, progress would become practically impossible, and the wheels would be destroyed or wrenched off before the vehicle had proceeded many yards. On the other hand, if the wheels

* Read before the Society of Arts, May 12th, 1897.

were to be, say, 30 feet in diameter, even considerable obstructions on the road would not be materially felt, as the wheels would pass over them with the utmost ease. In practice such large wheels could not be used. I will therefore suppose that the usual diameters as generally seen on carriages are employed when dealing with this subject, so that the wheels are from, say, three to five feet in diameter. We all know why, thanks to the careful investigations of the late Mr. Froude and others, the fish moves with such freedom in water when it is completely immersed, the reason being that the power necessary to divide the water in advance is compensated for by the closing of the water behind the fish, which gives it a push. Its curved outline is so admirably formed that the fish is capable of moving through the fluid in which it lives with virtually nothing more than skin friction to be overcome. The same might be thought to take place in the case of a carriage rolling along a rough road —*i.e.*, the extra power required to get the wheels over an obstacle should be compensated for by the downward run when descending the other side. To some extent the theory would hold good for exceedingly rapid motion, but not for speeds permitted on high roads, and for the following reasons:—It is evident that a wheel, in surmounting an obstacle, rises gradually, but it descends through a less distance as a rule, because the obstacle, a stone for instance, has probably been sunk into the ground or broken smaller by the wheel's passage. But supposing no crushing action takes place, as might well be the case with a very light vehicle, then why should the work be harder to pull it over a rough than a smooth road? The answer is, that in passing over a rough road, the speed being slow, the sum of the pulls necessary to get over the obstructions is far greater than the sum of the accelerating forces on descents, owing to the tendency of the wheel to push into the ground before surmounting the obstacle, and this applies in all cases. If the obstructions on a highway consisted of a series of symmetrical waves, switchback in form, it is clear that the carriage would run slowly up an incline, and more quickly down. The average power used, supposing these undulations to be on an otherwise good road, would be no greater than had these undulations not existed, although the carriage would have advanced by fits and starts. In giving these various explanations I have assumed that the horse is drawing the vehicle, and the line of draught is therefore at a point somewhat higher than that of the axles—in other words, inclined backwards to the road, which is a great advantage, because the pull tends to lift the wheels over the obstructions. Supposing, now, we place the horse behind the cart and make him push it with his chest, what would be the result? The wheels, instead of being assisted in surmounting obstructions by the lifting tendency, would now tend to drive themselves into the ground behind the obstruction, and the horse, which might have advanced with the greatest of ease when placed in front, would have his work cut out to push the cart from his new place. Here we have the condition imposed upon a self-propelled vehicle. This difference between dragging and pushing is well shown in the case of a railway-truck on which porters move passengers' luggage. If the truck, when loaded, meets with an obstruction, the only way to advance easily is to turn round and pull it along. I should like for a moment to consider the manner in which the power is derived from the horse. Of course, we must all admit that primarily it is muscular action, but most people think that a horse advances solely in consequence of the anchorage obtained on the road by means of its feet, whereas there is another very important action brought into play, which those who watch these animals carefully will easily observe. It is well known that a heavy horse can drag a greater load than a light horse, and I think, when you consider the special point to which I will refer, the reason is very obvious, although of the two horses in question one need not have greater muscular power than the other. Riders are aware that during a trot, and indeed at all times, the body of the horse rises and falls. The rising of the horse is due to muscular power exercised against gravitation, whereas the fall is due to gravitation alone. Since the horse is advancing during the time, a curve of a wave-shaped form would represent graphically the rise and fall of the horse's body. It, therefore, appears evident that there is during half the period of advance, a time when gravitation materially assists the progress of the vehicle, and the greater the weight of the horse the more it will be in favour of the load being pulled. Consequently, the heavy horse has an advantage over the light one for heavy loads. It appears to me that this, what I would term undulatory advance, is in a large measure equalised by the spasmodic advance, due to the horse's feet pushing against the road, and here is to be found one of the chief reasons why the carriage runs with smoothness. No motor has ever yet been devised combining these two properties. Gordon and others invented vehicles with feet to imitate the progress of the horse, but the rising and falling of the heavy weight was absent in these devices, and may possibly have been the reason why they proved complete failures. It may readily be imagined how jerky the advance would be without this compensating governor.

Pneumatic Tyres.

A few words respecting pneumatic tyres are not out of place. An ideal road would be one of a hard elastic surface capable of permitting all inequalities to sink into it without friction, when the wheels meet any obstruction lying upon it. Such a road in practice cannot exist. It is, therefore, necessary to seek a means which will produce the same result. A pneumatic tyre, suitably constructed, will give the equivalent of the ideal road, *i.e.*, the obstructions which the tyre meets will sink into it, and the travelling load will not be raised against gravity. Losses by friction, however, remain the same. The advantages to be derived from the use of the pneumatic tyre cannot, however, be gained except by encountering many other troubles, of which those who use this class of rim are well aware. They may be summed up as the mechanical defects of the system. There is a popular notion that by the use of the pneumatic tyre advantages are always gained. This is only true if certain conditions are observed. It is evident that unless the tyre is inflated to a proper degree which must be regulated by the load, also that it shall be of sufficient diameter that the stones most generally met with on the road will sink into the tyre—the pneumatic, so to speak, must swallow all the obstructions it meets with in its path—its main virtue would be gone. Personally, I do not view with the utmost favour the pneumatic tyre, on account of the mechanical disadvantages. Indeed, if the springs of a carriage are sufficiently well made and adjusted, a circumstance rarely to be found, the advantage of the pneumatic is almost absent, and I believe that for motor traffic the steel or solid rubber tyre will prove the favourite in the long run, when sufficient attention is given to carriage springs. The chief function to be fulfilled by the carriage spring is to enable the load to travel on the level whilst the wheels of the under carriage are mounting up and down as they pass over road obstructions. The weight of the portions which rise and fall are very small, compared with the vehicle and its load. Although it has been asserted that the draft is greatly diminished by the use of pneumatic tyres, my own experience does not bear this out except in given cases. On bad roads an advantage may be gained, but on good ones the steel tyre carries the palm. Quite apart from experiments, it is only necessary to watch the pull exerted by a horse on various classes of roads with the same carriage tyred in different manners. It is found that the rubber of the pneumatic tyre will burn if the load is very heavy. Whether this is due to the successive compressions of the air when meeting obstructions on the road, or whether it is owing to the friction of the air in the tube, due to lag in having to pass through a very restricted opening in a portion of a tube, *i.e.*, that part which is in contact with the road, and to friction generally, it is difficult to say. The fact is there. Messrs. de Dion and Bouton had the greatest trouble on this score with their tractors, and finally decided to fall back on the solid rubber. It is quite possible to make a pneumatic tyre suitable for very heavy roads, but the thickness and size would be so great, that the advantages to be derived would be virtually absent. In the case of cycles and motor-vehicles of that type, the pneumatic tyre is an undoubted advantage, for in one case it removes much of the vibration from the feet, which would be conducted to the body, and in the other it might be found difficult to introduce suitable springs on the ground of the weight or of expense. The pneumatic axle is the true solution to the trouble, when a satisfactory one is made. The horse is able to start a carriage by exerting his maximum power. He anchors his feet to the road, throwing forward and dropping the weight of his body. An engine, however, does not possess this property. An engine of any given horse-power has its capacity calculated for a given rate of speed. For instance, if a six brake horse-power motor is purchased with a normal speed of 300 revolutions per minute, it is understood that this brake horse-power will only be given off when the speed in question is reached, at a given gaseous pressure in the cylinder. Consequently, when the crank, or its equivalent, is turning more slowly, six horse-power is no longer given off. It is at the moment when the vehicle is to be started on the road that a large horse-power is required, and it is at this time that the engine is incapable of giving it, unless it is run at a considerable speed first, and then geared to the carriage. This is a quality, and indeed a defect inherent to all the known oil and gas motors, where a clutch of some kind is necessary. Great pains have been taken to achieve success in starting and stopping oil and other motors of this class placed on carriages, when passing through traffic, but even if this latter end were attained nothing would have been gained, because of the time necessary for the motor to get up its speed before the carriage could start running afresh. It may therefore be concluded that until some further, and at present unknown, improvement comes about, the oil-motor will have to be kept running at all times during temporary stoppages, which, apart from other disadvantages, is very wasteful. The electro-motor offers certain advantages, inasmuch that it is easy to stop and start, for accumulators possess a reserve power similar to the steam-engine, but maybe at the risk of wearing the accumulator. Of course, if large electro-motors or other forms of engines were carried than are necessary, some of the difficulties pointed out would be greatly reduced; but practical considerations, such as expense, great additional weight, bad economy in working, bar such a procedure. With the steam-engine we have a great reserve power. It is merely a question of raising the steam-pressure by the application of more heat to the boiler, or of using the heat already given to the boiler in a more advantageous manner, to obtain the additional power. It might be urged that a four horse-power steam-engine would not be strong enough to render 10 horse-power at any time; but by putting a few pounds extra weight into the working parts there is no difficulty or danger in accomplishing this, though such an engine would not be suitable for running continuously at the higher power, on the ground of want of economy, as the boiler would be continually strained to its utmost, and this, although it might not be productive of danger, would be an unfair tax to place upon it, and would necessitate earlier renewal. This is why the steam-engine, when placed upon the road carriage, can start and stop in the traffic with the same facility as the railway locomotive does with its train. It has been urged by some leading engineers that the main success of the railways has been due, not to the locomotives, but to the nature of the road, and no doubt there is much truth in this, for plate-ways, granite-ways, and other tracks of a similar nature suitable for highway purposes have been proposed, and may in the future find still more favour. But it is hard to bring one's self to imagine that the ingenuity of man cannot modify the locomotive to suit the road, when it has harnessed far more difficult problems. Many devices have been put forward for constructing a road engine which shall lay its own rails as it proceeds. Some of the methods are very ingenious. In some cases planks or rails are laid and raised as the wheels pass along; in others, the wheels travel in a large circular ring. Patents for similar methods have been taken out over and over again, and it appears to me a disgrace that a Government Department should thus take money under false pretences. All the advantages to be gained by the use of movable rails or other equivalents can be obtained by modifications in the wheels, without the auxiliary. At the same time, there is much to be said in favour of some of the proposed schemes. I will give one or two instances. If a combined locomotive and wagon is to be taken over a ploughed field to collect produce, the process might be impossible if the ground were soft; yet, if planks were laid along the route to be taken, the difficulty would be overcome. The equivalent to this would be self-laid rails carried by the locomotive. Again, the wheels running within a large circle present the advantage to be gained by the use of very large wheels, which by any other method would be impracticable, so that a locomotive could proceed over very bad roads, which might otherwise not be possible without excessive engine-power. It has become the habit to pooh-pooh these devices, but I think that there is more advantage to be gained from them than it is usual to give credit for, especially under certain given conditions.

Steam Motors.

I will now turn to steam power on the highway. After a careful study of probably every self-propelled carriage which has been made from the earliest times to the present day, I have come to the conclusion that Hancock's disposition of the working parts cannot be improved upon. This was my opinion long ago, and I was pleased to find Sir Frederick Bramwell and others uphold the same view. I pointed this out to M. Serpollet, who, having examined the matter, is in full agreement, and his new carriages are being built on these lines. I regard this circumstance as a compliment to English engineering. Of all motors for carriages at the present day, I hold that steam is by far the most suitable and advantageous for real work, and that when the Serpollet boiler or one of a similar type is employed, nothing more can be desired for many years to come. Of English manufacturers already busy at work on steam road vehicles, Messrs. Philipson and Thornycroft may be reckoned amongst the leaders. The steam carriage which has been brought nearest to perfection at the present time is that designed by M. Serpollet. I will therefore give a brief description of his vehicle with its most recent improvements. M. Serpollet has adopted the present type from the instructions I gave for the carriages constructing for me. The engine and disposition of the parts are all simple matters not subject to patents, and not capable of material improvement, as they have all been common knowledge for the past 70 or 80 years. The boiler and furnace alone have been the main difficulties in connection with the subject. Many waterless boilers appeared before M. Serpollet's time, but to him the credit is due for having devised a form of boiler, simple, cheap, and effective. The principle of the Serpollet boiler is so well known that I need not enter into it again. It will only be necessary for me to describe the boiler and furnace in their most recent form.* The earlier ones were not practical from an engineer's point of view: the furnace was large, a great weight of fuel was necessary, and fumes were produced. The present boiler is made up of several tiers of crushed bent tubes, the steam space being horseshoe in section, and a petroleum furnace. The chief improvements consist in very materially strengthening the metal of the tubes, which gives the advantage of a reserve for storing heat, which is essential, as well as for durability's sake, and the method upon which the tubes are built up is far simpler and renders repairs, when found necessary, rapid and easy to carry out. Those tubes which are nearest the fire are thicker than the elements more distant. In some forms the tubes are further bent into spirals, thus giving additional strength and an increased heating surface. The fire itself being a heavy oil petroleum furnace, offers lightness and security against breakdown and accident. A large reduction in weight, due to this form of furnace, gives an all-round advantage, especially now that the engines are constructed to condense. The ton of fuel and water which at one time it was necessary to carry, is now largely dispensed with, and in consequence the carriage does not require to be so strongly built. Ten hundredweight, at least, are saved in the weight of the carriage and furnace. In consequence the older carriages, which weighed at least 2 tons

* See THE AUTOMOTOR AND HORSELESS VEHICLE JOURNAL for January and April.

when prepared for a long journey, could now be constructed to weigh 10 to 20 cwt. laden But as the carriages at present beiug made weigh nearly double the lower weight mentioned, it may be asked why should this be so? The reply is, that there is a growing tendency among French manufacturers to build on English lines of solidity rather than elegance and lightness, and a great deal more weight is being put in those portions where the strains come. Six cwt. is very soon accounted for when this is done, and in order to secure the convenience of a movable body, portions of the framework are duplicated, *i.e.*, the underframe must be there as usual, and the frame for the body must be a separate one, so that additional weight is found in this direction. The modern steam carriage weighs about 18 cwt., and is far more satisfactory than the old forms, and decidedly superior to any of the oil-driven motor-carriages which have appeared before the public. There are many points of importance in the construction not new in themselves, in which strength and lightness are the main features obtained. The guiding bar does not act directly in steering operations, but by means of a multiplication wheel, for unless some method such as this is adopted there is a danger when meeting a large stone on the road of overpowering the driver and throwing the carriage to one side when travelling at a fair speed. The multiplication arrangement gives better control to the driver rendering such an accident impossible. Another way is to place the turning point of each wheel within or over the axle. The body of the carriage, so far as the eye is concerned, appears as one. In reality it consists of three divisions: the conductor's seat with a place beside him in front; a boot at the back, similar to that of the phaeton, but no seat in it; and between the boot and the box seat the space is occupied by a Victoria, brougham, van, or any other kind of body that may be desired, these bodies being removable without recourse to tools, and interchangeable at pleasure. The front place can be covered by a glass cab to protect the driver and his companion from the weather. At the back of the boot are two doors. On opening the right hand one the boiler is seen, and the left hand cupboard contains a vertical engine. The engine is a double tandem expansion type, and the reduction of speed as between the engine and driving wheels is not great, this being effected by means of a specially constructed strong single chain situated midway between the right and left driving wheels just as Hancock placed it in his carriage. This chain is dispensed with in some cases so that the driving is direct. The engine cranks, chain, and any other working parts are completely encased, so that no mud, dust, or wet can reach them. The engine is capable of giving off powers varying from four horse-power normal to 10 maximum. The boiler pressure can be raised to 16 or 17 atmospheres without danger. Briefly, the following is a summary of the advantages presented by the new petroleum furnace:—

(1) No smoke is produced when the burner is preparing to be lit.
(2) Very little methylated spirit is required for lighting.
(3) When making a stoppage for a considerable time, such for instance as paying a call, the petroleum is cut off from the main burner whilst the auxiliary burners keep the former hot for starting afresh.
(4) The burner can also be cut off when descending a hill.
(5) The expenditure of heavy petroleum, which can be obtained in this country at from 3*d*. to 4*d*. per gallon, would not, on the average, exceed in the case of a carriage such as described $1\frac{1}{2}$ gallons per hour when carrying four people at a speed of 12 miles per hour on average roads.
(6) The weight of the carriage unladen will not be greater than one ton.
(7) Six minutes only are necessary to prepare the carriage for running, and being free from all complications any intelligent man can drive it.

The natural question suggests itself, should the boiler or burner wear out how often is renewal necessary? In the case of the boiler it is only the lowermost tube which requires occasional renewal, though, of course, in time the boiler will wear out. The present cost of this tube is about £1 10*s*., and, perhaps, one or twice a year it might be necessary to replace it if the carriage is greatly used. The whole boiler is priced at the present time at £30, but total renewal is necessary only after many years of wear. I should estimate that even with hard work, *i.e.*, working the boiler harder than is fair, the annual expense would be considerably under £5. These boilers when made in England will undoubtedly be cheaper. The expense of renewing any part of the burner is exceedingly small, a few shillings would be the outside, and it would probably not be necessary to do this every year. The repairs and expense of certain renewals in the case of petroleum driven carriages is far greater than this, as all those know who own these vehicles, so that steam possesses the advantage over all such motors, although I am ready to admit that when a light, cheap, and lasting high-capacity accumulator makes its appearance, electricity will stand before steam for attention and comfort, if changing and charging etations exist throughout the country at easy distances. There are several points in connection with steam-carriages which cannot be over-rated, and greatly to be appreciated, by those who have been in the habit of using petroleum-driven motors. The chief one is that the crawling process up a hill is dispensed with, and 12 miles an hour up the steepest hill which horses and carriages at present climb, can be obtained without an effort. Secondly, when stopping and starting in the traffic, the engine is stopped and started as would be done in the case of a horse. Since the whole of the steam is condensed none of it passes into the atmosphere. Should by chance any do so, being superheated, no vapour escaping is visible, and days may go over before it becomes necessary to take in a fresh supply of water to make up for any slight waste there may be. There are no valves to grind, no cylinders to clean, no inflammable material to store at home or carry when on a trip, no unpleasant smell is produced, there is absolute freedom from vibration, no chance of a breakdown when least expected, no accumulator to charge, or platinum points to be renewed, no ignition lamps and tubes requiring attention and occasional renewal, all repairs that may become necessary at any time, the carriage builder, or even the village smith, can carry out. Quite apart from the advantages mentioned there is another which is of great practical importance; and is, that any moderately intelligent man, with a few hours' instruction, becomes master of the engine and carriage. It is possible to find men who have been accustomed to steam-engines in large numbers. There ought, therefore, to be no difficulty in finding a supply of drivers in proportion to the demand. This is not the case with oil-driven vehicles, on account of the complexity of the working parts, combined with a quality unknown to the steam-engine—that of developing some new defect when least expected.

Oil and Gas Motors.

All motors may be divided into balanced and unbalanced sections. By "balanced," I do not refer to the parts of the machine being duly poised, such for instance as additional weight placed on some part of the fly-wheel to balance the weight of the crank and any rods on the opposite side. I use the expression in regard to the primary force. For instance, we all know that in the gas-engine the running is spasmodic, and can only be overcome by the use of enormously heavy fly-wheels, so great indeed that in practice a certain amount of jerkiness is preferred. All oil-motors are gas-engines, and nothing more and nothing less. They may, therefore, all be classed under the one head. Steam and compressed-air motors come under another category. It is well to point out the difference between the two classes of engines. With the gas-engine, the pressure starts at a maximum and falls. With steam and compressed air, the pressure may rise gradually to a maximum, and then fall. This is why steam and compressed-air motors run so smoothly. It may be contended that the same result could be obtained in the case of the gas-engine, by using a separate vessel to explode the gas in, and then admit such gases into the cylinder, under steam-engine conditions.

Many years ago I made a large number of experiments in the hope of obtaining success in this direction, and many others have done the same. Although the results are successful in one sense, it is at the expense of efficiency and extra weight. There is a method of obtaining smooth motion from gas and oil motors, by counterbalancing the explosion. Many such engines have been constructed, and consist as a rule of two cylinders in each of which there are two pistons moving away and towards each other. Complete success can be obtained by this means, but only by the introduction of great complication in valves and gear so that in practice it is probably more convenient to be subject to vibration in an oil or gas motor-carriage when running at low speeds than to incur the risk of difficulties which must arise with still more complex machinery. When oil motor-carriages are running at a moderate speed the vehicle becomes the fly-wheel, and the greater part of the vibration disappears, but there is no means of obtaining regular and steady motion at slow speeds, however good the governor may be. There will always be a tendency for the engine, when the full power is not necessary, to run faster than the governor allows, and the speed is arrested. This action keeps on repeating itself, consequently the carriage advances by fits and starts. The oil motor-carriage is only comparable with the horse-drawn vehicle for comfort when running at high speeds. With steam, compressed air, and electricity, these disadvantages are completely absent, likewise the necessity of a clutch or its equivalent. I have made some experiments with my oil motor-carriage on roads covered with snow and ice. It is known that many possessed of such carriages have traversed portions of Switzerland and elsewhere covered with snow. I am ready to admit that such carriages, lightly laden, travel well over snow, but after a thaw, succeeded by a frost, hill climbing becomes a dangerous proceeding. I have found on several occasions, although the motrice wheels were revolving, the carriage body slipped backwards, and naturally no brakes are of any avail under such conditions. I took the safest course at such times, and turned the carriage gently into the hedge, and waited for help, or procured sand to get a grip on the road. It is evident also, under such conditions, the power of the engine is not a factor in the case. I would strongly recommend possessors of these carriages to supply themselves with an ice brake similar to that which I have put on my own carriage. It consists of two rods of iron with prongs at the free ends, the other ends of the rods being hinged to the carriage. When mounting a hill covered with ice, the rods are lowered to the ground, and if by chance the carriage cannot advance, the spikes at the free ends of the rods stick into the ground and prevent an accident. This brake is inclined at an angle of 45° to the road when resting on the ground. Ice wheels may also be required in some climates.

Electric Motors.

A few words may now be said in regard to carriages driven by electric energy. It may be desirable to point out why electricity is not in the competition at the present time, except to a very limited degree, so far as independent traction is concerned. The only known practical method now for storing electricity is by means of batteries, either primary or secondary. The primary batteries are too troublesome and expensive in the present state of knowledge to call for any remarks. The secondary battery is either too heavy, and if light, too costly for repair to be regarded otherwise than as a luxury. It is claimed by some makers that the vibration to which they would be subjected, both in the case of the heavy and the light type, does no harm and the maintenance is greatly reduced. I have no desire to let it be thought that all these statements are false, but I would point out that there is absolutely no evidence to bear out such assertions. All the evidence of the past is against the probability of such statements being fulfilled, and no new discovery has come to light to reverse past experience. Moreover, the only proof which can be brought forward contains the factor of time, and this has been so far impossible on account of the supposed improvements being very recent. It is only fair to state that some of the accumulators which have appeared of late, are more suitable for traction than the earlier ones. The modifications consist in using celluloid pots, which are lighter than glass, transparent, and not brittle. These pots can be closed effectually. The plates in the sections are made thinner, and in some cases wrapped round with perforated celluloid, the intention being to prevent possible contact between plate and plate. The most promising separator is the material devised by Mr. Joseph Swan. It is like cotton wool in appearance, though in reality celluloid. This "wool" is packed between the plates and around the section, converting the cell into practically a dry one. Notwithstanding these improvements, there is yet an element of possibility that the maintenance will work out higher than is anticipated, but at any rate, the mechanical advances referred to have greatly improved matters, although the electrical properties and efficiency remain much the same. But to leave the subject of maintenance out of the question, the light accumulator is very heavy, and the losses for any type cannot be estimated at less than 20 per cent., and in practice 30 per cent. is much nearer the truth. Hence it would be unfair, from a commercial point of view, to regard the cost of the energy otherwise than one-third more than that at which it can be produced. There would be few who will disagree with me when I state that a very fair price for the electric energy per unit is 3*d*. Although I do not contend that under exceptional conditions it cannot be produced for less, yet the figure given is by no means an unreasonable one, from the extensive knowledge we have of the cost of the production of electric energy at lighting-power stations throughout the kingdom. Consequently, if the electric energy is to be carried, about 4*d*. per unit is a fair estimate of the cost when used on a moving vehicle. Roughly speaking, three-fourths of a unit is a theoretical horse-power. In practice, unless the motor is very large, say, exceeding six horse-power, one unit per horse-power is the approximate expenditure of energy per hour. No doubt many will say that this is excessive for a carriage carrying a six horse-power motor, capable at times of giving off a larger power, but I would point out that when the roughness of the roads comes to be considered, and the stops and starts necessary when approaching and running through towns, my estimate is an exceedingly fair one. To sum this up, I contend that, as matters stand to-day, it is impossible to reckon the power delivered in an electric carriage at less than 4*d*. per horse-power per hour, which, of course, is enormous, when it is further considered that maintenance has not been taken into consideration at all, and that only a short distance can be run before the accumulators must be re-charged, and that unless charging stations are to be found throughout the locality where such carriages run, a useless mileage must be added for getting the vehicles to the charging station and back to the points where they have to be used.

Benzine and Steam Carriages.

Now compare these conditions with those of benzine and steam carriages. The cost of benzine gas may be roughly taken as equal to coal gas at 3*s*. 6*d*. per 1,000 cubic feet. Hence a gas-motor using benzine works out nearly one-fourth of electric energy. In the case of steam, using petroleum for the furnace at, say, 6*d*. per gallon (in large quantities, however, it can be purchased at about half this price), the cost per horse-power per hour would not differ materially from the cost of the benzine-motor, and consequently far cheaper than electric energy. In steam-engines using coal or coke, taking the price of fuel at £1 per ton and the consumption at 12 lbs. of fuel per horse-power per hour, the cost is about the same as crude petroleum.

It has, however, been found in the case of locomotive engines that the petroleum fire is nearly double the price of a coal one. In this case it must be remembered that coal was costing about half the figure I have just given, so that if coal, say, at 12*s*. per ton, can be obtained for road traction, the working cost is still further diminished. Practically benzine and steam come out four times cheaper than electric energy. All these facts should be borne in mind by those who think of embarking money in electrically propelled vehicles. In round figures the efficiency of a good steam engine may be taken at 10 per cent., but for a

x 4

road carriage this would probably not be better than from 5 to 7 per cent. A gas engine, whether using coal benzine, or other gas, has an efficiency of about 25 per cent. Electro motors have a commercial efficiency of from 80 to 85 per cent., but in this latter case so many conversions of energy are made between the coal and the electro-motor, that the actual efficiency is very low indeed.

Electric Motors.

I have always held the view that a perfect accumulator will not appear until the discovery of some new and cheap metal, not that the ideal accumulator cannot be produced to-day, but only at forbidding expense. At the same time discovery may lead to the production of a battery of some type, quite different to that to which we are at present accustomed, depending possibly on some new principle. It must not be thought from the various remarks I have made on the value of electrically driven vehicles, that necessarily they have no future as matters stand. My remarks apply to those instances where the carriages are to be used commercially, to obtain a good money return. Omnibus horses have to earn a certain amount per day. But this is not the case with a pleasure horse, or with an animal kept by a professional man. In such instances the maximum commercial output of the horse is not sought for, and under these conditions electric energy may do very well, provided that the following conditions can be obtained :—

(1) A guarantee from a Company to keep the accumulator in order.
(2) That conveniences for re-charging the accumulator exist.
(3) That the distance to be travelled in one day shall not utilise more than the electric energy stored at one charging.

M. Jeantaut was one of the first in France to make an electric carriage, though many had been constructed in England previously. M. Duracq's carriage, which was shown at the Salon de Cycle in December, 1896, is undoubtedly the best carriage of the kind which has yet appeared. I have had the opportunity of examining the vehicle closely, as well as riding in it, and it is admirably adapted for town use. M. Duracq, in a pamphlet, gives calculations to show that electric energy is cheaper than living horse power. The whole of his estimates and allowances are faultless, but an error creeps in, according to my mind, at the start, where he assumes too small a power to pull one ton at eight miles per hour along a road. The figure he gives may be true on a level asphalte road, but my experience, which is verified by that of others, would go to show that at least three times the power allowed is required in practice, taking roads as we find them. Neither is any allowance made for re-starting after stoppages, when considerably more current is necessary; and since an electric carriage is more likely to be used in towns than elsewhere, such stoppages in the traffic will be frequent. If these various points are taken into consideration, instead of electric traction coming out, as M. Duracq makes it, 40 per cent. less than horse traction, it will be found to be very much greater. In order that there shall be no misunderstanding I will quote the figures upon which the calculations are based. M. Duracq takes a well suspended carriage, and estimates 35 kilogrammetres per ton, for speeds varying from 12 to 15 kilometres the hour. In English this means less than ½-h.p. to do the work named, and all those who have experimented with self-propelled vehicles know that this is much too small an allowance, except under the most favourable conditions.

The Power of the Engines.

I will now turn to the question of the power of the engines to be placed upon motor vehicles. It cannot be too strongly impressed upon those who intend to take advantage of this class of traffic that the following conditions are essential for success :—

(1) That whatever is the proposed speed decided upon, it should be calculated upon the assumption of being an average speed, whether the country be level or hilly and the roads good or bad. Climatic changes must also be taken into consideration. Thus, if for a light vehicle, weighing when laden, say one ton, twelve miles per hour has been fixed upon for the speed, then the power carried should be sufficient to run at this rate in all weathers and over all highways, and to climb every hill with a maximum ascent of say one in ten, at the proposed rate. The vehicle should also be able to mount a hill of one in five, but at a less speed.
(2) That the mechanical construction shall be such that any intelligent man after a few hours' practice shall be able to manage it.
(3) That there shall be nothing about the carriage likely to prove a danger to the occupants, or the general public.
(4) That the vehicle shall be strongly made, and no part likely to wear out quickly.
(5) That dangerous fluids and fuels be excluded as far as possible.
(6) That the construction be such, that when repairs become necessary, they can be carried out either temporarily or finally, by any intelligent village smith.

In respect to the above considerations, there is only one which needs special comment. It is evident that the power required to obtain a given speed on the level and down-hill, needs no consideration, for if the engine is strong enough to mount hills of one in ten, ample power exists to do the rest. I have come to the conclusion from experiments, and practice, that for every ton, not less than ten horse power should be carried. This does not necessarily imply that a 10-h.p. engine is required. It means that the engine shall for considerable periods, and without injury to itself, be able to give off 10-h.p. It must be remembered that when the carriage is started, a far larger amount of power is necessary than when it is running. It is therefore very important to have a good reserve. I have examined with close attention probably by far the greater majority of the benzine motor carriages in existence, and have ridden in a large number of them. I think it is quite unnecessary to give scientific evidence to disprove the various clap-trap which has been put before the public by company-mongers, in the hope of drawing money. Statements as to 60 miles per hour, and a variety of other nonsense, needs no comment. Anyone present is capable of running a carriage strongly made at 60 miles per hour, without a motor, and without a horse, by merely starting the vehicle down a long steep hill! In fact all statements as to speed, in connection with motor carriages, are worth nothing. There is no difficulty in obtaining enormous speeds with very small power, under favourable conditions. The real test is: Will the vehicle mount a hill, say one in ten, when the thermometer is 90° in the shade for a distance of five miles, at the respectable speed of twelve miles per hour? Any test short of this, supposing this speed is desired, should end in a decision to reject the vehicle as unpractical and probably worthless. You must not understand that I necessarily fix twelve miles for the rate, for many would be content with a lesser speed; and for haulage where vans and similar vehicles are employed, five or six miles per hour would be deemed sufficient on steep hills. It may prove of interest to give a few statistics, calculated by some of our greatest engineers. They were compiled with reference to haulage on roads in general, and the figures must not be accepted for self-propelled vehicles, for the many reasons already referred to, the chief one being that when the motive power is self-contained, the haulage factor must be multiplied two, three or four times, according to circumstances, but the tables will hold good for self-propelled traffic when the factors are multiplied by a constant.

Experiments made by Telford showed that draught for a wagon weighing about 21 cwt., was a follows :—

	lbs.
(1) On well-made pavement	33
(2) On broken stone surface on old flint road	65
(3) On a gravel road	147
(4) On broken stone road on a rough pavement foundation	46
(5) On broken stone surface upon a bottoming of concrete formed of Parker's cement and gravel	46

Babbage has stated that the friction or resistance of roads are as follows :—

Well-paved roads	$\frac{1}{77}$ part of load.
Gravel road	$\frac{1}{35}$ "
Fresh earth	$\frac{1}{16}$ "

By his experiments the following results were obtained :—

Loose sand	$\frac{1}{4}$ part of load.
Fresh earth	$\frac{1}{8}$ "
Bye roads	$\frac{1}{9}$ to $\frac{1}{10}$ "
Dry meadow	$\frac{1}{25}$ "
Dry high road	$\frac{1}{40}$ "
Hard macadam	$\frac{1}{35}$ "

Telford's Table gives in round numbers as the difference between the lowest and greatest figures a proportion roughly of one to four-and-a-half. Babbage's Table for equivalent roads by theory gives the ratio roughly one to two, and by experiment, taking hard macadam and a bye road as an eqnivalent comparison, the ratio is one to three. Strikiug a general average, it may be assumed that the power required to draw a vehicle over a good level road as compared with a level rough road, wonld be four times greater in the latter than in the former case. Here is another table of considerable interest which deals with a stage coach. It may be observed how very close the figures are to those I gave in an article published some time since in *The Engineer*, although I had not seen the statistics in regard to the stage coach at that time.

With a stage coach weighiug 18 cwt., exclusive of seven passengers, the following were the results :—

Rate of Inclination.	Rates of Travel'ing.	Force Requ red.
1 in 20	6 miles per hour	268 lbs.
1 in 26	6 "	213 "
1 in 30	6 "	165 "
1 in 40	6 "	160 "
1 in 600	6 "	[illegible] "
1 in 20	8 "	296 "
1 in 26	8 "	[illegible] "
1 in 30	8 "	196 "
1 in 40	8 "	166 "
1 in 600	8 "	120 "
1 in 20	10 "	318 "
1 in 26	10 "	225 "
1 in 30	10 "	200 "
1 in 40	10 "	172 "
1 iu 600	10 "	128 "

The following experiments may also be giveu as affording some further idea of the power required for haulage :—

An engine drawing 18 tons on a fairly level road. Separate locomotive 18 tons, when charged with fuel and water, must give i.h.p. of 30 to reach speed four or five miles an hour.

Another engine, 12 tons, drawing 25 tons load, for same speed, 40 h.p.

Another engine, 15 tons, drawing 32 tons, same speed, 50 h.p.*

Although the question of rapid mechanical traction has come to the fore after a lapse of about half-a-century, it cannot be said that the interregnum has been due to any failure in regard to this mode of traffic. It is right to point this out, because the French and Germans claim to have revived this class of traffic, and that it had never been done before with success. The French also claim that the first self-propelled vehicle was made in France, by Cugnot. The latter point may be conceded, but I claim that the English nation were the first to make really practical road carriages, as they were the first to construct railways, and that the early motor traffic of the period about 1830, was killed, partly by the attention drawn to railways, but in a large measure by the monstrous Acts which were passed, dealing with the tolls to be imposed on them when travelling ou the turnpike roads ; and although these Acts were modified at a later date, the definition of a locomotive, as laid down in the Act of 1865, finally stopped the way until the passing of the Act of last year. I have no hesitation whatever in saying that the steam coaches of Hancock, and of many other former designers, could be run to-day with perfect success, and that the only improvements we can now add to their designs are due to the better and cheaper material we have at our disposal. That this view is reasonable let me give you the parallel. Compare the locomotive of to-day, with that of 1830. The improvements are those simply due to the increased demands placed upon the railway system. The general principles aud design remain the same. It is mainly in detail and size that the alterations are to be fouud. To expect, as some people do, an extraordinary invention will sooner or later appear to render motor traffic on the highway a success, is simply ridiculous. Not that wouderful discoveries may not be made, but I think that all engineers will agree with me that at the present time we have everything at our command to make this class of traffic all to be desired. The only thing now wanting is practice, with the relegation to the background of the Company promoter. Our great manufacturers are perfectly competent to deal with the question, and it will be these firms which will not only survive, but will also bring the whole matter to a happy issue, in conjunction with such factories which may come into existence, placed upon an honest commercial basis, and as already stated, I do not believe there is any chance, as matters stand to-day, of benzine, oil, gas or electricity competing with steam, where real work is to be done with certainty. I should like to refer to the evidence given before the

Parliamentary Committee of 1831.

Telford, Gurney, Macadam and others were witnesses. They appear to have agreed in regard to two points, viz., that the wear from the horse shoes was greater than that from the carriage wheels, and they also expressed the opiniou that there should be one inch width in the tyre for every ton carried, inclusive of the weight of the carriage. Of course we know the roads of to-day are not made in the same manner as they were at that date. We believe that our roads have been greatly improved since that time. My observations do not bear out the two points mentioned. I do not think that the general law of one inch width of tyre per ton must necessarily be followed up the scale. A proper width of tyre for a carriage weighing oue ton, I think, should be two inches instead of one inch ; then add oue inch for every ton up to say three tons. At this, the tyre would stand at four iuches, and on high-roads this is ample width for very much heavier weights. Then again in regard to the wear and tear due to horses' feet, I believe that the wheels do far more mischief, particularly in the case of a narrow road, as it will always be found that the ruts are the worse portion of the road, and not where the horses tread. Even ou wide roads, the wear of the wheels appears to do the mischief. I am quite ready to take a different view if the road is practically perfection, and "quartering" is coustantly taking place. Then the wheels will wear the road very equally. The remainder of the evidence before the Committee tended to show that steam carriages were at that period a success and likely to contiuue so.

Electric Traction for Canals.

I cannot refrain from pointing out a possible mode of traction, which appears to have been completely neglected. When the construction of railways was on the *tapis*, great opposition was offered to their construction, on the ground that England was well served with canals, and that the companies, owning these, would be greatly injured if the railways were made. I have, in my possession, copies of some remarkable letters which appeared early in the century on this subject. I have not the least hesitation in saying that if electric traction could be applied to the existing canals, they would be made far more useful, as well as more profitable, to their owuers. Electric traction could be applied in this case at a comparatively small expense, and it is worth while to have an experiment made on an extensive scale. For light traffic on railways, the self-propelled vehicle has a fair opening ; and abroad, experiments are being made in this direction. One or more railways in

* See "Fletcher."

Germany are making trials, also the Northern and other railways in France. For compulsory service, as in the case of postal mails, and for lightly-laden night trains, the French Serpollet Company have constructed carriages to carry from 40 to 50 people, with a sufficient engine power to run at about 30 miles an hour for such purposes. It is estimated that the cost of running these compound carriages is about one-third the cost of an ordinary train, and the wear and tear to the permanent way is far less On almost every railway system in England there must be an opening for this class of traffic. It may also be mentioned that these French steam carriages are capable of drawing one or two ordinary railway carriages, but at a reduced speed, say at 18 to 20 miles an hour.

The Revival of Motor Road Vehicles.

Without doubt, a great many people are puzzled why self-propelled traffic has again come to the fore. In England this traffic has been going on unostentatiously for years, traction engines being largely in use, but their speed is so limited by law, and they are so surrounded by legal technicalities, such as a license necessary in every county, and taxed, that no advance could be made in the direction of light traffic. In residential districts these restrictions have proved a blessing. In France and Germany, although there are laws affecting self-propelled traffic, they are far more lenient. The great success which cycling had in France, following upon the prize given by *Le Petit Journal*, which also gave so large an advertisement to that newspaper, led to the energetic proprietors offering a prize for quick self-propelled carriages, with the result which is so well known. Consequently the revival is not due to any new discovery or special invention, but simply that many minds were turned to the subject in the hope of gaining the large money prize. The French nation, possessed of a character highly enthusiastic, always goes to extremes. A perfect rage set in for the class of vehicle under consideration, and those who became possessed of these carriages, being wealthy, gave a great impetus to manufacturers. You have here in a nutshell, the whole history of the revival of self-propelled traffic of the lighter kind. A great deal of agitation took place last year to obtain a satisfactory Act of Parliament, to enable the same freedom to be given in England as abroad for the use of motor vehicles on highways. It was generally expected that as soon as Englishmen obtained this freedom, a great nuisance would be produced by the presence of vast numbers of motor carriages in the streets of towns. I never took this view myself, but always thought that the change would come slowly but surely. There is no doubt, that the position taken up by certain of the motor companies, has, for the moment, created a lull. Nobody, when purchasing a carriage, desires to buy a legal action at the same time. Tremendous opportunity is therefore offered for honest commercial companies to start at the present time, and I find that this fact is well appreciated in financial and commercial circles. The Society of Arts may be said to deal more largely with commercial interests than with any other. It has taken part in many of the great movements during the Victorian Era, which have so materially increased the wealth of this country.

Master Patents.

I therefore feel that it is not altogether out of place to say a few words in regard to patents, so far as they touch the particular question under consideration, as well as on patents generally, as they affect the manufacturer and the public. The present hesitation to take full advantage of the Locomotives on the Highways Act, 1896, is due in a large measure, to the blemishes existing in our Patent Law, which enables any set of people to bully or blackmail, not by right but by might, the assumption being that the threatened parties will not fight. In dealing with the question of patents, it is not my wish to deliver a legal discourse upon the subject, and the numerous "ifs" and "provided" are omitted. My object is to give you a general view rather than a complete technical analysis of the subject. There is too much tendency in the present day to patent an article in the hope of it accomplishing something for which it was not intended. There is no doubt that our Patent Law does a good deal to prevent useful inventions being made in regard to any particular matter where a number of patents already exist. No man will turn his attention seriously to develop a piece of machinery where he thinks he may be stopped from reaping the harvest he may deserve, by finding that in some little detail a patent has already been taken out. That my view is correct is corroborated by manufacturers on all sides. It may be contended that the present Law would permit him, notwithstanding, to work his invention, and no doubt this contention is true if the inventor can afford to enrich a number of lawyers first and hand his profits over to others. It is not the question of patents which I attack, but the method by which they are worked, and a great improvement could be made in this respect. Much of the advance which has taken place in foreign countries, to our disadvantage, has I think been due to defects in our Patent Law. Our Patent Law is evidently unsatisfactory. How could it be otherwise expected, when the principle by which our Governments work is to deal with these matters in a kind of political way, and place men in charge of the work, who as a rule know nothing about the special subject they have in hand? I could give innumerable instances of this process, but to do so would open me to the charge of personalities, which I am anxious to avoid, because I know well that those who carried out the work did so under instructions, and to the best of their ability, often limited. All practical men will recognise that no Patent in England is of value until there have been decisions in the Law Courts in regard to infringements, and that if a defendant instead of fighting, gives way and perhaps pays agreed damages, the Patent stands exactly where it did before the Action arose, since it has not been upheld nor has it been overthrown. Again, if a good fight is made and the defendant loses, there is nothing to prevent another infringer being proceeded against, and he might be more successful in the Action and overthrow the Patent. Then there follows another injustice, that the first defendant who lost his case obtains no relief, although the Patent has been declared invalid subsequently. Any article which is patented in England cannot be brought from abroad except under two conditions, firstly that the individual doing this is willing to pay what may prove to be blackmail to the holder of the English rights, or to submit to an Action with the possibility of losing his case. The patented article moreover is liable to confiscation without claim for damages. This state of things, although it exists in many other countries, is eminently unjust and against the interests of the nation. I will give two instances bearing upon what I have said to show how unfair things are at present. A few years ago I took out a Provisional Specification for an improvement in keys. It was brought to my notice about a week or a fortnight later that another Provisional Specification had been lodged identical in character. Indeed I learnt the circumstance by pure accident. The question to decide was whether I had been anticipated or not. If so, it was not my intention to proceed any further. I then found that my Specification had been lodged a few days—not a week—earlier than the other one, which had been entered in the name of some one living at Norwich and a stranger to myself. Here was a case of two persons hitting upon the same idea practically at the same time and each applying for a Provisional Specification which was granted to each within a week. The sole difference between the two Specifications was that the Norwich application included watch keys, and this was covered in mine by using words to the effect that the improvement was to apply to every form of key, for whatever purpose it might be used. According to common sense and equity the Norwich man ought to have had his money returned, which of course was not done A second instance is the following: A desire was expressed to me by a gentleman living in France to give him all the information I could, to render agreeable a proposed trip in England to be made in his horseless carriage. I wrote to him to say that if his carriage came under certain Patents it might possibly be confiscated if it came to the knowledge of the owners of the English rights. Failing this, he might have to fight the matter out in the Law Courts, and as neither of these conditions were likely to render his journey to England pleasant, he had better ascertain from the makers whether anything about his carriage was patented in England, and if so, whether the rights were held in this country by hostile persons, and further to request the manufacturer to make arrangements for him with any holder of English rights to permit the carriage to enter without molestation. It appears to me that apart from the larger question, the following amendments should be made without delay in the Patent Law :

(1) If it can be shown by the applicant for a Provisional Specification or Patent, within twelve months from the date of first paying the fees he has been anticipated, the fees shall be returned. Provided he can shew that at the time of application, he was ignorant of the anticipation.

(2) That if in any action, a Patent is declared invalid in consequence of anticipation by the issue of prior patent, the fees shall be returned. With the same proviso as in No. 1.

(3) That a patent shall become void, unless the present holder be registered.

(4) That English patented articles may be imported into England on the following conditions: that the individual so importing gives notice to the Patent Office or some other selected Government Department, of his intention to do so, with a declaration that the article imported is for his private use, and that he shall deposit a sum equal to 10 per cent. of the cost of the article, which will be handed over by the Government Department to the holders of the Patent rights, and that the owner shall not be precluded from selling the patented article provided he does not import more than two in a given year, there being a *bonâ fide* understanding that the importations have not been made with a view of trading.

(5) That if a patented article enter the country for a short period with no intention of trading, that providing it does not remain more than one year in England, the sum paid shall be one instead of ten per cent.

(6) That in no case shall a patented article be liable to confiscation, but the aggrieved party may have the power of applying to the selected Government Department who shall ascertain whether more than ten per cent. shall be regarded as the fair compensation, the costs to be apportioned according to circumstances.

(7) That patented articles may be made by any manufacturer with the same freedom as if they were not subject to rights, provided that the manufacturer declare to the selected Government Department his intention to manufacture, and that department shall enquire whether a royalty of ten per cent. paid to the holders of the rights is deemed to be sufficient, and that the Department shall not take into consideration the amount of capital which the holders of the Patent may have invested in or watered their business, but determine the question simply on commercial principles. This condition may be said to exist now, but with insufficient freedom.

(8) That a patented article in the *bonâ fide* possession of a member of the public, *i.e.*, private person, shall not be confiscated under any conditions whatever, but in the event of the Patentee gaining an Action, the damages shall be paid by the manufacturer, and if the goods are foreign the private individual may be called upon to pay 10 per cent. of the value of the article, unless he desires to defend an action with a view to upset the Patent, in which event, if he loses, he shall be liable only for the costs beyond the 10 per cent. mentioned.

(9) That no back royalties extending beyond 12 months shall be claimed.

The above amendments are greatly needed, and if they could be obtained with possibly certain variations, considerable impetus would be given to British trade, apart from benefit to individuals of the general public. It often occurs that a good invention is held by parties who are incapable or unwilling to manufacture, thus establishing the position of dog in the manger, simply to levy blackmail. A new manufacture which might employ many hands, and bring capital into the country is stopped for a number of years, and perhaps for ever if the invention or inventions in question have been superseded before the expiry of the Patents. It is well known that many inventors of a low type take out patent after patent in regard to various matters, few of which are really original ; but the process is carried on in the hope that some one will be caught, sooner or later, in the net. It is a means of speculation most disadvantageous to the industry of this country. It must be evident that no inventor can sit down and solve problems with a pile of patent specifications at his side for continual reference. No man could produce useful work by such a process. It is therefore obvious that inventors should receive the greatest freedom, which can only be attained if patents are not granted for trifles according to the present system, and only after some kind of reasonable investigation. The present Government would do much good if they would look into a matter of this kind, which is affecting the employment of the working classes in a large degree, as well as the introduction of those economies which save the nation money. With a better patent law, opening for the employment of capital at home would be extended. Such subjects, which Ministers probably consider trivial, have a more far-reaching effect than the passing of Party legislation, or a variety of other Measures before the House, which a twelvemonth's delay would add to the peace of all parties. The Patent Laws can be made a blessing to the inventor and the public, or the reverse, according to their nature ; and those of England partake rather of the latter character. At Liverpool, I used the following words :—" One opinion from which I have never swerved upon this question is that no Patent connected with Self-Propelled Traffic is worth the paper it is written upon, whether the Patents will bear the test of the Law Courts or not." The above remark was very rightly made use of by the majority of the newspapers when criticising the various Companies which had been formed, and were being formed about that period, and I was led to understand that those connected with the Companies in question complained grievously of what I had said, it being contended by some of them that they held Master Patents and monopolies. I think it therefore right to say something more upon this question, for to set up such untenable claims is unfair to the English manufacturer and to the English public. I intend, with your permission, to examine the whole question of patents more narrowly than I have done, and to prove that there is no Master Patent or Monopoly whatever, which can apply to the construction of motor carriages generally, whether they be driven by steam, oil, or electro-motors. I will not ask anyone to go further than to consult a book published by the Patent Office, and which may be purchased for a shilling from any bookseller by giving the order. This book is the Abridgements of Specifications, Class 7, Oil and Gas Engines, period 1877-83. Here will be found patents connected with the subject, all of which have now lapsed. There are other volumes of abridgements dealing with velocipedes, and with other matters, which also bear upon the subject, but the book mentioned is sufficient for the purpose, while if every detail is sought for, the original Specifications can be consulted as well. I will first examine whether any claim can be made for a Master Patent, in regard to motor vehicles. The possession of a Master Patent would mean a monopoly on the part of those holding the rights. Let us see what a Master Patent means. Without entering into technicalities, it must be a " manufacture, useful, novel and ingenious." Consequently if the patent is a Master one, this useful, novel and ingenious manufacture can only and solely be made under the patent specification, or may be, under a group of such patent specifications. The patent might, in certain cases, be the embodying of some new idea of great value and novelty. To explain more clearly, I will take the well known case of the Edison-Swan electric incandescent lamp. Quite apart from the morality of the case, we find a Master Patent (or rather group of patents), *i.e.*, a lamp of special form suitable for a definite purpose, which can practically be made in only one manner for commercial success. These patents are of the class termed a combination, which means a combination of old things to form a novel, ingenious and useful new one. Incandescent lamps can be made in other ways it is true, but they have not the same value commercially. Hence the only lamp of practical value was covered by the patents, and was of a particular type, viz., a high resistance carbon filament in a practical vacuum, enclosed within a case of glass, hermetically sealed, with platinum leads passing through the glass, and the filament strengthened by the process of flashing. Here we find a combination which has not been improved upon to the present day. In the history of the world there has occasionally appeared a Master Patent, but these are comparatively rare, and always for some entirely new invention or discovery. We will now examine whether it is possible for such a patent to exist for motor traffic, in the present state of things.

The only possible Master Patents which could exist would be of the following nature :--

(1) The combination of a motor, other than steam, with a carriage suitable to run on highways.
(2) Combination by which gas in the cylinder of a gas engine can be ignited at any suitable time by means of an electric spark.
(3) The use of a carburetter, when the gas is produced from an oil or spirit.
(5) The use of a silencer for the exhaust in the case of gas engines, when applied to a road carriage.
(6) The existence of a gearing which is only and solely suitable for light traffic.
(7) The use of a clutch in connection with light traffic.

This list is sufficient without dealing with other points which have virtually no importance. In the majority of cases no distinction is drawn between the gas engine, oil engine, and benzine engine, since the word gas covers gas produced from any material suitable for the engine in question. But, suppose a judge, who was not a technical man, were to hold a different view. Then his attention would be called to the existence of a list of patents, dealing with engines which used gas produced from coal gas, oil and benzine, all of which have expired, so that no claim whatever could be made by any living man of rights connected with coal gas, oil, or benzine engines, of an exclusive character. Further, if a judge were to hold that a combination of an oil engine, with a carriage, was "useful, novel and ingenious," he would again be confronted with several old patents, which have expired, in which this combination was claimed. The same remarks apply to the whole list of various possible claims, which I have enumerated above. Patents have been taken out more than 14 years ago, for oil motor tricycles and bicycles, for electric ignition, for ignition tubes, for clutches, and as for gearing, we all know that there cannot be an exclusive right, as various forms have been used in connection with road traffic since the early part of the century. It may be inferred from these remarks, that no patent taken out in connection with motor traffic is valid, but this I do not say. Some special device for doing a particular work may be a valid patent, but it will not be a Master Patent, and therefore will not prevent anyone else doing the same work by a modified device. To show you more clearly what I mean, I will analyse a de Dion and Bouton tricycle. I will not say that there may not be some parts in the tricycle which are patentable, but if these were upheld, it would not prevent anyone else making a motor tricycle, leaving out the patented portion. The motor itself, as far as I can see, has nothing novel about it. Its success depends on good manufacture. If there was any point in this motor upon which a valid patent could exist, a motor could be made just as good leaving this point out. The electric ignition has nothing particular about it to commend itself, although it is said that current is saved by the method adopted. It is an old laboratory device, namely, a tetanus spring set in motion by a rotating cam, which was "common knowledge" when the patent was granted ; but from an electrician's point of view there are far better ways of achieving the same result, supposing it to be held that the ignition device is a good subject for a patent, and these are open to all. To sum this up, an equally good tricycle can be made to do all which the one in question will do, without being subject to patents. The success of the tricycle in question is unquestionably due to excellence of manufacture, and not to any novel invention. I will not weary you by going through all the types of carriages, whether driven by steam, oil, compressed gas, compressed air, or electric energy, but I could prove with the greatest ease that the same remarks which I have made in regard to the tricycle, hold equally good as regards other types, and consequently there is no such thing as a Master Patent for motor traffic, nor can anyone claim a monopoly in this respect. At the present juncture a few words of advice to existing or intending manufacturers of motor carriages will no doubt be acceptable, when offered by one who stands in a completely independent position. When a manufacturer is threatened with an action for infringement, if he desires to continue to manufacture and place upon the market the article complained of, there are the proverbial three courses open to him :

(1) To knock under and make terms.
(2) To continue to take no notice and risk an action.
(3) To take steps to compel the patentees to start an action first, and oblige the threatening parties to prove their case.

I strongly advise the latter course to be followed in every instance, and the method of procedure which I would recommend is the following : When a manufacturer has the slightest doubt as to his position, he should make one of the articles stated to be an infringement, and place it on the market, then give notice of the fact to the parties who claim the rights and demand a reply within seven days. The reply must definitely state the intention to commence an action for infringement, or some equivalent form of proceeding. If not, it is evident that the parties claiming do not intend to face the Courts. If the answer takes the form of a threat, and no further action is taken, then the manufacturer should start an action on his own account to compel the parties to go into Court. It is a very simple matter to prove or disprove whether the device which has been made is an infringement or not. There is a general idea that an enormous expense attends these matters. This is quite unnecessary. There is no doubt a judge is very apt to look upon any mechanical device with a certain amount of awe, because he is not a technical man, and probably has admiration for what he thinks is ingenious. The manufacturer, therefore, should ask for a technical assessor to sit with the judge. A technical man is hardheaded and will probably see no particular virtue in a device which is commonplace, and unworthy of a Patent. The assessor has not to be paid for by the contending parties. If it is then decided that the device in question is not the same, nor a colourable imitation of the article claimed to have been infringed, or that the patent is not valid, then the manufacturer is free, and may continue to manufacture without risk. If, on the other hand, the decision is in the contrary sense, it is open to the manufacturer to make terms, or, which might prove the better course, to use a device outside the patent which would be more modern. This could only be done if the patent upheld were not a master patent, and such cannot exist in connection with motor traffic. In fact, any manufacturer with £100 at his command can thus protect himself against any individual or company, who may have hundreds of thousands to threaten with. Quite recently a small company which was threatened by the Dunlop Company, brought an action against them for undue interference and won their case. I trust that the above remarks, brief as they are, may assist in clearing away doubts and hesitation on the part of many intending manufacturers. If the present clouds could be lifted, not only would the coming industry show signs of life, but even those who now seek to obtain all the profit, must benefit with the crowd. The Self-Propelled Traffic Association, of which I have the honour to be President, effected good work last year in helping to obtain for the general public, an equitable Act for light motor traffic, and now it is equally desirous to secure for every Englishman that which he so highly values—his freedom. This is a fitting occasion to pay a tribute to the memory of an able engineer and a leader of the motor-traffic movement. Monsieur Levassor expired suddenly last month, leaving a gap which may never be filled again with such intelligence. As a man he was upright and honest; as an engineer he was able and clear headed; as a manufacturer he was conscientious; and as a friend he was true.

Summary.

I will now conclude by summing up in a few words what I have said in regard to motor-traffic.

For motor-cycles, benzine motors probably have the advantage.

In all other cases, steam promises to be the motive power when real work is called for, and where a return upon capital expenditure is required.

Electric energy, if the necessary adjuncts exist, has a great field open in towns, as a luxury, where the question of upkeep is not a vital item.

Finally, the best existing motor the world has yet seen, for its power, method of fueling, suspension springs, and travelling long distances before recharging, is one which is likely to remain with us for many a long year to come, whatever may be the future development of motor-traffic. It is known and loved by all, young and old, under the name of the Horse.

The Motor-Car Club.—On the 5th inst. a contingent of members and friends journeyed from Euston to Coventry, where they boarded, at the Motor-Car Works, several motor-cars, and journeyed to Birmingham. About 20 cars took part in the procession. Birmingham was reached at about 5.30 p.m., and after a drive round the environs, the club dined at the Grand Hotel, and, judging from the enthusiastic reports in the local papers, the entire outing was a great success.

NEVILLE'S MARINE OIL MOTOR.

MESSRS. J. NEVILLE AND CO., of Water Street, Liverpool, have designed and manufactured a very compact and well-arranged motor for launches and other small craft. This motor works on the "Otto" cycle, the explosion being determined by an incandescent tube heated by a special lamp, the outcome of many years of study and experiment, the products of combustion being exhausted through a tube overboard. There is, of course, a fly-wheel and the starting is easily effected by giving a half turn either way. A small pump is attached for circulating the jacket water. Reversing is effected by the device of altering the pitch of the propeller blades. Motion to the shaft is transmitted by means of a friction clutch. The special advantages claimed for this motor are:—Positive diaphragm valve motion, tube ignition, reliable burner lamp, no smell from exhaust condenser, no gear wheels, compact, and self-contained, no loose parts, uses common lamp oil, less weight, and less space occupied than by steam, no danger, no smoke or soot, no heat, and no stoker required.

Ordinary lamp oil is used about ·8 specific gravity, and the consumption is about one pint per brake horse-power per hour.

NOTES OF THE MONTH.

MR. JAS. E. TUKE gives a very favourable account of his experience with a motor-car during the past six months. In a recent communication he says:—"I have been using one since the commencement of October and during all the bad weather; during this time I have found it very satisfactory. I have run one 60 miles a day for several consecutive days, and in all sorts of weather, and all sorts of roads. The vibration when running is less than with a horse and trap, and the speed averages 10 to 12 miles on the level, and 5 to 6 miles an hour up hill. (The cost of running is about $\frac{1}{2}d.$ per mile for a two-seated car.) These have $1\frac{1}{2}$ horse-power motors, on the gas-engine principle, using petrol vapour, and give off practically no smell. As such large numbers of persons are desirous of having information about them, and as I am an enthusiast in regard to this new development, I have written a small book giving a short history of their development and present position, with descriptions of steam, oil, and electrical methods, and hints on management and working, illustrated."

LIVERPOOL is just now vexing its soul about the propulsion of its street cars. It seems that public opinion will not tolerate trolleys and overhead wires. Storage batteries are regarded as being too heavy and occupying too much space (a conclusion singularly at variance with the experience of the Hanover Tramway authorities). The choice lies between an underground cable or haulage plant, and one or the other electrical conduit systems. There is little doubt but that the latter, probably that known as the "Simplex" form, will be adopted.

THUS *The Engineer*: "As to electrical engineers, no word that can aid a misguided young man to enter their ranks shall flow from our pen."

AN electric motor-cycle has lately beaten tho record for all distances up to six miles. On Good Friday last, at the Catford Cycling Club Sports, an electric tandem motor, driven by Messrs. Dacier and Hunter, succeeded in beating all previous records for all distances over two miles to six miles, the length of the test, the six miles being covered in 10 minutes and 34 seconds, which is $28\frac{3}{5}$ seconds inside the world's record for any class of machine. It was stated the electric motor tandem had been tried capable of covering 40 miles an hour. The only point calling for criticism was the inability of the motor-cycle to graduate its speed to that nicety required.

SAYS the *Leeds Mercury*:—"The boom in motor-cars, which most people expected after the Bill allowing light locomotives to run at a fair speed on public roads became law, has not yet come off. Some of the reasons for this were hinted at at the last meeting of the Yorkshire College Engineering Society. The motor has evidently not yet been brought to such a degree of mechanical perfection as justifies popular faith in its general utility and efficiency. Mr. Frederick Grove, of the Institute of Civil Engineers, gave the College Society some idea of the difficulties that have to be overcome, and of the great divergence of type among motor-cars. The opinion was expressed at the meeting, that if the chemist and the engineer were to put their heads together they might be able to devise something of value in the way of a motor-car driven by an oil-engine; and another speaker gave utterance to a wholesome and timely truth when he said that the development of the motor-car should be taken out of the hands of the company promoter and the faddist, and placed in the hands of the practical engineer." With the last sentence we cordially agree. We give a *précis* of Mr. Grove's paper in another column.

FROM the results obtained by the Hon. Chas. Parsons in the *Turbinia*, as recorded in the paper that he read at the recent meeting of the Institution of Naval Architects, we have formed a high opinion of the suitability of this motor for road locomotion. It certainly possesses many distinct advantages; there is no gearing, all the motion parts being completely enclosed. Perfect expansion of the steam is obtained in one stage. We hope to describe this motor at length in a future issue.

WITH a view to rendering the common use of acetylene less dangerous, Messrs. Claude and Hess have proposed to store it in solution. The solvent chosen is acetone, which is capable at atmospheric pressure and at 60° Fahr. of dissolving 25 times its volume of the gas, whilst at a pressure of 12 atmospheres it can hold no less than 300 times its volume in solution. Thus 1 lb weight of acetone is capable of storing practically the whole gas which can be generated from 1 lb. of calcium carbide. The solubility of acetylene in acetone is only about half as much at a temperature of 120° as it is at 60° Fahr.

IT is stated by the *Journal of Gas Lighting* that calcium carbide may be manufactured by heating calcium tartrate to 930° Fahr. in a cast-iron retort. A dry, hard, grey, spongy mass, effervescing freely on contact with water, is obtained, and is stated to be composed of calcium carbide.

THE Thames Valley Launch Company (Limited), of Riverside Works, Weybridge, are delivering a 45-feet electric launch to the Corporation of Southport to run on the artificial lake at Southport, and also one of 30 feet in length, a cabin boat, and a small open electric boat to the Chester Boat Company to run on the Dee. They have delivered since last season six launches and one large down-river sailing craft of entirely new design, among the launches being one for the War Department. We understand that the electric launches are very popular on the Thames; their cleanliness and absence of smell and noise greatly recommending them.

ACCORDING to the newspapers, a motor-car, an air-propelled car, a traction-engine, and a boiler exploded at Charing (Kent) recently, severely injuring the owner, who is also the maker of this apparatus. From more reliable sources we learn that the owner, with considerable ingenuity, had mounted an oil-engine of a somewhat obsolete type upon a framework on wheels, and, as so arranged, it was very convenient in driving sawing machinery or other operations. Owing to some cause not clearly ascertained there was a premature explosion, the plummer blocks were broken from their places, and the shaft, connecting rod, piston, &c., were by the force of the explosion hurled some distance away. A portion of the *débris* struck the owner. It will be seen that the machine was not a motor-car, but in many quarters the story that it was had been implicitly believed, and the public duly warned against the dangers of all vehicles not pulled by the "friend of man."

ANOTHER accident, near Scarborough, to an electric motor-car, the property of Messrs. Walker and Hutton, has been extensively circulated through the Press of the country, and made much of as usual because it was a motor-car. Mr. Hutton, writing upon the subject, says:—"The real cause of accident was an ignorance (which, I believe, is fairly widespread) of the principles upon which curves in the road are constructed. There is a prevailing impression that such curves should be banked up towards the outside edge, but theory and practice evidently disagree, and if we are to take a lesson from the particular road on which the accident occurred, we now know that the proper way is to bank up the road on the inside edge, this having the effect of varying the monotony of existence both to residents in the neighbourhood and travellers along such roads. Indeed, one of the above residents told me that this accident was the third that had occurred at that corner within a week. Evidently, therefore, such mishaps are not entirely confined to motor-cars, although all others are too usual to merit headlines and large type in a newspaper. As near as I can judge our speed at the time would be about seven miles an hour, and although we had the brakes on going down the hill we had just taken them off prior to ascending the hill round the curve when the accident happened. The only damage done was the buckling of one of the wheels, and the incident has served the purpose of demonstrating that such accidents are not necessarily attended with the disastrous results that some people have pictured, and during our involuntary ariel flight we had the satisfaction of knowing that our steed would neither kick nor run away, as the engine stopped immediately. I thank the gentleman who—obviously for our consolation—remarked that a horse and cart had just dropped over the cliffs on to the sands."

THE Dublin Corporation evidently does not attach much importance to the adoption of electric traction by the United and Lucair Tramway Company, although, in the opinion of those claiming to judge, its installation would be of great benefit to the inhabitants of the city. Recently a special meeting was convened to meet the representatives of these companies, who, after waiting a considerable time, were perforce informed no business could be gone into in consequence of their being "no house," *i.e.*, no quorum. The general welfare of the taxpayers, it would therefore appear, is hardly of sufficient moment to bring a solid gathering of the Corporation together, and possibly the Lord Mayor, who patiently waited for a "house" to assemble, may another time when he wishes to ensure a quorum take the hint naively put forward by the *Dublin Express* to "put on the agenda paper that the first business would be to pass a resolution calling upon the Queen to celebrate her Diamond Jubilee by letting out all the political prisoners."

MOTOR COMPETITIONS.

HAVING in view the motor-car tests that have, with such public spirit, been inaugurated by our contemporary *The Engineer*, we are not sure that our other contemporary the *Irish Field* is well advised for the present in instituting a series of motor-car races in order to test the merits of the various machines. The object of our Irish contemporary is laudable enough. The motor-car industry has extended to Ireland under the auspices of Mr. Pennington, and before investors are required to "sink" (*sic*) their money, our contemporary thinks very rightly that the public should know more about the subject, so as to be able to use some discretion in investing. But we would point out that the question of merit cannot be altogether solved by means of a "great race," as our contemporary suggests; at the same time, such a test undoubtedly has value as indicating speed and endurance. The merits of motors will be authoritatively analysed in the forthcoming *Engineer* contest, when a committee of leading engineers will undertake the investigation. On the reports of this committee the public may rely for accurate and unbiassed information. A further examination of the various motors will also form part of the programme of the Royal Agricultural Society's summer meeting, so there will be no lack of scientific analysis. Investors would certainly be well advised to exercise extreme caution in subscribing to motor company shares till they are better in a position to estimate the commercial value of each machine.

THE Great Horseless Carriage Company have taken extensive showrooms at 47, Holborn Viaduct.

MOTOR-CAR AND CYCLE EXHIBITION.

IT is a pleasing sign of the growing popularity of the automotor industry that, from time to time, it is found necessary to indicate the progress that is being made by means of an exhibition. For some time past an energetic committee, of which the Hon. W. F. B. Massey-Mainwaring, M.P., is president, and Mr. W. M. Paterson is secretary, has been arranging details, and the St. Stephen's Hall, better known as the Royal Aquarium, Westminster, was selected as the site. The Exhibition was officially opened on May 1st, and closes on the 22nd. Owing, however, to the press of work under which manufacturers are labouring, it was not found possible to open quite so early as was intended. It is rather a difficult matter to bring motors from France, and many exhibitors experienced considerable trouble in getting their machines over. However, after a deal of hard work a very satisfactory collection of self-propelled vehicles has been got together. As most of them have at various times been fully described in the columns of THE AUTOMOTOR AND HORSELESS VEHICLE JOURNAL, any detailed description would be out of place. We notice, however, that in many respects, chiefly in matters of detail, there has been an improvement. Thus springs, levers, nuts, bolts, &c., now bear a more finished and workmanlike appearance than formerly. There is a marked absence of what we may term amateurism about the machines. These remarks are especially applicable to such well-finished vehicles as Arnold's "sociable," and Arnold and Hewetson's victoria. These cars are in their appointments, &c., equal to anything which is seen in the park. They represent the carefully finished fashionable carriage. An equally well-appointed car is that built by Peugeot, and owned by the Hon. C. S. Rolls. Th. Gambier and Co., whose sole representative in England is Mr. F. Frentzel, show a serviceable and well-built motor-car, which is especially interesting as showing how little a well-designed motor-car is affected by hard work; this car has travelled for over two years, and beyond looking rather faded in its upholstery, it is as good as ever. Messrs. Leutzman show a large and substantial looking motor-car, while Mr. Carl Oppermann has a very fine electric motor-car. Messrs. Hildebrand show two well-finished specimens of a motor-tandem and a motor-cycle; as do Messrs. Duncan. A peculiar-looking motor-cycle is the Kane-Pennington motor. As an ingenious piece of mechanism it is interesting as indicating early effort in motor-cycle construction. Mr. Powell, of Hoxton, shows a well-finished model gas-engine. Among motor accessories we may mention a wheel intended for heavy motor-car work designed by Mr. G. Jobson. There is a large and varied exhibit of cycles, the principal exhibitors being the New Howe Company, the Griffin, the Yost, the Wilkinson, and Victor. Although small, the show is well arranged, and will bear careful inspection. It is quite a new departure and hence the originator and manager, Mr. August Villers, has been well advised in not engaging a too large space. We understand that this Motor Exhibition is to be an annual affair, and as the industry grows so will the Exhibition. Owing to the pressure upon our space and that we are going to press at the time of writing, our notice has necessarily been short and incomplete. We hope, however, to describe the more important novelties in our next.

"The Engineer" Road Carriage Competition.

IN its issue for May 7th *The Engineer* publishes the following notice:—"We are now in a position to announce that the judges have decided to make their preliminary examination of the vehicles entered for competition on Friday the 28th, and Saturday the 29th May, at the Crystal Palace, and that they will start the competitors on the long-distance run on Tuesday, the 1st June. Mr. H. Graham Harris, M. Inst. C.E., will act as secretary during the trials."

A full report of these trials will appear in our June number. As the subject is so important, we have arranged to issue a special supplement describing the trial as fully as possible.

Y 1

A MOTOR WAGONETTE.

The accompanying illustration shows an exceedingly useful design of a Daimler motor-car, well adapted for hard work in the country. Most of the mechanism is out of sight, and well enclosed against dust, &c. The starting handles, brakes, &c., are all conveniently placed within reach of the driver. We are informed that the design has given great satisfaction to the inhabitants of Brighton. One day last week Mr. Monk, of the Brighton Cycle and Motor Company, Limited, Marine Parade, to whom the car belongs, drove to London and back, conveying five passengers and himself, very comfortably in 9½ hours, inclusive of stoppages. They started at 7.30, reached Horley at 9.30, where they stayed half an hour, arriving at Peckham at 12.30. The return journey was completed in 4½ hours. The oil consumed was exactly 7 gallons, which cost 7*s*., or about 1*s*. 2*d*. per passenger, and little more than ¾*d*. per mile.

Cycle Tyre Patents.—The action brought in France by the Welch-Dunlop combination against the French manufacturers of pneumatic tyres for infringement of patent rights was on the 7th instant finally decided by the Third Chamber, after dragging on for over two years. The judgment of the Court was against the Dunlop Company on every point.

EFFICIENCY OF STEAM-ENGINES.

Hardly any word excepting that of "gentleman" is less understood and more misapplied than "efficiency." In steam-engines a high efficiency is always claimed by makers naturally enough, but, according to how the word is employed, it is difficult to say what is really meant. The Institution of Civil Engineers have had a committee at work for some time past on this subject, and this committee reports :—

1. That the statement of the economy of a steam-engine in terms of pounds of feed-water per I.H.P. per hour is undesirable.

2. That for all purposes except those of a scientific nature it is desirable to state the economy of a steam-engine in terms of the thermal units required per I.H.P. per hour (or per minute), and that, if possible, the thermal units required per brake H.P. should also be given.

3. That for scientific purposes the thermal units that would be required by a perfect steam-engine working under the same conditions as the actual engine, should also be stated.

The proposed method of statement is applicable to engines using superheated steam as well as to those using saturated steam, and the objection to the use of pounds of feed-water, which contain more or less thermal units according to conditions, is obviated, while there is no more practical difficulty in obtaining the thermal units per I.H.P. per hour than there is in arriving at the pounds of feed-water.

For scientific purposes, the difference in the thermal units per I.H.P. required by the perfect steam-engine and by the actual engine shows the loss due to imperfections in the actual engine.

A further great advantage of the proposal is that the ambiguous term "efficiency" is not required.

TRAVELLING WITHOUT HORSES IN 1770.

MOST students of the history of self-moving carriages are familiar with the name of Francis Moore, the London linen-draper, who in 1769, the date of the construction of Cugnot's steam-carriage, obtained two patents for motor-carriages. The first of these was to be "put in motion by fire, water, or air, with a small assistance of horses or manual labour," the second was "constructed upon peculiar principles, capable of being wrought or put in motion by force or power without being drawn by horses or any other beast." Unfortunately no specifications were enrolled, so we have no means of ascertaining what the inventor had in view.

Moore is referred to in the correspondence of James Watt (*see* Muirhead's "Life of James Watt"); thus, in a letter dated April 28th, 1769, Watt writes:—"If linen-draper Moore does not use my engine to drive his chaises he can't drive them by steam. If he does I will stop them. I suppose by the rapidity of his progress and puffing he is too volatile to be dangerous." Further on in the same letter, apparently in a jocular mood, he writes: "Here I work five or more years contriving an engine, and Mr. Moore hears of it, is more *éveillé*, gets three patents at once, publishes himself in the newspapers, hires 2,000 men, sets them to work for the whole world in St. George's Fields, gets a fortune at once, and prosecutes me for using my own invention."

There is no evidence, however, that Moore actually did set to work upon the construction of a motor-carriage, or at any rate that he completed one, although some references in the public journals of that period have been read, and not unreasonably too, as referring to such carriages. Thus in the *Leeds Mercury* of April 11th, 1769, the following paragraph appeared:—

"A correspondent writes that Mr. Moore's new invented machine to go without horses, for which he has obtained His Majesty's patent, is not only adapted to wheel carriages in general, such as coaches, chaises, carts, wagons, &c., but to ploughing, harrowing, and every other branch of husbandry, also to all other machines and engines now in use throughout the kingdom, in various branches of manufacture wherein draught horses are now employed. We hear that the ingenious inventor has sold all his own horses, and by his advice many of his friends have done the same, because the price of that noble and useful animal will be so affected by his new invention, that their value will not be one-fourth of what it is at present."

The *Gentleman's Magazine* for the same year informs us that "Mr. Moore, the ingenious contriver of the carriage to travel without horses, waited upon His Majesty, at Richmond, with one of them, who was graciously pleased to express his approbation of it."

These references, however, in point of fact, notwithstanding the employment of such terms as "self-moving," "to travel without horses," &c., refer only to horse-drawn vehicles, to the improvement of which Moore devoted much time and money.

This view is confirmed by an article in the *Scots Magazine* for 1771, which refers to "the coach Mr. Moore had invented to be drawn by one horse having been a subject of general consideration." And still more strongly by the accompanying illustration, copied from a print in the possession of Mr. Rhys Jenkins, and entitled "Mr. Moore's New Invented Machine for Travelling without Horses." There is no denying the presence of the horse; possibly what was meant was that one animal did the work of two or more usually employed. The novelty appears to have consisted in using a single pair of wheels of great height.

DEATH OF M. LEVASSOR.

ALL interested in the evolution of the automotor will regret to hear of the death of M. Levassor, who has done so much to make horseless traction a practical success. The deceased was an engineer of considerable distinction, but his *rôle* lay rather in improving existing machinery than in inventing new types. It was in 1888 that M. Levassor turned his attention to road locomotion, and, being impressed with the possibilities of the then new Daimler motor, he took it in hand and effected many improvements in detail which have rendered it, or rather, in its improved state, the "Phœnix" motor, one of the most reliable petroleum motors in the market. Applying it to road carriages M. Levassor achieved the most remarkable success. His feat of riding from Paris to Bordeaux and back last year was not less a proof of mechanical ability than of physical endurance and courage. M. Levassor was the junior partner in the firm of MM. Panhard and Levassor, whose motor-carriages are too well known for excellence and durability to need any commendation from us. In engineering and especially in motor circles M. Levassor was deservedly regarded as an authority, while his personal qualities made him a distinguished friend to all who sought his advice. In the Automobile Club he was especially regarded, and it was largely due to his enterprise and tact that this club has become so influential. M. Levassor was taken ill quite suddenly with an affliction of the brain and expired soon afterwards at the comparatively early age of 54. His obsequies took place on April 18th at the Church of Ivry. A very large number of professional and private friends, including a large contingent of the Automobile Club, attended to pay respect to the remains of their late distinguished colleague. Among those who sent floral marks of respect was Sir David Salomons on behalf of the Self-Propelled Traffic Association.

The "Master Patents" of the British Motor Syndicate and Roots and Venables.

EXTRACT FROM THE ADVERTISEMENTS OF THE BRITISH MOTOR SYNDICATE.

"WHEREAS the British Motor Syndicate have acquired and are now further acquiring by purchase a large number of valuable inventions and discoveries in the manufacture of motors, the results of many years' experiment and research in this and in other countries, and

"WHEREAS the said inventions and discoveries include the first master patents for the first successful application of oil and explosion engines to vehicles as a means of their propulsion, and

"WHEREAS the said discoveries which have taken place in Great Britain, France, Germany, and America, include in combination all the various methods of tubular ignition, electric ignition, and explosion by heat in motor vehicles, and

"WHEREAS the said inventions cover the latest improvements in motor vehicles, and motor vehicles propelled by electrical motors, and

"WHEREAS the acquirement of the same has cost the said British Motor Syndicate over £250,000, and

"WHEREAS the said British Motor Syndicate has and is expending large sums of money in creating and establishing the motor-car industry in this country, and in the tuition of mechanics, the teaching of drivers, the holding of exhibitions and various competitions, and in other ways advertising and causing a popular demand for the said business of motor-vehicle construction, and

"WHEREAS the said Syndicate has caused by advertisement notice to be given to persons to discontinue the infringement of their patents,

"THIS IS TO GIVE NOTICE that a sum of £50,000 having been specially set aside by the said Syndicate for the purposes of defending and supporting the said patented inventions, proceedings will be immediately begun against all persons importing into this country motor vehicles, also against all persons riding or using the said motor vehicles, also against any persons manufacturing or offering for sale the said motor vehicles, the inventions of which belong to this Syndicate, and that the Syndicate hold all persons liable for heavy damages in the matter of such infringements."

As an example of the manner in which the intimation cited above is enforced, the following correspondence is instructive. It refers to an action which we suggested in our March number as being imminent. But evidently we were not fully acquainted with the methods of the British Motor Syndicate in upholding their rights. The last letter to hand, now published under date May 4th, apparently postpones the issue of a writ until long subsequent to *March 12th*, the original date which peremptorily granted four days' grace to Messrs. Roots and Venables in which to climb down, or supply the names of their solicitors to receive service of process for alleged infringement. To-day is May 14th (nearly two months), and still the British Motor Syndicate writ has not arrived. Therefore, all ye who are concerned read, mark, learn, and inwardly digest the contents of the following correspondence, and understand the true value of any threats of legal action which may be hurled promiscuously at the head of any innocent manufacturer who is desirous of further qualifying himself for duly discharging his duty to the public and otherwise increasing his income by means of securing some of the large profits foreshadowed by the British Motor Syndicate, and likely to be earned by either that body or traders in general, or both, from the rapidly approaching trade likely to be transacted in connection with automotor vehicles:—

12, New Court, Carey Street,
London, W.C., March 12th, 1897.

Dear Sirs,—We have been instructed by our clients, the British Motor Syndicate (Limited), to write you with reference to your infringement of their patents as applied to motor-cars, and also to call your attention to the advertisement which appears on the last page of the *Autocar* of the 13th inst. Unless we receive by the 16th inst. an undertaking that you will discontinue the infringement of our clients' patents and also the advertisement of your machines, we are instructed to commence proceedings against you, in which case we shall be glad if you will let us know the name of a solicitor who will accept service on your behalf.—Yours truly, SHARPE, PARKER, AND CO.

Messrs. Roots and Venables,
100, Westminster Bridge Road, S.E.

100, Westminster Bridge Road,
London, March 13th, 1897.

Messrs. Sharpe, Parker, and Co.,
12, New Court, Carey Street.

Dear Sirs,—Your favour of yesterday's date to hand. Kindly inform us the number and date of the patent or patents you allege we are infringing, and in which part of our motor or car the infringement lies.—Yours faithfully, ROOTS AND VENABLES.

We have pleasure in enclosing you our lists.

March 16th, 1897.

British Motor Syndicate and Yourselves.

Dear Sirs,—We have now seen our clients with reference to your letter of the 13th inst., and they inform us that the patents they claim under, and which they say you infringe, date from 1884.

We are also instructed to inform you that our clients claim, firstly, the invention of an oil-engine suitable for the propulsion of vehicles; and, secondly, the application of such engines to vehicles.

We understand that you are infringing about 47 of the patents belonging to our clients.

Kindly let us know by return of post whether you are prepared to give the undertaking asked for; if not, we are instructed to commence proceedings against you.—Yours truly,
SHARPE, PARKER, AND CO.

Messrs. Roots and Venables.

March 17th, 1897.

Messrs. Sharpe, Parker, and Co.

Dear Sirs,—Your favour of the 16th instant to hand. You have not replied to our letter of the 13th instant asking for the numbers and dates of the patents you allege we infringe, also specifying what part or parts of our car infringes, and which particular patent such part or parts are alleged to infringe.

Without these particulars you must perceive it is not possible for us to take your letter seriously.

The claims you say your clients make, headed "firstly" and "secondly," are really too absurd for us to reply to.—Yours faithfully, ROOTS AND VENABLES.

March 25th, 1897.

Messrs. Sharpe, Parker, and Co.

Dear Sirs,—We should be glad to have an answer to our letter of the 17th inst. with reference to our alleged infringement of the British Motor Syndicate's patents.—Yours faithfully, ROOTS AND VENABLES.

In the sixth letter, dated April 1st—a significant date—Messrs. Roots and Venables reiterated their request for particulars of the alleged infringements, and in their communication expressed their opinion of the value of the Syndicate's patents, and suggested that their own patents (more particularly No. 23,786, dated December 24th, 1892, which covers the conveyance of the jacket water for cooling purposes through the frame of the carriage) were being infringed by the Syndicate; this letter being simply acknowledged as under:—

April 2nd, 1897.

British Motor Syndicate and Yourselves.

Dear Sirs,—We have your letter of yesterday's date, and have forwarded a copy to our clients.—Yours faithfully,
SHARPE, PARKER, AND CO.

Messrs. Roots and Venables.

Their request being still disregarded, they again wrote as follows:—

April 27th, 1897.

Messrs. Sharpe, Parker, and Co.

Dear Sirs,—As you have now had ample time to communicate with and receive a reply from your clients, the British Motor Syndicate, we shall be glad to hear what they have to say with regard to their infringement of our patent No. 23,786, dated December 24th, 1892. An immediate reply will oblige.—Yours faithfully, ROOTS AND VENABLES.

April 28th, 1897.

British Motor Syndicate and Yourselves.

Dear Sirs,—We have received your letter of yesterday's date, and have written our clients for their instructions thereon.—Yours truly, SHARPE, PARKER, AND Co.

Messrs. Roots and Venables.

April 30th, 1897.

British Motor Syndicate and Yourselves.

Dear Sirs,—We have now heard from our clients on your letter to us of the 27th instant, and are instructed by them that they are not using, and do not intend to use, the alleged invention covered by the letters patent No. 23,786/92, and they are not, therefore, infringing, and do not intend to infringe, your rights thereunder.—Yours truly, SHARPE, PARKER, AND Co.

Messrs. Roots and Venables.

This communication was immediately followed by a further letter direct from the Syndicate, as under:—

Hertford Street, Coventry,
May 1st, 1897.

Messrs. Roots and Venables.

Dear Sirs,—Referring to your communication of April 1st, addressed to Messrs. Sharpe, Parker, and Co., we beg to inform you, for your satisfaction, that we have never used your water-cooling patent, No. 23,786/92, nor have we any intention of using it.—Yours faithfully,

The British Motor Syndicate (Limited),
CHAS. MCROBIE TURRELL, General Manager.

May 3rd, 1897.

The British Motor Syndicate (Limited).

Dear Sirs,—We were glad to receive this morning your assurance that you are not using our water-cooling patent, No. 23,786/92.

Kindly inform us if, in any of the Daimler motor-carriages the jacket water is conveyed through the tubular frame of the car.

Your attention will oblige.—Yours faithfully,
ROOTS AND VENABLES.

May 4th, 1897.

Messrs. Roots and Venables.

Gentlemen,—Regarding ours of the 3rd of May, so far as we are aware, and we consider we have good grounds for making this statement, none of the Daimler carriages convey their cool water through a tubular frame, for the obvious reason that the frames are not tubular.—Yours faithfully,

The British Motor Syndicate (Limited),
CHAS. MCROBIE TURRELL, General Manager.

It is significant that in neither the letter of April 30th from Messrs. Sharpe, Parker, and Co. (on behalf of the British Motor Syndicate), or in the letters of May 1st and 4th, signed on behalf of the same body by Mr. C. McRobie Turrell as general manager, is one word of reference to the very peremptory demands set forth in Messrs. Sharpe and Co.'s original letter of March 12th. We shall, therefore, await with restrained curiosity and suspended interest, the threatened but oddly enough still deferred enforcement of the British Motor Syndicate claims, as it is obvious, we submit, that they must either enforce their original demand, or for ever hold their peace.

MARINE MOTOR NOTES.

MESSRS. THORNYCROFT AND Co., of Chiswick, the well-known torpedo-boat builders, are just completing a steam turbo-life-boat for the R.N.L.I., named the "Queen," and which is to be stationed at Liverpool. The new vessel is 55 feet long and 16 feet beam. At the draught of 3 feet 3 inches she displaces 30 tons. She is propelled by a steam turbine driven by engines of 250 horse-power indicated. The boiler is one of Thornycroft's well-known type, and is fitted for burning either oil or coal; the steam pressure being 145 lbs. per square inch. The speed attained under favourable conditions is, we understand, from 9 to 10 knots. There is a large rudder which can be raised if necessary. The hull is built of steel, and is divided into 18 water-tight compartments. In a future issue we hope to fully describe and illustrate this craft.

Now that the House of Commons is investigating by means of a Select Committee the administration of the National Life-boat Institution, we should be pleased if some competent naval architect would draw the Committee's attention to the fact that propulsion by oars is about the most inefficient form of propulsion known. There is no reason why lifeboats should not be propelled by screws suitably designed and carried, driven by automotors. This form of propulsion is cheap and efficient. The fact is there is a prejudice against the use of screws, because it is alleged that they would be fouled by floating wreckage, and would also render the boat unable to be beached. It all depends how you carry the screws; and how and who designs the vessel. It is quite possible to propel lifeboats by screws, and beach them too without in any way risking damage to the propellers. At present the steam turbo-lifeboats are enormously costly; while the method of propulsion is very inefficient. Fancy 250 indicated horse-power to move 30 tons at nine knots! So many people resent any criticism directed to public or semi-public institutions engaged in "good works," that we shall no doubt be thought captious in drawing attention to this matter; but to show what a waste of power there is in the present mechanically-propelled lifeboats, we may mention that a coasting steamer 200 feet long and 26 feet beam, and of 1,550 tons displacement, can be propelled at nine knots with the same power; that is, a vessel 50 times heavier, and nearly four times longer than the latest lifeboat, only takes the same power to produce the same speed. As another example, we might mention that some Admiralty steam pinnaces now being built by the Thames Ironworks Company, of Blackwall, are 56 feet long, 9 feet 9 inches beam, and 4 feet 7 inches deep, at the load displacement of 27 tons they are propelled at 14·6 knots by engines developing 214 indicated horse-power.

WHEN so much is being attempted to resuscitate our canal traffic, it is surprising that the propulsion of barges and small craft by gas-engines has not been tried. That there are difficulties in the way we know, so there are before anything can be achieved in this world. We are sorry to observe that our French friends have in this, as in so many naval methods, shown us the way; and canal boats propelled by gas-engines are not uncommon in France. A new boat of this type has recently been put in service for the Havre-Rouen-Paris line, the speed attained being seven knots. It is 100 feet long, with 7 feet draught, divided into four water-tight compartments. The gas is supplied from on shore, and is stored on board in a steel holder, an accumulator composed of steel pipes, under a pressure of 95 atmospheres, about 850 lbs. The engine employed is a two-cylinder one, of 40 horse-power. The gas is stored in tubes or receivers, each of which is about 5 metres long, and weighs about 715 lbs., the gas being compressed to a pressure of 100 kilos. per square centimetre, or about 1,400 lbs. per square inch.

THE MOTOR-CAR IN SOUTH AFRICA.

THE credit of having been the first to introduce the motor-car to South Africa belongs to Mr. J. P. Hess (brother of the editor of the *African Critic*). Mr. Hess has lately arrived in London, and has furnished us with an interesting account of the commotion and excitement caused by the appearance of the motor-car. It appears that it was first exhibited at the Berea Park, Pretoria, hardly a month after the famous Brighton run.

Mr. Hess had invited the principal officials to witness the turn out, and, amongst others, his Honour the State President, with his staff, accepted the invitation, as did the State Secretary, Dr. Leyds. The former seemed highly delighted when the mechanism was displayed to him, but he had evidently not studied "motor-cars," as he shook Mr. Hess heartily by the hand and expressed his pleasure that Mr. Hess had introduced such a clever invention into the Transvaal, and said, "You deserve a gold medal." This we reproduce. The inscription, which is in Dutch, says:—

"Presented by H. H. PAUL KRÜGER, State President of the South African Republic, to MR. J. P. HESS, in remembrance of his introducing the First Motor-car to South Africa, Monday, January 4th, 1897."

We have inspected this valuable medal, which is of solid gold, carrying on one side, beautifully enamelled, the arms of the South African Republic, and on the obverse the inscription, and is the first medal ever presented to an Uitlander. After Mr. Hess had thanked the State President, he invited him to take the first ride, but his Honour jocularly remarked, "I am afraid a dog might bark, and it might buck and run away with me." Mr. Hess then invited Dr. Leyds, the State Secretary, who at once consented, and went whirling round the track at excellent speed, amid cheers of the spectators. From the time of the landing of the motor-car at Port Elizabeth until the successful exhibition, the South African papers, both English and Dutch, simply teemed with references to motor-cars.

The motor-carriage which Mr. Hess exhibited came direct from Messrs. Benz and Co.'s works at Mannheim. It was only a 1½ horse-power dog-cart. He, however, has arrived in England to specially study machines most suitable for South African roads, and several influential people out there are also greatly interesting themselves in connection with motor-carriages suitable for that country. Mr. Hess's address is—c/o the *African Critic*, 156, Leadenhall Street. The historical motor-car imported by Mr. Hess was at once purchased after the show by Mr. A. H. Jacob, a well known coffee manufacturer in South Africa, and although he paid a high figure for acquiring the same, he admitted he was perfectly satisfied, as he never had had a better advertising medium. The Sanitary Board of Johannesburg tried to stop the car being used in the streets, but Mr. Hess advised Mr. Jacobs to ignore their officious interference, as the Government of the Republic had hailed the introduction of the motor-car with satisfaction, and this view was expressed to Mr. Hess by some of the high officials at Pretoria. The Republic will soon have the opportunity of getting used to motor vehicles, as we understand upwards of 200 delivery vans have already been ordered for South Africa.

MOTOR-CARS.

By Mr. F. GROVER, Assoc. M.I.C.E.

THE following is a *précis* of a paper read on the 26th ult. by Mr. F. Grover, Assoc. M.I.C.E., before the Yorkshire College Engineering Society:—

"Cars might be driven by steam, gas, oil, or spirit, and electricity, or by compressed air, though he regarded the latter as being out of the question for a considerable time to come. He was of opinion that no one of the other four sources of power could be regarded as fulfilling the conditions required by different persons in pursuit of their business. The steam-engine, to his mind, was the most suitable form of motor hitherto designed, for the following reasons:—(1) Heavy traction on ordinary roads by means of specially designed engines, engines and boilers being contained in a separate vehicle; this was typified in the ordinary traction-engine of to-day. (2) Transport motors for the carriage of heavy cargoes, such as parcels or luggage in bulk, or for the use of tradesmen whose wares were of considerable weight. (3) Vehicles for passengers, and built to accommodate more than six persons. The present form of traction-engine was capable of improvement in such details as the introduction of three-speed gear for high speed on good, level roads; but the regulations recently issued by the Board of Trade precluded development along this line, for no carriage weighing over two tons unloaded was allowed to travel at more than five miles per hour. If, therefore, speed was required, as was, indeed, necessary for the rapid distribution of goods, they must seek a type of engine that would enable the weight to be reduced so as to run at 12 miles an hour, and in that case engine and boiler and carrying space must be included in one carriage."

After discussing the regulations affecting speed he proceeded to discuss the question of boilers:—

"The combination he regarded as best fitted to meet the requirements stated was steam raised in a water-tube boiler, preferably of the flash type, of which the Serpollet boiler was the best practical example. The steam turbine, either of the Parson or Laval type, was very suitable for driving, absence of vibration being its great recommendation. Among the advantages of tubular boilers of the flash type was that there was no danger of serious explosion, no large weight to be carried as water in the boiler, no fear of the fire-box crown overheating, and no trouble in keeping the feed at a constant level. Disadvantages were that the tubes were liable to make up, the engine cylinders were liable to score, and that the tubes in the bulk were heavy. Nevertheless, he considered the balance was in favour of this type of boiler. He considered the ordinary tubular boiler as the next most suitable. Its advantages were the rapidity with which steam could be raised, the small bulk of water to be carried, and the small space occupied. Its disadvantages were the great fluctuations of pressure, the absence of steam reserve, and the very careful stoking required. With respect to the engine, it should certainly be reversible, and that was one drawback of the Serpollet carriage. As to the compounding of engines for cars, it was advisable in flat country, but of little use in hilly districts. Before leaving this part of his subject, he would urge the following advantages which steam offered:—(1) Simplicity of mechanism; (2) no necessity to carry large quantities of water or fuel (for both could be procured in any out-of-the-way place); (3) large power available when wanted; (4) starting quite easy; (5) when the carriage was standing, the engine was also stationary; and (6) certainty of action unknown to many gas or petroleum-engines. He did not consider compressed gas at all suitable, except for driving tramcars running on rails, and only then in special circumstances."

Passing on to oil-engines, he said :—"Oil-engines were divided broadly into two classes—one working with heavy oils and the other with light oils or petroleum spirit. He knew of only one case in which heavy oil had been successfully applied to small motors of the type usually applied to motor-cars and cycles, and as to light oils the danger was great, the smell objectionable, and generally speaking the design of the engines was not good. Nevertheless there was a great future for the oil-engine as a motor for cars, but he thought it would be restricted to very light carts or vans, and to pleasure vehicles carrying less than six persons, including the cycle. As to the form of ignition to be adopted, he thought the electric spark was greatly preferable to the hot tube. There was, however, great need of a good storage battery for purposes of ignition. As to electricity, the weight of the accumulator was out of all proportion to the power obtained, and the cost of maintenance was larger. With reference to the subject of motor-cars in general, there were many points, such as the value of pneumatic tyres, the limitation of load, the disposal of exhaust steam, gearing, &c., any of which was sufficiently important to mar the success of a design if not properly carried out."

INDIARUBBER.

Few vegetable products that grow without the aid of artificial cultivation are in more demand than Indiarubber. Not many years ago its use was so restricted that it hardly paid to import it from such distant places as the basin of the Congo, but now rubber trees are among the most valuable products of Central Africa, and formerly, when expeditions would set out for ivory, gold dust, &c., they are now undertaken in search of rubber.

Needless to say it has been the Submarine Telegraph and the Cycle that has chiefly occasioned the enormous demand for rubber. To such an extent has this demand grown, that in many quarters it is feared that the supply will in a few years become unequal to it.

Except in a few instances the rubber tree is a perfectly natural growth and owes nothing to human aid for cultivation. It is found in nearly all tropical forests, but the principal sources of supply are Central Africa, the East Indies, and Tropical America. Owing to the reckless manner in which it is collected, and the absence of proper measures for conserving the forests, whole districts have been denuded of their trees, and hence the supply of the natural gum has in these places fallen off. About 100,000,000 lbs. are annually collected, and of this, 21,500 tons, worth about £16 10s. per ton, are consumed in this country alone. It is perhaps unfortunate for the cycle industry that only the best kind of gum is suitable for pneumatic tyres, and this is known as Para rubber. We, of course, do not assert that every tyre is made of Para rubber, but if a tyre stands a long course of hard work well the probability is that it is. Para rubber being so expensive and so indispensable—there being really no efficient substitute for it, it is evident that any diminution in the supply of the gum will seriously affect the light motor industry. Another unfortunate thing about rubber tyres is that after use they are practically of no value. In the process of manufacture the rubber is vulcanised by which process it obtains its great permanent elasticity and stability, under extremes of temperature, but this very process renders the rubber all but useless for any other purpose but that for which it is shaped. The chemistry of rubber is not well understood, and apparently light and air exercise some subtle harmful influences. However, at present there is "nothing like rubber,"—at any rate for the electrician and cyclist. If there are any enthusiastic inventors, possessed of great patience, good chemical and mechanical knowledge, but principally ample means, they might well investigate rubber, and if they can devise a substitute which will do all that rubber will, and which can be produced at a reasonable price, they will be benefactors to the cycling world.

PRACTICAL HINTS.

In using oil motors pains should be taken to prevent, as far as possible, any leakage of oil. Owing to the great diffusive power of oil, absolute oil tightness is very difficult to ensure; and in all metallic holders or vessels more or less "creeping" of the oil takes place. In this way a thin film of oil gets deposited on hot surfaces, and in evaporating gives off a pungent smell, at the same time depositing a layer of carbon. This oil creeping cannot wholly be avoided, but its effects may be lessened by instructing the attendant to keep all hot surfaces frequently wiped with waste. In designing tanks for carrying oil too great care cannot be bestowed upon the rivetting, as if this is at all inferior leakage will take place; the rivets should be closely spaced, and if the tank is likely to be subjected to much vibration chain rivetting should be employed. Tanks for oil are best well galvanised, as the deposit of zinc acts very effectually in caulking the seams. The joints of hand holes, pipe flanges, &c., are best made by using brown paper steeped in glue. Indiarubber insertion should never be used for joints, as the oil softens it. For the same reason care should be taken that the oil does not get spilt upon the rubber tyres. Special care should be also taken to see that the tank containing the oil does not get heated by the motor, as, should the temperature of the oil reach the flash point, vapours are generated, which, mixing with the air in the tank, form an explosive atmosphere, not necessarily dangerous in itself, but unquestionably so in the vicinity of flame.

MR. J. H. MANN ON AUTOCARS.

At the last monthly meeting of the Leeds Association of Engineers, Mr. J. H. Mann read a paper on motor vehicles. He said that French engineers had been running motor-cars for two or three years with at least sufficient success to encourage the idea of a new industry in this country, providing a cheap and convenient method of locomotion. He briefly referred to the new Act of Parliament for legalising their use, and criticised some of its clauses. As an engineer, he was disappointed at the slow progress motor-cars appeared to be making, which he attributed to the fact of well-established firms being too busy to experiment with them. Perhaps, also, many of them were keeping in the dark with a view to the forthcoming competition promoted by *The Engineer*, and that some were waiting to see how others succeeded. It was not a difficult thing to make a machine that would run on the roads, the difficulty was in making one that would do its work better and cheaper than horses. Mr. Mann drew a comparison between the cost of the two. Horses and their keep were never so cheap as at the present time; and stony roads, especially in winter and wet weather, would tell considerably against motor-cars, in the use of which increased attention and less comfort would be involved. In order to succeed, simplicity in construction was a prime necessity. As a means of propulsion, electricity could only be used in limited areas, and he thought steam-engines met the requirements more completely than oil-engines. The Serpollet boiler, or instantaneous steam-generator, was a move in the right direction, on account of its simplicity and freedom from danger. He described various methods of using liquid fuel, the most successful he had tried being to burn it with an injector over a slow-combustion coke fire, but he thought the use of coke alone better still. By means of wall diagrams he showed the details in construction which he recommended, pointing out what to avoid and where trouble was likely to arise. He looked forward with keen anticipation to a great future for autocars, but at the present time, from a manufacturer's point of view, he should not care to put into inexperienced hands a complicated machine, especially with a guarantee for any considerable time.

THE TYRES OF MOTOR-CAR WHEELS.

It seems to us that with the application of motors for the propulsion of the heavier types of road cars, such as railway vans, brewers' drays, &c., some modification in the design of the wheels of such vehicles will be necessary. It must be remembered that with horse haulage the wheels merely roll on the road; the tractive effort being exerted by the horse. In a motor-van the tractive effort is exerted through the wheels, or at least by those termed the drivers, and hence the wheels must be capable, not only of sustaining the ordinary stresses set up in it when passing over a rough road, but also of transmitting the necessary tractive power. It can hardly be expected that the usually accepted design of wooden wheels can be much improved; but what can be done is to give greater strength and rigidity to the whole structure by careful tyreing. The ordinary system of shrinking on the tyres by employing the enormous natural forces of expansion is theoretically perfectly correct; in practice it involves subjecting the periphery of the wooden wheel to a charring process—not conducive to the improvement of the structure itself, and unless the operation is most carefully conducted, distortion of the wheel through irregular contraction is bound to result, at any rate it often occurs; while the rapid quenching process, as every metallurgical student is aware, sets up intense molecular stresses in the tyre itself, which in inferior metal manifest themselves in sudden fractures. The old system, in spite of these disadvantages, when properly used by conscientious mechanics is no doubt suitable for ordinary purposes, but for passenger traffic where compensation for injuries is a contingency to be provided for, and for locomotor vehicles in which the tractive effort is transmitted through the wheels, too much attention cannot be given to, not alone correct design of wheel, but also to proper tyreing. The points to be considered in the design of motor-car wheels are of course those which determine the similar problem in locomotoric and cycle wheels. In both of the latter we see great accuracy of form and manufacture attained, all the operations nearly being effected by mechanical means. In both, too, the tyre is perhaps the most important part of the wheel, but so long as the tyre was a matter of handicraft neither was satisfactory. It was the use of the hydraulic press and of high grade steel that enabled the present perfection to be attained and for motor-car wheels a similar means will have to be adopted. Already mechanical means have been applied to the tyreing of heavy horse-drawn carts and vans with, we understand, very good results, the tyres being put on cold by hydraulic pressure. Not only does this put a uniform compressive stress upon the periphery of the wheel, but it ensures correctness of form and prevents distortion. We should, then, strongly advise those of our friends who are interested in heavy motor-car traffic to see that in the specification for the wheels it is stated that they must be tyred by hydraulic means.

ELIESON'S ELECTRO MOTOR-CAR.

We recently inspected an electro motor-car, the invention and manufacture of Mr. C. P. Elieson, of the Lamina Accumulator Syndicate, Camden Town, London, N.W. As this new motor-car has several ingeniously worked-out mechanical details of great interest and of considerable novelty, an account will be interesting. Its general appearance is illustrated in the accompanying engravings. From these it will be seen that the framing of the car is composed of jointed and braced Manessmann steel tubes. Thus not only is great strength and rigidity obtained, but lightness also. Suspended from the two side girders is a small double armature series Wound motor, the connections so arranged that the coils can be placed either in series or parallel. On each end of the armature spindle and suitably supported by bearings is a bronze sprocket-wheel so formed as to its teeth as to engage with a specially formed chain. This chain has a steel pin passing transversely through every third link. This chain passes round a driving wheel attached to each hind wheel of the car, but the manner in which motion is transmitted from the fast speed and small-sized sprocket on the armature spindle to the slower moving car wheels is novel, ingenious, and, as we can testify, very efficient. On the periphery of the driving wheel are two bands of leather between which the chain passes, the latter being kept in position by the leather, but the friction or grip being obtained by the steel pins passing through the bulks as before said. It certainly took us some little thought to overcome our engineering prejudice, but after having seen the gear at work we have no hesitation in recommending it. Its great merits in our opinion are: it obviates the necessity for differential gear, it transmits the motion, and, lastly, it overcomes a serious difficulty in road traction. Should, as in turning a corner, or going over an obstacle, one wheel be checked, the other revolves at its normal rate, while the chain slips on the former, and, as soon as is necessary, is revolved, by friction, like the other. Current is supplied by a battery of 28 Lamina cells, having a capacity of 80 ampère hours. These cells are packed in what is the "boot," and occupy but little space. They are discharged at the rate of 20 ampère hours, and hence suffice in the car in question for a run of four hours, or about 40 miles at 10 miles. We should say that a feature about these cells is, that they are discharged always in series, the current being varied by putting the motor coils in series or parallel. We tested this motor-car on a pretty steep gradient and amid some heavy traffic, and found that it maintained a fast speed and was easily manœuvred. We think that this type of electro motor-cars has a distinct field for its operation, especially in the city.

NOTICES.

Contributions and articles likely to prove of interest to our readers will receive due attention, but in all cases the name and address of the writer must be given, not necessarily for publication.

All matter intended for publication should reach us not later than the 10th of each month. Stamped envelope must be sent if the manuscript is required to be returned. The Journal is published the middle of each month.

All Advertisements should be sent to the Advertising Department, F. KING AND CO., LIMITED, 62, *St. Martin's Lane, London, W.C., where Advertising Rates may be had on application.*

The Annual Subscription is 7s., including prepaid postage to any part of the world. Single copy 7d., post free.

Cheques and Post Office Orders should be made payable to F. KING AND CO., LIMITED, *and crossed London and County Bank; otherwise no responsibility will be accepted.*

SPECIAL NOTICE.

THE AUTOMOTOR AND HORSELESS VEHICLE JOURNAL *can be obtained from all* MESSRS. W. H. SMITH AND SON'S *bookstalls, and the following Agents :—*

London : POTTLE AND SONS, 14 and 15, Royal Exchange, E.C.
Wholesale : BRETT AND CO., 5, Pilgrim Street, Ludgate Hill, E.C.
Birmingham : J. McCANN, 37, Union Street.
Manchester : JOHN HEYWOOD, Deansgate.
Newcastle-on-Tyne : C. C. ROSS, 35, Side.
Paris : HOMÈRE MOREAU, 97, Rue Nollet.
Victoria (Australia) : PHILLIPS, ORMONDE, AND CO., 169, Queen Street, Melbourne.

When any difficulty is experienced in procuring the Journal from local newsvendors, intending subscribers can obtain each issue direct from the Publishing Office, by forwarding remittance of 7s. for 12 months' subscription, post free (or at the rate of 7d. per copy).

The Automotor and Horseless Vehicle Journal.

A RECORD AND REVIEW OF APPLIED AUTOMATIC LOCOMOTION.

MAY 15TH, 1897.

ANSWERS TO CORRESPONDENTS.

McCONNELL (Co. Donegal).—We think the only power at present likely to be successful for your purpose would be steam. If you are unable to secure a Serpollet motor, possibly Thornycroft's might be able to supply what you want. For smaller vehicles the Daimler motor or Roots and Venables heavy oil motor should meet the case.

J. OLIVER (Edinburgh).—Messrs. J. and C. Stirling's address is Hamilton Carriage Works, Hamilton.

J. H. (Streatham).—If your invention is any good a small advertisement should soon bring you a purchaser. You might also answer inquirers in our JOURNAL who are anxious to purchase motor-car patents.

R. W. B. (Godalming).—The address of the Wolseley Autocar is Sydney Works, Alma Street, Birmingham, and we believe they are taking orders for delivery in rotation.

MOTOR DRIVER (Brighton).—Yes, oil-motors have been applied to the propulsion of small boats with marked success. Several can be seen on the Thames.

JAS. WEST (London).—You should always carry a small bag of tools on your motor. A shifting spanner, a cold chisel and hand hammer, a flat file, and a few clips will occupy little space and may save much expense.

F. YOUNG (Liverpool).—No, we do not hold any personal interest in any motor. We, however, are strongly interested in promoting and encouraging the industry.

J. B. (York).—We do not think your idea is feasible.

PETROL CYCLE.—If you use a very light lubricating oil, and occasionally wash the moving parts with ordinary paraffin, you will find the gummy matter disappear.

SUBSCRIBER (Bradford).—We do not know the Carmont Motor Attachment. If we obtain any information, will let you know.

J. RICHARD.—A Company has lately been formed for the supply of calcic carbide. Their address is Queen Victoria Street, London. A copy of our Automotor Diary has been sent as requested.

THE BRITISH MOTOR SYNDICATE'S "MASTER PATENTS" AND ROOTS & VENABLES.

IN the face of the correspondence in the above matter, conducted through Messrs. Sharpe and Parker, acting for the Syndicate, which we publish on page 310 of the current issue, the conclusion forces itself upon one that the threats of instant action and confiscation of cars, &c., in the case of suggested infringement, so publicly advertised, are all bark and no bite, and that the real value of any patent rights which the British Motor Syndicate claim to possess is not altogether clear in the minds of those controlling the affairs of that body, although appraised at a substantial figure, presumably for the public benefit (?). With respect to the correspondence, it will be noticed that, after charging an honourable firm with the infringement of patent rights, the British Motor Syndicate have so far not, we believe, furnished particulars of the alleged infringements, but appear to us to content themselves with a general statement that the patents alleged to be infringed date from 1884, and number some 47. The first letter fixing a definite date (March 16th) for legal proceedings to be instituted, implies that they are fully prepared, after consideration and with sufficient evidence, to establish the alleged infringements. Having reference to the vast number of patents connected with motors taken out since 1884, it is surely the duty of the Syndicate to furnish the fullest and clearest particulars of the alleged infringements. They have not done so, and the only conclusion one can come to is that the Motor Syndicate realise that the charge of infringement cannot be sustained. The vaguely comprehensive claim that the Syndicate make to the invention of an oil-engine suitable for the propulsion of vehicles and the application of such engines to vehicles, looks to us in the circumstances, as Messrs. Roots and Venables observe, "really too absurd" for discussion. According to an advertisement that the Syndicate are publishing, it appears that they claim "the first master patents for the first successful application of oil and explosion engines to vehicles." For these inventions they state also that they have paid the very respectable sum of £250,000, and they are still buying! Not only do Messrs. Roots and Venables claim that their patents are of anterior date, but that they refer to *oil* motors, whereas they suggest that the Syndicate patents refer to *spirit* motors; the distinction that Messrs. Roots and Venables draw is thoroughly scientific and correct. There is all the difference in the world between the physical properties of oil and spirit; the latter evaporates, whereas the former does not, at least not appreciably under ordinary temperatures. Ordinary petroleum (lamp oil) often contains naphtha, as much as 5 per cent. or more, but this does not make petroleum a spirit. Again, as regards the invention of using the frames of the car as a kind of condenser, this is claimed by Messrs. Roots and Venables, and it appears to us with good reason; at any rate the Motor Syndicate does not appear to lay any claim to it. We cannot but think that in advancing such claims and failing to comply with the perfectly reasonable and repeated demands for particulars, the Motor Syndicate have been most injudicious, and also in their manner of attempting to prevent competing firms from manufacturing motors by threats of legal proceedings for alleged infringement.

If the British Motor Syndicate have any real novelties under their alleged patents, by all means let them enjoy the full benefit to which they are legitimately entitled, but let the vague and sweeping claims and disquieting cautions now being issued be things of the past if they are to eventuate in a series of letters of the character we now publish. We repeat what we said in an earlier issue —that any action which will set at rest the real value of the patent claims of the British Motor Syndicate must be of material benefit to the industry generally, whether the result be for or against the British Motor Syndicate. If successful in upholding their alleged rights, then they would receive their royalties and profits; and, moreover, we should be the first to congratulate them and support them in every legitimate way to enforce their legal claims, the possession of which so far there has been practically no serious attempt to demonstrate, as the nominal "consent to judgment" in the case of the British Motor Syndicate *v.* The Hon. C. S. Rolls (a minor) can hardly be regarded as conclusively defining the right of the British Motor Syndicate to the "master patents" of the motor-car industry. On the other hand, should the judgment be against the British Motor Syndicate, the result would be that the industry would practically be thrown open to the entire engineering trade, including a large number of eminent firms who, provided they are not within measurable distance of saddling themselves with a prospective law suit for infringement of patents, are not only prepared but anxious to manufacture motor-cars of such a nature as to be a credit to their already well-earned reputation and a guarantee of safety and quality to the public; and the British Motor Syndicate should still be able to earn plenty of money for its shareholders by prompt delivery of good motor-cars from their works in the ordinary course, which earning power should be greatly enhanced by the advantage which a good start and being first in the field always affords.

We sincerely trust, therefore, that Messrs. Roots and Venables will not allow the matter to rest where it is, but will insist on the British Motor Syndicate either establishing or withdrawing their claims. Sir David Salomons, a great authority upon the subject, in his paper on motor-cars read on Wednesday last before the Society of Arts (a full report of which appears in another part of our JOURNAL), sums up the principles involved in patent law very lucidly, and Messrs. Roots and Venables, by following up their apparently present advantage, would undoubtedly earn the gratitude of a vast number of people in Great Britain who are deeply interested in this already firmly-established industry. The "greater world" looks to England, as usual, to supply the ideal motor of the future, and therefore let there be no unnecessary obstacles or delay placed in the way of what promises to bring substantial profit and real benefit to the world at large, and particularly to the English-speaking race—greater even than the immense advantage realised from the rapid development of the cycle trade in recent years, or any other industry which has helped to build up the industrial and material prosperity of the empire.

A MUNICIPAL TRIP.

DOUGLAS (Isle of Man) rejoices in two things and is not satisfied. The inhabitants live in a lovely town and seaside resort, and they are paternally governed by a Model Corporation, but they thirst after such vanities as Electric Traction and Electric Lighting. Now you can obtain information in two ways: You can instruct your engineer, who ought to know, to prepare a report, or you can go and see and prepare your own. As a rule, providing you are not an engineer of high standing (and usually you are not) it is better to instruct someone who is to act for you. If, however, you are a member of a Town Council, such as that of Douglas or Birmingham, you will in your zeal for the public welfare not be content with a mere engineer's report, but will see with your own eyes and use your own judgment. It does not matter at all that you will see things and pass and form opinions on things you don't understand, but you will just see. Hence the Town Council of Douglas appointed a deputation (fortunate fellows!) with "instructions" to visit Continental towns for the purpose of inspecting various descriptions and methods of tramway traction. The deputation, so we learn from a local paper, before returning from the Continent decided by a unanimous resolution not to make any communication to the representatives of the Press with regard to the conclusions at which they had individually or collectively arrived as regards the objects of their mission. Then follows a description of the visit, *viâ* London, to the Continent. London was reached at 8.30 p.m., and we read:—"Some two hours were subsequently occupied in inspecting the electric lighting installation which has recently come into operation under the St. James's Vestry in Regent Street, Piccadilly, Pall Mall, and the immediate neighbourhood." Oh, Paris was also reached in the evening:—"Fully three hours were occupied in closely inspecting the installations of electric light and incandescent gas which are identified with Paris. The places visited included the Champs Elysees and Place de la Concorde, about which so much has been said by the *Gas World* in commenting upon the visit of the Corporation of Leicester."

After wandering through Germany they reached Brussels, and spent a quiet sabbath in inspecting Waterloo and its environs; all received reverent and respectful observation, and every man left the field proud that he belonged to the great British nation, and could claim a personal interest in the field of Waterloo. So on to Dover, thence to Bristol and Liverpool, inspecting electric light plant all the way. "The members are unanimous in stating that their journey was one involving a considerable amount of hard work, and was by no means one of pleasure. A very large portion of the time, either by day or by night, was occupied in railway travelling in carriages which at times were overheated to such an extent as to be very uncomfortable for the deputation. Other members suffered from colds, and even now for some little time some of them will be unpleasantly reminded of the expedition from that particular cause. One member, and he by no means the oldest of the party, was desirous of giving the Town Clerk three months' hard labour because that gentleman gave the members no rest day or night, but persistently kept them to the grindstone of duty. They have travelled considerably over 3,000 miles; they have laboured very hard at high pressure rate; they have seen and inspected every description of traction in use; they have gleaned the opinions and collated the experience of the various municipalities and authorities consulted on the subject; and they have come back with an abundance of material for the guidance and consideration of the committee and the Council." We shall await anxiously the result of this municipal trip; in the meantime we would ask, how much did it cost?

THE USE OF PETROLEUM IN PRIME MOVERS.

THOSE who have so far watched the development of the automotor industry without being in any way biassed in favour of particular methods of obtaining power have, speaking generally, arrived at the conclusion that the problem of heavy motor-car propulsion, such as, for instance, that required in the Liverpool-Manchester trade, will eventually be solved by some motor using petroleum. For reasons which need not be enlarged upon, steam is not always the most suitable agent for this purpose; were this not so, we may be sure that it would have been more largely adopted than has been the case. It is quite true that steam at present is preferable to petroleum for large powers; but we must recollect that four generations of engineers have been working at steam, and so by this time it might be a perfectly understood thing, whereas the use of petroleum in motors is a matter of merely a few years ago, and to assume for one moment that the fast-running unequal-turning-moment oil-engines of to-day represent their highest point of development is to confess one's self unaware of or unable to appreciate the after all slow progress of engineering science. At present the oil-engine, considered as a gas-engine, has a very high theoretical efficiency. By efficiency we, of course, mean the ratio between the difference of absolute temperatures and the final temperature. The steam-engine even in its most perfectly developed state has a low efficiency, the figures being for oil-gas 70 per cent., and steam 30 per cent. On the other hand the *actual* efficiency of an oil-gas engine is much less than that of an ordinary steam-engine. Bearing in mind, however, experience as well as theory have amply demonstrated that liquid hydro-carbons, such as petroleum, may be employed in prime motors as a substitute for either coal or steam, or both, it will be seen how very wide is the field for further improvements in petroleum-motors. In fact, it is not too much to say that in the course of another decade the present methods of utilising the energy contained in petroleum will be more or less obsolete. We have thus briefly glanced at some of the elementary science of the matter in order to impress upon the investing public the necessity of using caution in taking shares in motor-car undertakings formed to purchase and work a type of motor which in a few years may, in all probability, be superseded by others of an improved type. There are, of course, many excellent motors in the market for road traction purposes; but we must not forget that in reversibility, graduation of speed, starting, stopping, &c., the best oil-motor is inferior to the steam-motor. This need not deter the capitalist from supporting a legitimate and promising industry in which the possibilities are so great. Oil-motors are but yet in their embryonic stage, and we think their development will be similar to that of the dynamo which in less than a generation has reached, practically, perfection. Those who are familiar with the electrical industry will not forget how it was crippled by unsound and injudicious financial methods. Vast sums were paid for patent rights which, however valuable at first, quickly lost that quality by the rapid march of improvement. Those then that have invested money in patent rights in oil-motors will be well advised in seeing that their directors set aside out of earnings a proper sum for depreciation of patents; how much this should be it is, of course, not for us to say, nor indeed could we give any useful opinion; but this much we may suggest, that the proportion so set aside should be substantial, because it is certain that owing to the large field of employment for a reasonably efficient petroleum-motor that will be as simple and as controllable as a steam-motor the want is bound to be supplied. Scientific inventors are everywhere busy in this direction, and improvements are continually being made. At present owing to their inferiority in many respects to steam-motors the employment of oil-motors is somewhat restricted. In this respect they stand on the same footing as the Otto gas-engine. As is well known this motor has been for those firms that owned the patent rights a most valuable property, and even now that these rights have expired its manufacture is very profitable. But there are certain things that no motor using the Otto cycle can do well, and there are certain purposes for which petroleum-motors are not well adapted such as, for instance, heavy road traction and canal boat propulsion. As soon as the imperfections of the oil-motor for these purposes are removed there will be an unlimited field for its employment.

THE POLICE AND THE MOTOR-CARS.

It is only to be expected that many people will find themselves in the Police Courts for running their motor-cars at high or excessive speeds contrary to the laws made and provided. Lots of giddy youths think furious driving to the danger of the public a most exhilarating pastime, but an ever-watchful police usually manages to restrain such persons before much damage is done, and magistrates, as a body, manifest no undue leniency to the perpetrators of the always stupid, and frequently dangerous, practice of furious driving. What, however, is really "furious driving" in the case of a horse and trap, may be a perfectly safe speed in the case of a motor-car, even allowing that the speed is the same in both cases, because once a horse gets up a speed of, say, 12 miles an hour, his natural excitement makes it extremely difficult to check his career; with an automotor the case is widely different—the source of power can be at once shut off and the brakes applied with the result of bringing up the vehicle "all standing," as a sailor would say. Indeed, to apply the adjective "furious" to any mechanically-produced speed is simply absurd. Who ever heard of the "furious" speed of a torpedo-boat, or who ever speaks of the "furious" speed of an express locomotive? Yet an animal can indeed be very furious. Leaving this point, we would as strongly deprecate as we can the employment of anything like excessive or even very fast speed by the users of motor vehicles, and we are sure that all those interested in the new locomotive share our opinion and would co-operate with local authority in putting down anything in the nature of "scorching," which has created not a little prejudice in the case of cycles. Between seeing that drivers go at a moderate speed and exercising an undue discrimination against them merely to gratify prejudice or dislike to the new locomotion there is all the difference in the world, and we are not at all sure that this prejudice does not operate in more than one provincial town to the detriment of those who are engaged in running motor vehicles. In most county towns the local magistracy and the local police are not distinguished for liberal views of any kind, and both frequently exercise an intolerance which often comes near illegality in matters upon which they entertain views the result of usually ignorant prejudice. We are led to make these remarks in consequence of some prosecutions against the users of motor-cars which have recently been conducted in Coventry, Dublin, and Warwick. It is unnecessary to state that the charges were for furious driving and not obeying a policeman, and so forth. In the Coventry and Warwick cases Mr. Charles Turrell, described as the Secretary of the British Motor Syndicate, was the defendant. In the first place, it is in the last degree improbable that any responsible person who is so interested in the motor-car industry as Mr. Turrell would so far encourage the prejudices of the ignorant as to break the law, and we do not for a moment believe that he did, or if he did, it was an offence which might well have been met by a caution. The majesty of the law in the case at Coventry is reflected in the person of a gentleman who occupies the lofty position of being the Deputy-Clerk to the Warwickshire County Council. This person was, it seems, driving a restive horse in the streets, and seeing a motor-car approach held up his hand as a signal for the driver of the latter to stop. The driver in question, Mr. Turrell, probably seeing no cause for alarm, did not, we regret to say, appreciate at its proper value a minatory hand held up by a "deputy-clerk," and continued on his way. With the assistance of the local and energetic police, who naturally entertain proper feelings of respect for deputy-clerks, beadles, magistrates, and other lawfully-constituted authorities, a charge was laid, and it appears that not only had the law-breaker committed three distinct offences, but he had, we regret again to say so, been rude to the "deputy-clerk" in question. It was evident from the proceedings that all this was very seriously regarded, and a substantial fine was inflicted. Mr. Turrell had, however, hurt the feelings of the local Bumbles, and so the next time he appeared on a motor-car he was naturally guilty of something very wrong. In this case, too, he did not obey a policeman, and was driving "furiously." As his counsel contended, it was evident that the police were making a dead set against motor-cars, and the Warwick magistrates, finding that the defendant was not in charge of the car, had to dismiss the case. In the Dublin prosecution an employé of the Pennington Motor Company was charged with driving at a greater rate of speed than six miles per hour. This was proved in the wholly crude and unscientific manner of accepting a policeman's word to the effect that he had paced the distance, and this policeman gave the speed as being in one case 18 and in another 20 miles an hour. If this evidence is reliable of course the offence was serious, but we doubt it. Apart from its inherent improbability, very few people can estimate speed approximately, and pacing is a distinctly improper and unreliable method of estimating distances unless done by a trained walker. In such cases as these no pains should be spared to get at the facts, and while we feel sure that no responsible person will give cause of offence we feel equally certain that in many country towns the local authorities will for some time yet be not indisposed to regard with a prejudiced eye the proceedings of those who drive motor vehicles. Perbaps a Motor-Car Defence Association and a few appeals to the High Courts, the collecting of exact evidence, &c., will have the effect of making proviucial magistrates, "deputy-clerks," and local police be careful in their treatment of automotor drivers.

A PARK PHAETON MOTOR.

We are indebted to our contemporary, the *Coach Builders', Harness Makers', and Saddlers' Art Journal* for the accompanying illustration and description of a park phaeton motor. Although somewhat *outré* in appearance to English ideas, we should explain that this phaeton is designed for Oriental use, and those familiar with India will recognise that the design is quite in accordance with Eastern ideas and requirements. No doubt when built the frame will be of a more substantial nature than the lines given in the sketch. Says our contemporary :—

"The body is hung low and poised at such an angle of inclination as cannot fail to give the greatest comfort in sitting room to ladies, together with a reclination harmonising with a polished and cultivated deportment. The dash is of the broad old-fashioned style peculiar to this kind of carriage, and which gives an important and aristocratic air to the vehicle; the dash is fitted with bottom foot wings projecting down the front of the body for about a foot, thus protecting the body from the mud coming from the front wheels; this is not only a necessity but also improves the general appearance of the carriage; those little details have a wonderful effect in the aggregate, whether on a motor or horse-drawn carriage.

"The front under-carriage is fitted up to work with compensating gearing, therefore requires no transom wheel plate nor perch bolt, the front part being fitted solidly to the springs, the axles being pivot-jointed as heretofore explained.

"The canopy should be at such a height as to give at least the clearance of a Landau or Victoria head in the sitting room, it is an accessory that should receive careful attention as to proportion in every way, so as not to look top heavy, nor to have the appearance of being an after-thought; the front support stays are curved to harmonise with the design of the carriage, with the old-fashioned ornamented swaged centres prevalent 35 years ago.

"The motor case would have to be made the sizes to suit motor, but detached from the body, with the exception of the bottom stay fixing; the side fixing of the case would take the solid inside flap of the pump haudle, in this way the motor case would lend relief to the body as a fixture, and could be let down as near to the axle top as convenient or the axle could be cranked to still further help its necessary and harmonious fixing."

THE WEDDING MOTOR-CAR.

On Tuesday, April 20th, a wedding, which excited much interest, was solemnised at St. Augustine's Roman Catholic Church, Solihull. The contracting parties were Mr. Albert Edward Day, eldest son of Mr. Edward Day, of Radnor Road, Handsworth, and Miss Irma L'Hollier, daughter of Mr. Leon L'Hollier, of Robin Hood House, Hall Green. The ceremony, which was attended by a large number of people, one party coming in a motor-car, was conducted by the Very Rev. Canon McCave. At the conclusion of the ceremony the wedding party adjourned to the house of the bride's father, where motor-cars were employed in the diversion of the company.

We may add that Mr. E. Day is assistant manager of the Anglo-French Motor-Carriage Company (Limited); while Miss Irma L'Hollier, the bride, is the daughter of Mr. Leon L'Hollier, one of the pioneers of the autocar industry in England.

Among those recently elected as members to the Automobile Club of France we notice the names of Baron Henri de Rothschild, of Paris; Mr. P. Peacock, of London; M. le Baron de Leyssac, director of the International Bank; M. Siegfried Singer; M. P. Deschamps; M. G. Renard; and M. G. Dupont. In fact, it is not too much to say that many of the leading men in science and industry are members of this prosperous club.

A 52-page diary, printed on excellent paper, is one of the features of The Automotor and Horseless Vehicle Diary and Pocket-Book for 1897, which contains over 100 pages of information. Price 6*d.*; post free, 7*d.*, of Messrs. F. King and Co., 62, St. Martin's Lane, London, W.C.

CONTINENTAL NOTES.

Electrical storage batteries for propelling tramcars do not find much favour with us, and just now all the rage is for overhead wires and trolleys. Before municipal guardians of the public purse go in for the latter, or even the conduit system, we should advise them to study a report recently published by the directors of the Hanover Tramway, in which they narrate their experiences with accumulators as the source of power for their cars. In Hanover both overhead wires and accumulators have been used for a considerable time, so that the managers are in a position to institute a reliable comparison. Taking everything into account, they pronounce in favour of the storage cell. The cost of maintenance has been determined with the utmost exactitude for the year 1896, and the average comes out at 40 marks per wagon per month, equivalent to 75 groschen per kilometre. The estimate includes the cost of renewing the plates. Having regard to the expense involved in the maintenance of the overhead line and its accessories, as well as to other circumstances, the managers arrived at the conclusion that the additional cost of accumulators does not exceed one groschen, or one-tenth of a penny, per mile. Consequently it has been decided that the entire system shall, as soon as the requisite arrangements can be made, be driven by secondary batteries.

French railway companies are not quite so conservative as ours; thus Le Chemin de Fer du Nord has lately purchased a Panhard and Levassor motor quadricycle fitted with a four horse-power Phœnix motor.

We understand that a Motor-Car Company is in course of formation at Amsterdam. Mr. W. Smith, Assoc. M.I.C.E., is the consulting engineer; his address is 8, Doclenstratt, Amsterdam. He will be glad to hear from manufacturers of motors, &c.

The Serpollet motor-car employed in connection with the postal service on the Northern Railway (France) gives great satisfaction to the authorities.

La Locomotion Automobile for April 29th contains a most interesting and instructive article by M. E. Hospitalier upon the influence of plain and pneumatic tyres on the co-efficient of traction.

The Conseil Générales of Calvados and La Mouche are not unlike many of our own bucolic provincial bodies. They are interested in maintaining the breed of horses, and hate the automotor with a fervent and sincere hatred. We learn from *Le Sports* that these two bodies have expressed a wish or voted that a tax should be placed upon automotors, and the proceeds devoted to horse-breeding. Our contemporary devotes considerable space to discussing this insane project, which it calls "automobilophobic" (good word that). So say we. We do not know how they manage these things in France, but here, in spite of all the power of local authorities, such a proposal could not be carried out unless with the sanction of the Imperial Parliament. Still, the good people of La Mouche are quite right to preserve the horse while he is yet to be found. In another century he will be a curiosity seen only in local Zoos and museums.

According to our contemporary *La Locomotion Automobile*, French provincial authorities are, in many instances, just as narrow-minded and as prejudiced as our own in their treatment of the motor-car. Great as our own magistrates, "deputy clerks," policemen, and other governors of the earth manifest a disposition to put their own interpretation upon the law, so do the French "Dogberry's." Human nature, or rather police nature, is evidently much the same everywhere.

In *La Locomotion Automobile* for May 6th is an illustration and description of the "Avant Train" Motor and the "Attelage" Motor. As their names imply, the former is a motor placed under the fore part of a vehicle and driving the front wheels, while in the latter case the motor is suspended or carried by the transverse axis of two wheels, and thus forms an independent autocar. In its latter form it can be attached to any vehicle, and replaces the horses. For many purposes this system of M. Amiot would have advantages, but we do not think it is likely to be largely taken up by motor-carters in general, as in both cases the motor is much exposed to damage from collision, and the arrangement is, moreover, anything but satisfactory from the æsthetic point of view.

The motor-car parade that had been arranged to take place in Paris under the auspices of the Automobile Club was hardly the success that had been expected owing to the rainy weather. Out of 80 entries only about 30 turned up. The cars were gaily decked out with flowers; those of Baron de Zuylen, M. Archdeacon, M. Peneau, and M. Trouette being much admired. After lunch at the Club's villa the cars returned to town, but their flowery embellishments were somewhat marred by the bad weather.

L'Industrie Velocipéderne does not entertain a very high opinion of the much talked of Brambel motor. After describing it very fully, our contemporary, whom we render freely, says Brambel's principal invention is his new system for preventing the steam from escaping upon the sides of the piston. This is accomplished by having concentric grooves both on the rotating piston and upon each side of the casing. The oil is forced into these grooves by centrifugal force, thus forming an hermetical packing. It is upon this point alone that the Brambel motor presents any patentable novelty and not upon its general working, which is not after all anything more than a fortunate application of well-understood principles.

As the result of a meeting of engineers a technical Association for the Study of Automobilism, or as we prefer to call it motor-traction, has been formed at Lyons. M. Victor Cambon is director of works, &c.

In his work, "La Traction Electrique," M. Paul Dupy describes some very interesting experiments upon canal propulsion that have been carried out on the Burgogne Canal by the Society for Electric Traction on Canals. It seems that a dynamo driven by a turbine fed by the canal supplies current to an air conductor, from which it is led by suitable means to the armature of what is really an electro-locomotive, but which has but three wheels, and would be termed an electric tricycle. The experiments have been very satisfactory, and have demonstrated that with an expenditure of energy at the rate of 1 kilo. watt hour per 100 tons, a speed of 2½ kilometres is obtained.

The President of the French Republic has promised a prize for the Automobile Race from Paris to Dieppe, while the Council of Seine Inferienre has voted 300 francs as a prize. It is very satisfactory to observe the support which the enlightened French superior authorities accord to the automotor industry.

President	Sir DAVID SALOMONS, Bart.
Secretary	ANDREW W. BARR, Esq.
President of the Liverpool Centre	The EARL OF DERBY, G.C.B.
Hon. Local Secretary	E. SHRAPNELL SMITH, Esq.

SELF-PROPELLED TRAFFIC ASSOCIATION.

LIVERPOOL AND DISTRICT CENTRE.

THE Annual Meeting of the Self-Propelled Traffic Association (Liverpool and District Centre), was held on Tuesday evening, at the Royal Institution, Colquitt Street. Mr. Alfred Holt presided.

Letters of apology were read from Messrs. F. C. Danson, A. L. Jones, and A. G. Lyster.

The CHAIRMAN, in opening the proceedings, said that for some time past the question of self-propelled traffic had attracted a great deal of attention, and there were many people interested in the conveyance of goods who seemed to see salvation from the rather onerous railway rates in the advent of self-propelled vehicles. He earnestly hoped that that salvation would be obtained, and that the Association might have its fair share of the honour and glory. The Association was yet young, but they had already had many interesting papers, and had learned a good deal that would be valuable in many respects.

The first session's report, 1896-7, was then presented by Mr. E. Shrapnell Smith, the Honorary Secretary. After pointing out that the objects of the Association were particularly for "the scientific investigation of self-propelled vehicular and locomotive road traffic," it states that the accounts to April 30th, 1897, have been duly audited by the London Secretary, Mr. Andrew W. Barr, and that under the auspices of the Association, Mr. W. Worby Beaumont, M. Inst. C.E., M. Inst. Mech. E., gave an address to the members of the Liverpool Incorporated Chamber of Commerce, upon the subject of "Motor Vehicles for Heavy Traffic," on September 9th, 1896

The session was opened on October 26th, 1896, by Sir David Salomons, Bart., President of the Association, who was entertained at luncheon at the Exchange Station Hotel by Mr. Alfred L. Jones (Vice-President), who also invited the members of the Council and a number of leading citizens to meet him.

In the evening Sir David Salomons delivered an inaugural address entitled, "Self-Propelled Traffic," in the course of which the position of affairs up to that date was reviewed. After glancing at the legal restrictions, shortly to be removed, the question of patent rights was dealt with, and it was pointed out that so-called "master" pateuts which some persons were putting forward in connection with motor vehicles had no existence in point of fact.

Various incidents of the Paris-Marseilles road race were referred to at some length, and it was claimed for steam that it would prove the most convenient and serviceable power.

In conclusion, the numerous important uses to which self-propelled vehicles might soon be put were briefly considered.

The President, the Right Honourable the Earl of Derby, G.C.B., was unexpectedly but unavoidably prevented from presiding, and his place was taken by Mr. Alfred L. Jones, one of the Vice-Presidents.

Subsequent meetings were held, at which papers were read and discussions were conducted upon the several subjects enumerated in the following summary :—

1896.

December 1st.—Prof. H. S. Hele-Shaw, M. Inst. C.E., M. Inst. Mech. E.—"The Pneumatic Tyre." (With experiments and lantern illustrations.)

December 15th.—Mr. William B. Cook, C.E., and Mr. Frederick Willoughby, M.A. (Joint Authors).—"A new method of utilising canals for traffic—with special reference to the canals of Lancashire and Yorkshire."

1897.

January 5th.—Mr. Geo. F. Thompson.—"The Motor Wagon Scientifically Considered."

January 19th.—Mr. W. Worby Beaumont, M. Inst. C.E., M. Inst. Mech. E.—"Mechanical Haulage on Common Roads."

February 16th.—Mr. Rhys Jenkins, M. Inst. Mech. E.—"Compressed Air as a Motive Force for Road Vehicles."

Unfortunately, through unforeseen circumstances arising from various causes, four papers which were intended to have been read were unavoidably cancelled or postponed.

The Inaugural Address was specially printed and issued in pamphlet form, and the proceedings of the Centre have been fully reported in THE AUTOMOTOR AND HORSELESS VEHICLE JOURNAL.

The Honorary Secretary is taking steps to form a library comprising books and journals of both historic and contemporary interest, and the assistance of the members is requested in this direction.

PRIZE SCHEME.

Mr. Alfred L. Jones (Vice-President) very generously offered to place £1,000 in the hands of the Association for the purpose of promoting a competition between motor-wagons capable of carrying heavy goods. A sub-committee of the Council was appointed to deal with this matter, and after considerable deliberation it has recommended that the premium be not offered at present.

EXHIBITION.

It is in contemplation to organise an Exhibition of Motor Vehicles, to be held some time in the spring of 1898, by which time there is reasonable ground to expect that makers of both light and heavy types will be in a position to take part. When the arrangements are concluded, particulars will be duly announced to the members.

The Council desires to place on record their high appreciation of the zealous services of Mr. Shrapnell Smith, the Honorary Secretary of the Centre, who then exhibited a number of slides on the screen, tracing the development of the motor-car up to the present time.

Mechanical Haulage between Liverpool and Manchester.

WE understand that Messrs. Elder, Dempster, and Co. received several tenders in response to their advertisement which appeared in THE AUTOMOTOR AND HORSELESS VEHICLE JOURNAL for February, and desired the assistance of the special Sub-Committee of the Self-Propelled Traffic Association in considering these offers. Several contractors were willing to undertake the haulage at a rate approximating to 2*d.* per ton-mile, and to start within a month of receiving the order, but owing to the fact that all the schemes submitted were limited by conditions that were regarded as too onerous, it was not thought that any one of them could be advantageously accepted.

REVIEWS OF BOOKS.

"The Law Relating to Motor-Cars." By H. LANGFORD LEWIS and W. HALDANE PORTER. (London: Butterworth and Co., 1896.) Price 3*s.*

IN the small space of 60 odd pages the authors have succeeded in compressing the by no means unextensive literature relating to locomotives on highways and exceedingly well have they performed their task. Such a small and handy volume will stow conveniently in a bag or under a seat, and is at once available in the event of meeting with, as sometimes happens in provincial towns, a too zealous policeman, magistrate's clerk, or other high officer of state, who not infrequently does *not* know all about it.

After a brief survey of the law up to the passing of the Locomotives on Highways Act of last year, the latter measure is discussed and explained in language which while sufficiently legal is yet easily understood by the layman. Thus we learn that cycles fitted with auxiliary motors are "Light Locomotives" within the Act, and any vehicle drawn by a light locomotive is referred to also as a light locomotive. A light locomotive is also a "carriage" within the meaning of *any* Act of Parliament. Indeed, a motor-car is abundantly cared for by the law, but as usual there are those *lacunæ* in the various Acts which will no doubt give plenty of scope for judicial interpretation. Thus a local authority may mean anything from a parish council to a grand jury, but in London we learn with surprise on the authority of the authors that it is doubtful if it includes the London County Council, which we also learn has no direct control over the streets of the metropolis except the Thames Embankment.

As we know, any breach of the bye-laws and regulations made under the Act may be punished by a fine of £10, but if the peccant motorer thinks that this fine settles the case he is woefully mistaken. Our authors blandly state that "this is, of course, in addition to any penalty incurred under any other Acts." A light locomotive is of course subject to a tax not only because it *is* a light locomotive but also because it is a carriage or it may be a hackney carriage; but here comes in the glorious inequality of the law—no duty is charged or payable upon light locomotives in Ireland. Naturally the law is not the same for England, Ireland, and Scotland, but this is one of those things that one requires to have experience of in order to appreciate. Our authors carefully explain the points of divergence. The Regulations of the Local Government Board are next discussed, and we should strongly advise all in charge of motor-cars to make themselves conversant with the rules, because these regulations really are to motor-cars what the rule of the road at sea is to ships. It may not be generally remembered that if the name, &c., of the owner of a motor-car is not painted on the right side of the machine in large legible letters not less than one inch high, any person may demand the name and address and the person in charge must truly state them. The Regulations as to Petroleum are dealt with, followed by a copious appendix and index. Altogether a most useful handbook.

"Motor-Cars or Power Carriages for Common Roads." By A. J. WALLIS-TAYLER, C.E. (London: Crosby Lockwood and Son, 1897.)

THIS work will no doubt appeal to that large class of readers who like popular and condensed accounts of machinery, but to those who may take it up with an idea that it, being written by a professional man, is a technical description of automotors will, we fear, be disappointed. The early history and development of road traction has not been better done by anyone than Mr. Worby Beaumont, and that so recently that we confess we see very little good in a work of the present description unless it contains original and fresh matter. Mr. Wallis-Tayler does not, however, profess "to devote any special attention to the design pure and simple of the vehicles," but contents himself with describing what has been accomplished; neither does he do "more than touch upon the theoretical side of the subject," but refers the seeker after knowledge to "the many able treatises that have been written upon the sciences of thermodynamics, chemistry, and electricity," not to mention that of the "mechanical questions which would especially apply to the several sources of energy in use." Commencing with a useful report of trials of motors made in Chicago, from which we learn that although the various motor-cars approximate in weight to a horse, yet their individual pulls were very much less than that of an average horse, we are next given an account of Hele-Shaw's experiments in tyres. Then follows a historical sketch of early steam road-carriages. The third chapter treats of recent examples of steam road-carriages, and among those described and illustrated are the Serpollet, Le Blout, De Dion's, Thornycroft's, &c. As most of these types have been dealt with in the columns of THE AUTOMOTOR AND HORSELESS VEHICLE JOURNAL and are pretty well known, it is sufficient to say that Mr. Wallis-Tayler does not add to our stock of knowledge, although we have been looking out for reliable extended consumption tests of these motors. Passing in the next chapter to internal combustion-engine carriages, all the better known types are described fairly well, and little exception can be taken until we come to the Pennington motor. So much has been said and written about this and so much needless mystery has gathered round it that we are sorry not to find here a, at any rate, sufficiently full explanation of its action. The account of the motor is merely a patent specification transcribed, in which such legal, useful, but hardly, from a literary standpoint, graceful embellishments as "said," "aforesaid," "thereof," and "or other suitable material" occur. Mr. Wallis-Tayler is discreetly silent upon the *modus operandi* of the machine. He quotes, however, from an American paper which gives a really poetical account of the Kane-Pennington gasoline-engine, which considerations of space alone forbid our reproducing. Enough to say that the mystery of the Pennington motor is not solved, but the American authority quoted says: "It is in the igniter and in the double spark, or rather in the effect of the first spark apparently that the efficiency of the Pennington motor lies." This is vague enough, and it does not explain "the one great mystery"—the coolness of the naked cylinders; Mr. Wallis-Tayler is provokingly silent on the subject. There is a good description of the Roots motor and of some others, but little that is fresh. To the reader of light literature the book is useful enough, but we honestly cannot recommend it to the student or engineer. The illustrations, too, leave much to be desired; they are too small to be useful, and in some cases have a suspicious look of having formed part of patent specifications.

CORRESPONDENCE.

*** *We do not hold ourselves responsible for opinions expressed by our Correspondents.*

*** *The name and address of the writer (not necessarily for publication)* MUST *in all cases accompany letters intended for insertion or containing queries.*

A MOTOR-CAR RUN OF 300 MILES.

To the Editor of THE AUTOMOTOR AND HORSELESS VEHICLE JOURNAL.

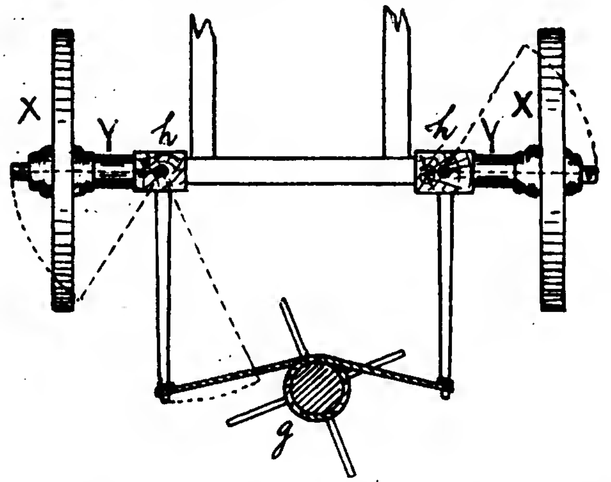
DEAR SIR,—I beg to corroborate your footnote on page 284 of your last issue to the effect that the Peugeot car which performed the above run was and is my property, though Mr. Wellington had the temporary use of same.—Yours truly,

C. S. ROLLS.

STEERING GEAR.

To the Editor of THE AUTOMOTOR AND HORSELESS VEHICLE JOURNAL.

SIR,—With reference to the illustrated description of Ackermann's steering gear in the last issue of THE AUTOMOTOR I should like to point out that the idea of the divided axle is much older than Ackermann's patent, and that as a matter of fact it was put into practice, and with a horseless carriage too, as far back as the year 1714.



In the "Machines Approuvées par l'Academie Royale des Sciences," tome iii, are given descriptions of carriages propelled by windmills brought before the Academy in the year 1714 by M. Du Quet. The figure herewith is reproduced from one of the drawings accompanying these descriptions. It will be seen that the wheels, *x*, *x*, are mounted upon short axles, *y*, *y*, each fixed in a vertical post, *h*, provided at top and bottom with pivots which work on suitable bearings in the framework of the carriage. Standing out from the posts at right angles to the axles are arms to which are secured the ends of a rope wound around a capstan, *g*, also carried in the carriage frame. The action of the apparatus will be quite clear from the figure.—Yours, &c.,

RHYS JENKINS.

THE LIGHTNING EXPRESS.

We wish Mr. Behr every success in developing his "Lightning Express Railway Carriage," but while we have no doubt that speeds of 120 miles per hour are quite possible, we do not think that such speeds will be reached for many years yet—not on account of any mechanical difficulties, but because of the economical conditions of the problem. Such a high speed would only be necessary over long distances, and this would mean building and equipping new trunk lines of railway or adapting the existing ones. The first alternative is practically out of the question, and the second is hardly likely to occur for many years. Also, is there any demand for high speeds such as are contemplated? It is generally admitted that 90 miles per hour is the limit of locomotives on railways when driven direct by steam. Higher speeds can be attained by electric locomotives, as has been proved in France, and that system of electric locomotion will be adopted that enables existing stock, rails, &c., to be used. We know of at least one great railway engineer who has everything prepared for the equipment of his line with electric locomotives to develop speeds of over 100 miles per hour, but his directors will not (naturally) move till the public demand these excessive speeds. Mr. Behr's system, as we understand it, involves the use of a single track built something like a continuous lattice girder. The cost of such a line would be high, to begin with, while the Board of Trade would require such extensive arrangements for signalling, &c., that the expenses would also be great. Lastly, as regards the proposed idea to build such a railway to carry the goods traffic between Liverpool and Manchester, we are extremely sceptical, because, owing to the great cost of such a line, the freight charges must be high, and the bulk of the goods that go from Liverpool to Manchester and *vice versâ*, such as cotton, metal, meat, &c., would not bear any increase in the freight, and unless Mr. Behr can show that the freight will be less than it is, we fear his scheme would not be entertained.

"PARISIAN" MOTOR-CAR.

THE INTERNATIONAL MOTOR-CAR CO.

The reproduction of the car which appears on this page is a specimen of a new design of motor-car which is now being supplied by the above Company. We have had an opportunity of riding in one of these excellently-appointed vehicles, which, under the guidance of the manager of the Company, answers every description set forth in their catalogue. The steering is exceptionally good; when in motion there is practically no vibration, and a speed of up to 10 or 12 miles an hour can be easily obtained. Upon the occasion of our run the route taken included several fairly steep gradients, which were readily negotiated. The motor used is on the principle of the well-known improved Benz system, the International Company being the sole licensees for this type of vehicle as supplied direct from the Parisian Manufactory, under whose auspices it is claimed the cars have received medals at Paris, Brussels, Berlin, &c., &c. The details of the machinery are perfectly simple, and easily understood by anybody with the slightest mechanical knowledge, and the simplicity of the working parts recommends this type of vehicle to novices who are anxious to become motor-car owners. A visit to the offices of the Company, which are at 369, Edgware Road, will ensure the fullest details and a practical demonstration of the capabilities of these cars.

THE BAZIN ROLLER BOAT.

We have not heard very much lately of the Bazin Roller Boat over which many of our contemporaries poured out their vials of praise and commendation. For ourselves we prefer to judge by facts and the teachings of applied science, and we doubt very much whether M. Bazin's ideas are possible of realisation, at any rate in the way he is said to be working. According to the accounts which have appeared in the papers he proposes to propel a vessel 130 feet long by 40 feet beam (depth not stated) at such a speed that the Atlantic voyage will be shortened to a little more than 90 hours, or a speed of 33 knots will be reached. In order to do this the hull is supported not by the water but by six hollow wheels of ungula section, each wheel being 33 feet in diameter, 12 feet thick at centre, and floating at a depth of 12 feet. There is an engine of 750 (presumably) indicated horse-power; of this power three-fourths or 560 indicated horse-power will be devoted to driving a propeller, diameter pitch and surface not stated, and the remaining fourth or 186 indicated horse-power will be utilised in rotating these immense wheels.

Let us assume that there is no skin friction, the hull being entirely out of water, then the only resistance to overcome would be that due to the air. Whether it would be possible to drive a body of the dimensions given at a speed of 30 knots against an ordinary Atlantic gale with 560 indicated horse-power is in itself a question that settles the whole thing. The resistance due to calm air is usually expressed by $R = \cdot 005\ AV^2$, where A=area in square feet of exposed surface and V speed in knots. Taking the area of the surface of the Bazin at only 1,000 square feet and the speed at 30 knots the resistance will be 4,500 lbs., which will require at least 400 *effective* horse-power. Of the 560 indicated horse-power not more than 60 per cent. can be usefully employed in propulsion, so the power provided is insufficient. Unfortunately skin friction cannot be neglected because the area of the wet surface is very large. According to the dimensions given it cannot be much less than 9,500 square feet, and although these wheels revolve yet this does not materially reduce the skin friction, and to think that 9,500 feet of wet surface can be forced over the water and through it with the expenditure of say even 1,000 indicated horse-power is so utterly opposed to the experience of our naval architects that it is useless to pursue the matter further, but, as an example, we may mention that to propel a well-formed vessel with this amount of wet surface at 16 knots or just half the estimated speed requires about 2,000 horse-power, or four times nearly that stated by M. Baziu. We, therefore, conclude that he will not obtain the results anticipated.

COMPRESSED-AIR MOTORS FOR TRAMCARS.

TRAMCARS operated by compressed air are now in regular service on some of the cross-town lines in New York, and the elevated railway authorities will soon experiment with a compressed air locomotive of the Hardie system on the Sixth Avenue Line. In length, weight, and general appearance the new engine closely resembles the steam locomotives now in service on the elevated lines, but there is no smoke-stack, and the cylinders are in the rear of the drivers instead of in front. But the most radical departure from precedent does not show from the outside. A number of tanks or flasks, which contain compressed air, are substituted for the steam boiler. The former occupy the same place and space as the latter, but are completely hidden by a suitable sheet-iron covering. There are 36 of these flasks, which are Mannesman tubes, each 15½ feet long and 9 inches in diameter. The steel of which they are composed is about $\frac{5}{16}$ inch thick. Although the highest pressure which they will be called upon to withstand is 2,000 lbs. to the square inch, they have all been tested up to twice that pressure without developing a defect. Reducing valves will give a cylinder pressure of 150 lbs., which is the same as in the steam locomotives. The combined capacity of the 36 reservoirs is 200 cubic feet, but the air contained therein when they are charged up to the limit will expand, when freed again, to 136 times that volume; and its weight, entirely aside from the vessels which hold it, is estimated at about one ton. The flasks are all in communication with each other, so that the pressure decreases or increases uniformly in them, precisely as if there was but one reservoir. The connection between them is made by means of 12 pipes, each of which has three branches. Each branch is securely attached to the pointed front end of one of the flasks, and the main pipe discharges into a hole in the side of an upright passage or header. There are six holes on each side of the header. The seventh hole, at the bottom, affords an outlet—through another pipe, of course—to the cylinder. It is estimated that the engine will develop rather more power than the steam engines now hauling trains on the elevated roads, because it has larger cylinders. Their diameter is 13½ inches, and the length of stroke is 20 inches, while the corresponding dimensions on the old locomotives are 12 inches and 16 inches. Even under unfavourable conditions of load and weather it is expected that the new engine will take a five-car train up the Sixth Avenue Road to Fifty-eighth Street and back again, a distance of 11 miles, with one charge of air. The storage capacity of the tanks on the tramcars in One-hundred-and-twenty-fifth Street is only about one-fourth that of the elevated-road motor; but each of those cars has not only its own reservoir, but its own engine, under the floor, and is not hauled by a separate machine. The tramcars run about 15 or 16 miles without renewing their supply of air. The elevated railway motor will, it is estimated, have fully 300 lbs. left on hand at the end of a round trip. In an emergency, however, the engine can run a short distance with only 60 lbs. pressure. A re-heater is provided.—*The Engineer.*

AMERICAN NOTES.

Important to Inventors.—Amendment to the United States Patent Law.

ACT OF MARCH 3RD, 1897.

IN our last issue we referred briefly to the amendments in the United States Patent Law. Messrs. Herbert Haddan and Co., of 18, Buckingham Street, Strand, have now supplied us with a digest of the new Bill, which was passed during the closing hours of the Fifty-fourth Congress. The following are the changes in the law made by this Act:—

Section 1.—Two years' publication by patent or otherwise prior to the application is a bar to a patent.

Section 2.—A defendant may plead such two years' publication as a defence against a patent.

Section 3.—The application on an invention patented abroad must be filed within seven months of the earliest foreign application; the patent will then be granted for 17 years. If the application is not filed within that time the patent, if granted, will be void.

Section 4.—Applications for patents must be completed within one year (instead of two years as formerly), and response must be made to any official action within one year (instead of two years).

Section 5.—Assignments, if acknowledged before a notary or other proper official, are self-proving.

Section 6.—In actions for infringement there shall be no recovery of profits or damages for more than six years before commencing the action.

Section 7.—This Act shall take effect January 1st, 1898. Sections 1, 2, 3, and 4 shall not apply to any patent previously granted, nor to any application previously filed, nor to any patent granted on such an application.

The Act, as passed, gives ample time to all parties whose interests are affected to protect themselves by the exercise of reasonable diligence. In every case in which an invention was made public by the issue of a patent or other publication prior to January 1st, 1896, it will be necessary to file the application for patent in the United States before January 1st, 1898. In every case in which an English or foreign patent shall have been applied for before June 1st, 1897, the application for the United States patent for the same invention must be filed before this Act takes effect, or the right of patenting the invention in the United States will be lost.

Every intending patentee should hasten to get his application on file before the Act takes effect, as thereby he will be able to enjoy the advantage which the present law gives of securing, in case he wishes it, a delay not exceeding two years for the prosecution of his application after rejection. After the Act takes effect this period will be reduced to one year, which in many cases will give rise to inconvenience, and force an earlier issue of the patent than might otherwise be desirable.

In the course of an able leading article on the above, *Engineering* says:—

"But the new United States law that is to come into operation on January 1st next provides, in effect, that no patent shall be granted in that country for an invention first patented, or caused to be patented, by the inventor or his legal representatives or assigns in a foreign country on an application filed more than seven months prior to the filing of the application for the United States patent.

"Comment is needless. But let every British inventor make a note of the fact, and, whilst taking care not to unwittingly delay until too late his application in respect of any invention he may desire to protect in the United States, let him also exert all the influence he can command in the endeavour to bring about a more just and equitable state of affairs as between the two great countries."

Horseless Cabs in New York.—According to the *Electrical Review* there are only seven or eight horseless hansom cabs in New York City, and these are not located at cab stands, but are kept in a stable ready to be brought out when ordered. While it is true that the charges are the same as for the hansom cabs drawn by horses, it should be remembered that cab hire is so expensive in New York as to make horseless cabs remunerative at similar rates. The rate of cab hire is 50 cents per mile. It is interesting to observe that although over six months have elapsed since the coming into force of the Horseless Carriage Act, motor-cars are rare in the London streets, and when let loose are generally followed by a laughing and a gaping crowd. One hardly expects a revolution of this sort to do its work in six months, but those who believed the reports of some promoters and inventors circulated last November expected something more than is to be seen to-day.

An American Street Railway Manager on Street Cars.—Mr. H M. Littell, the general manager of the Metropolitan Street Railway Company of New York, and ex-president of the American Street Railway Association, is in London on a holiday, and has been interviewed by a representative of a morning paper. In Mr. Littell's opinion our system of street car running is crude and primitive. He is astonished that in an old rich city like this we have no better facilities for travelling between the places of residence and the places of business. Why have we no tramcars on the Strand?

Continuing, Mr. Littell said:—"Of course, you will say that traffic is so congested there that the thing is not to be thought of. So said the merchants on Broadway. They bitterly opposed our scheme for a cable railroad there; said it would interfere with their business, and made other frivolous objections. The company carried their point—and their railroad. What was the result? The congested traffic was relieved to an amazing extent, and the facilities for business, instead of being curtailed, were increased. To-day I do not believe there is a single merchant who would not fight for the retention of the system, were any misguided person to attack it.

"Here you have a great many blockades—blocks, don't you call them? Three, four, and five 'buses are abreast, hansom cabs fill up the rest of the space, and the traffic is stopped for a quarter of a mile back.

"I do not know your tramway people here, but if they are of the same class as those in our country, they would be very ready to lay tracks if permission were given. You English say that there are hansoms everywhere, and that they cost next to nothing. My experience is that they cost a good deal. Your 'buses, also, I regard as very expensive. Some 'bus fares I find are 4*d*., 5*d*., or even 6*d*. In New York, by the use of transfer tickets, you can ride half a day for 5 cents. The charge is uniform—5 cents, whatever the distance. Does it pay? Of course it does. It educates a man to the conveniences of riding. He rides short distances as well as long. And he is not going to waste half a day on a car for the fun of the thing.

"Now in our cars," he continued, "you ride in comfort, and enjoy the view. What is the view from the inside of a London omnibus? Somebody's pills and somebody else's soap. In New York you hire advertising 'buses for the day. Here the American sees a 'bus rumbling towards him, and has not the remotest notion whether it's a 'bus for Piccadilly Circus or a 'bus for antibilious pills. The place for advertisements is the newspaper.

"The electric car would not be nearly so dangerous on your principal streets as your 'buses are. When the horses skid there is a pretty fair momentum on a 'bus. And coming to the worst, I would as soon be run over by a roadcar as a 'bus any day. In neither case should I take much interest in street traffic afterwards."

DOINGS OF PUBLIC COMPANIES.

Mr. Pennington has succeeded in getting together some very good men for the directorate of the Motor and Cycle Company of Ireland. It comprises the Right Hon. Joseph Meade, the Right Hon. Thomas Dickson, Sir Howard Grubb, Mr. Malcolm Inglis, and Mr. Pennington, who are respectively the Chairman of the Hibernian Bank, the Chairman of the Boyne Weaving Company, the Vice-President of the Royal Dublin Society (a distinguished scientist and a practical mechanician), and, finally, the Vice-President of the Dublin Chamber of Commerce, who is also chairman of an important trading concern. It is stated in the prospectus that orders to the extent of over £130,000 have already been received. The capital of the Company is fixed at £250,000, in shares of £1 each, in preference and ordinary shares. A good feature is that the first £50,000 and one-half of further subscriptions until £100,000 shall be provided shall be applied to building, equipment, and working capital.

The Irish Motor and Cycle Company have now, we understand, acquired a suitable site in Dublin for their works. The meadow on the north side of the London Bridge Road, Sandymount, adjoining the Gas Company's Works, and bordered on the other hand by the Dodder River, is the site chosen, which comprises close on 30 acres, and the facilities for transport, both by land and water, are exceptional. The offices of the Company are in Leinster Street.

New Companies Registered.

[Under this heading we give a full list of new Companies registered which take power to make, deal, or become interested in any manner in automotor vehicles. We shall be pleased to reply with detailed particulars to inquiries through the "Answers to Correspondents" column. All communications should be addressed to the Editor. The only stipulation which we make is that where the inquiry involves a search of the records at Somerset House—as in the case of information on the subject of the holdings of shareholders—a postal order must be enclosed to cover the Government stamp of one shilling which is charged before a search is allowed to be made.]

"IVEL" BALL BEARINGS.

One of the best designs of a hub fitted for ball bearings that we have seen is that known as the "Ivel," manufactured by Mr. D. Albone, at his cycle works, Biggleswade. The great feature of Mr. Albone's design is its applicability to ordinary wood wheels, the balls being enclosed in a box which is easily fitted to ordinary wheels. So far as we can judge, this method of using ball bearings has been very successful, both in its application to ordinary private carriages and also to motor-cars. As will be seen from the accompanying woodcut, the iron box is tapered and fitted with a couple of feathers to keep it in place. It can be fitted to wheels of all ordinary sizes.

Petroleum as Fuel for Steam Boilers.—Those inventors who may be thinking of using petroleum for heating steam boilers may be glad of a few figures giving the result of an actual case. The petroleum was ordinary burning oil, its calorific value being 21,209 thermal units. It actually evaporated 12·93 lbs. of water per pound of oil, being at the rate of 15·218 lbs. from and at 212° Fahr. It will thus be seen that petroleum is not more than about 50 per cent. better than coal, instead of being, as is often stated, 2½ times better. It may often be a question whether the use of oil as fuel is really desirable, especially in those motor-cars used in districts where the supply is not regular, or difficult to obtain.

NEW INVENTIONS.

Claiming particularly to apply directly or indirectly to Motor Vehicles, &c.

Compiled for "The Automotor and Horseless Vehicle Journal" by Herbert Haddan and Co., Registered Patent Agents, of 18, Buckingham Street, Strand, W.C., London.

*** *At the request of a number of subscribers we are pleased to announce that for the future we have arranged to more thoroughly cover the field of completed Patents referring to the Motor-Car Industry, by reproducing the latest Specifications and Diagrams.*

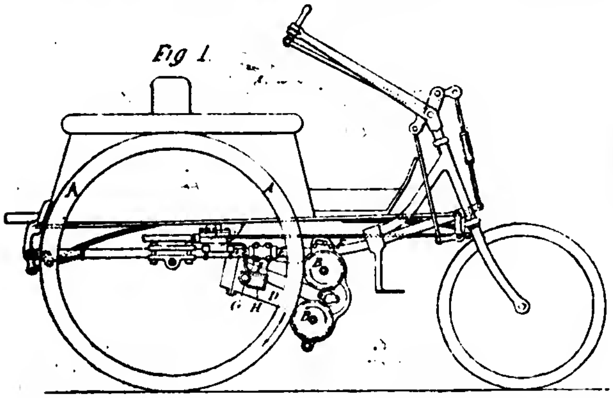
Specifications Published.

5,009. Driving Gear for Road Motor-Carriages. Henry Percy Holt, 22, Chancery Lane, London. March 5th, 1896.

Relates to simple means of driving a road motor-carriage.

The driving wheel is made with a strong pneumatic tyre, A, against which are pressed suitably shaped rollers, B, which may be of wood or other material presenting a more or less frictional surface. The rollers, B, revolve, either directly or through suitable gear, from the motor; as shown, the rollers, B, are driven by gear from the intermediate motor-shaft at C, the motor-engine and gearing being all enclosed within a casing, D, the front of which is suspended by a sliding block, F, from one of the tubes, E, belonging to the framing of the carriage. The hinder part of the casing, D, has projecting from its side a stud, G, engaged in the eye of a plunger which works in a cylinder, H, carried by a bracket, I, clamped on the tube, E.



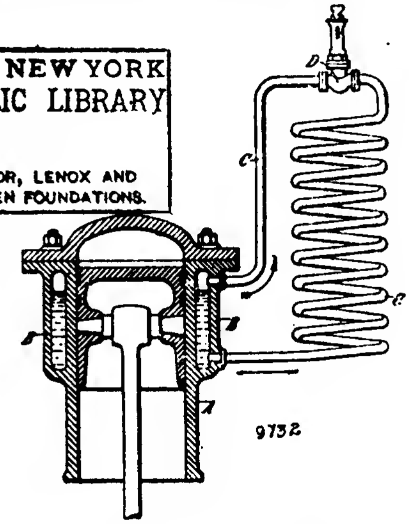
From a valve box, J, fluid under pressure can, when desired, be admitted to the cylinder, H, forcing its plunger with the stud, G, and the casing, D, backwards, thus pressing the rollers, B, against the tyre, A, so that they cause the road wheel to revolve. The two road wheels of a pair may be thus driven separately from two motors, one on each side of the carriage, or a single motor might obviously be arranged with suitable gearing to drive a pair of rollers such as B, B, on each side of the carriage, suitable means being provided for pressing them against the tyres, A, of the two road wheels.

When steam or compressed air is used as the working fluid of the motor-engine or engines, the same valve box, J, is conveniently used for the supply of the engine as well as for that of the pressure cylinder, H, and springs may be arranged to press the casing, D forwards, so that, when the supply to the engine is cut off by the valve in J, the rollers, B, are pressed by the springs out of contact with the tyre, A.

9,732. Explosion Motors. Count Albert de Dion and Georges Bouton, Puteaux (Seine), France. May 7th, 1896.

The invention has for its object to enable the cylinder and other water-jacketed parts of an explosion motor to be kept cool by means of a much smaller quantity of water than is generally required for this purpose.

A is the cylinder, and B is the water-jacket thereof, the upper portion of which may form a steam space. C is the condensing apparatus, which comprises a coil or a set of pipes in contact with



the atmosphere, the said pipes communicating at one end with the upper part or steam space of the jacket, and at the other end with the lower part or water space thereof. This coil extends above the level of the jacket, and is provided at its upper part with a safety-valve, D, of any suitable pattern, and, it may be, with a pressure gauge. When the valve, D, is shut, the coil and the jacket form a closed circuit extending from the upper part of said jacket to the lower part thereof.

By means of this arrangement the water becomes heated under pressure in the jacket when the motor is at work, and the steam produced is caused to condense in the said coil, and the water resulting from this condensation returns to the jacket, where it is again converted into steam.

The proper extent of cooling surface to be given to the coil, C, will depend on the difference between the temperature of the said steam and that of the air in contact with the coil. The greater this difference, the more rapidly will the exchange of heat take place, and, consequently, the smaller will be the surface required for condensation.

6,177. Mechanism for Driving Automotors, &c. Francis Herbert Wenham, The Beacon, near Woking, Surrey. March 19th, 1896.

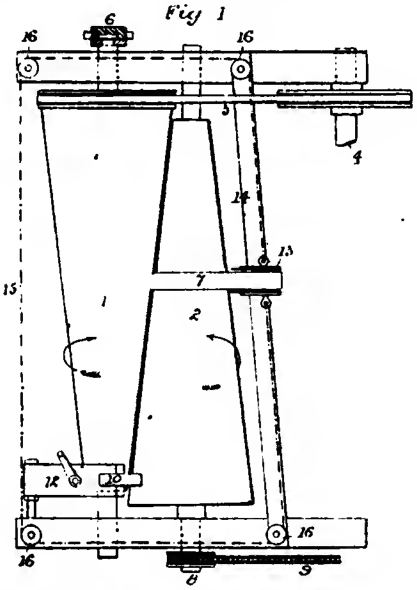
Two conical rollers, 1 and 2, are used, preferably of the same size and angle, rotating on axes, and with the large and small ends together. The first or driving cone, 1, is rotated by the engine, either directly or by a belt or chain, 3, from the main shaft, 4. Either the first or second cone is capable of being moved endways or to and fro in its bearings by a forked lever acting on the clutch like piece, 6, or by a screw or by other suitable means. Preferably surrounding the second cone, 2, is an endless or ring belt, 7, of leather, rubber, or other elastic or flexible material.

When one of the cones is forced forward by a parallel or endlong thrust from the clutch like piece, 6, it wedges the belt, 7, at any place at which it may at that time be between the two cones, 1 and 2, with any required grip causing the driven cone to rotate in a direction opposite to that of the driving cone. If the belt, 7, be gripped between the large end of the first or driving cone, 1, and the small end of the second cone, 2, the speed of the second cone is high, but if the belt, 7, be shifted towards the small end of the cone, 1, while the cones are rotating the speed is gradually reduced in accordance with the extent to which the said belt is shifted.

The motion of the second cone, 2, is conveyed to the running or road wheels, which may be done by securing to one projecting end or to both projecting ends of the said cone a pinion as shown at 8, over which passes an endless chain, 9, gearing with a wheel connected with the road wheel. When the first cone, 1, is drawn back the cones separate and the grip on the belt, 7, is released, and the rotation of the second cone, 2, ceases, and the carriage is stopped, although the motor and cone, 1, continue running.

For obtaining the reversal movement a spur wheel may be affixed to one end of each cone, and these may be geared together by dropping an intermediate or idle wheel between them, which causes the second cone to run the reverse way for obtaining the backward direction. Or preferably two rollers, 10, having frictional rubber tyres, are closed between the small end of the first or driving cone, 1, and the large end of the driven cone, 2, by a screw or lever arrangement, 12, applied when the cones are separated from the driving belt.

Fig 1



The belt, 7, is traversed along the cone, 2, for varying the speed by means of a forked shipper, 13, which slides on a guide bar, 14. The traverse may be effected by turning a screw of coarse pitch, but preferably as shown by a cord, 15, attached to the shipper, 13, running on pulleys, 16, any one of which may be turned by a handle convenient to the hand of the driver, thus carrying the shipper in one direction or the other to the position requisite for any required speed.

6,834. Horseless Carriages. Edmund Gascoine, Junior, College Road, Maidstone, Kent, and Charles Daniel Courtois, Chateau D'Ardon, Laon, France. March 28th, 1896.

This invention relates to improvements in horseless carriages of the kind in which petroleum or similar motors are employed for driving them, and has special reference to the means employed for cooling the water with which the working cylinder of the motor is jacketed.

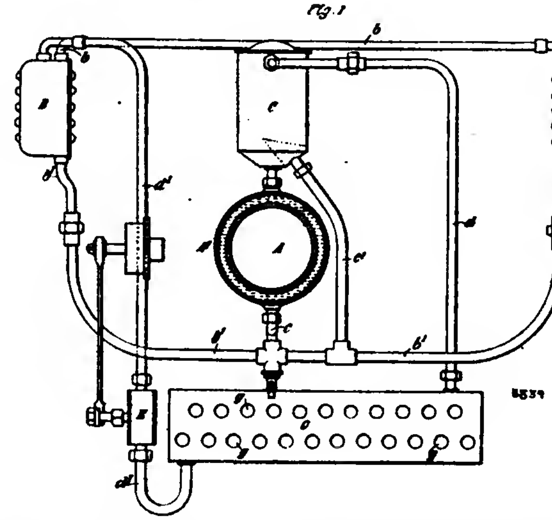
A is the working cylinder. B and B^1 are reservoirs for containing the cooling water. They communicate with each other at their upper parts by means of a horizontal pipe, *b*, and at their lower ends by means of a pipe, b^1, which passes underneath the working cylinder. A^1 is the jacket surrounding the working cylinder and communicating at its lower part with the pipe, b^1, by means of the pipe, *c*, and at the upper part with a chamber, C, situated above the level of the working cylinder. The chamber, C, also communicates directly with the lower part of the pipe, b^1, by means of an approximately vertical pipe, c^1, leading from the lower part of the said chamber.

G is the shallow box or chamber, preferably situated below the carriage near the front thereof. It is traversed by the horizontal tubes, *g*, which are open to the atmosphere at both ends, the said open ends being directed towards the front and rear of the carriage so that a current of air will readily flow through them when the carriage is in motion. The said box, G, communicates at one end with the upper part of the chamber, C, by means of the pipe *d*, and at the other end with the reservoir, B, by means of the pipe, d^1, leading from the lower part of the said box. E is a pump operated by the motor, and adapted to cause circulation of the water through the system.

The reservoirs, B and B^1, having been filled with water and the motor and pump set to work, the operation of the above system is as follows:—The water passes from the reservoir, B, through the pipe b^1 and the pipe *c* into the jacket, A^1. During its passage through the jacket, A^1, it is heated by the working cylinder, and the heated water, together with any steam that may be generated, pass together into the chamber, C, the water occupying the lower and the steam the upper portion thereof. The water will descend through the tube, c^1, into the pipe, b^1, and flow to the reservoir, B^1, whence it may pass again into the reservoir, B, through the pipe *b*.

The steam collected in the upper part of the chamber, C, is conducted through the pipe, *d*, to the box, G, wherein it is cooled and

Fig. 1



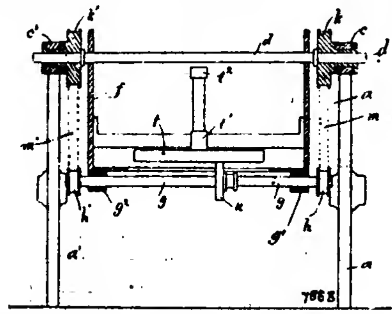
condensed, the water of condensation passing, by means of the circulating pump, through the pipe d^1, and being discharged into the reservoir, B, whence it descends through the pipe, b^1, and circulates again through the system.

By the circulation of the water and steam in the above manner and the passage of the air through the tubes, *g*, and over the outer surface of the box, G, a rapid exchange of caloric is ensured between the cooling water and the atmosphere.

7,668. Road Vehicles Propelled by Steam, Oil, Electric, or like Motor Mechanism. Frank Lister, Keighley, Yorkshire. April 11th, 1896.

The peripheries of the wheels, *a*, a^1, are prepared for the reception of friction driving wheels, *c*, c^1, which are mounted on a bearing shaft, *d*, in such positions as to enable the weight of the vehicle's body, *f*, to press their peripheries against those of the wheels, *a*, a^1, above referred to, so that the weight of said body (when loaded or otherwise) exercises a direct and beneficial influence over the driving power of the said wheels, *c*, c^1, while the wheel, *c*, on one side of the vehicle is driven entirely independently of the wheel, c^1, on the other side thereof.

The driving shaft, *g*, of the motor mechanism is arranged so that it may transmit its rotary motion to the friction driving wheels, *c*, c^1, through the medium of the pulleys, *h*, h^1 and *k*, k^1 (the former being secured to the shaft, *g*, while the latter is fixed to the wheels, *c*, c^1, respectively, and rotate freely upon—*i.e.*, without transmitting motion to—the shaft, *d*) through driving belts, *m*, m^1 (shown in broken lines), or in place of these belts, *m*, m^1, chains may be employed, or even, instead of either of these or the pulleys, *h*, h^1 and *k*, k^1, toothed gearing wheels may be used, the helt pulley, k, on one side of the vehicle being entirely independent of the pulley, k^1, on the other side, by which means the necessity of having the hearing axle, d, to rotate is entirely avolded, and by the levers and connecting rods or wire ropes being coupled so as to be operated by and whenever the steering mechanism is moved, the whole hody, f, may be raised on



one side or the other to carry with it its wheel, c or c^1, as the case may be, clear of its wheel, a or a^1, thus only one of such wheels, c or c^1, will be in effective operation, and so its wheel, a or a^1, will alone be moved; consequently the vehicle will be quickly and readily turned around or caused to travel at an acute angle.

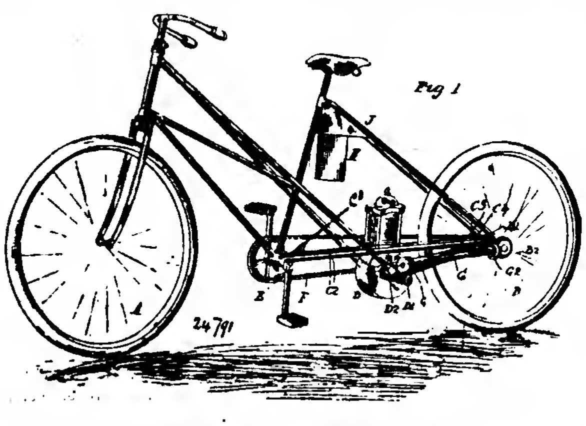
The driving wheel or disc, t, of the motor mechanism is arranged to rotate with its axis at right angles to the horizontal plane, while the shaft, g, to which its motion is transmitted through the friction pulley, u, extends horizoutally beneath it from one side of the vehicle to the other, by which means the said friction pulley, u, mounted on this shaft, g, and for contact with the disc, t, forms suhstantial support for relieving it of the friction that would otherwise be caused had said disc, t, to depend on its journal bearings, t^1, t^1, alone to counteract its weight or gravity.

Modifications are described and shown.

24,791. Motor Cycles. Henry John Lawson, of 40, Holborn Viaduct, London. November 5th, 1896.

Relates to motor cycles, its ohject being the construction of a motor hicycle with a high-speed motor.

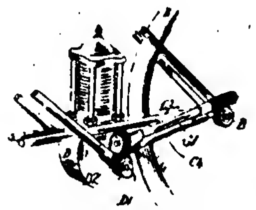
The leading and trailing-wheels, A and B, support a frame which has attached to it in rear of the bottom bracket, C^1, a motor, D, supported



by and between the two stays, C^2, and also by the stays C^3, C^4. D^1 is the main shaft of the motor, which is geared to the trailing-wheel, B, in the manner hereinafter described. E is the pedal shaft, geared hy a chain, F, to a chain-wheel, B^1, on the trailing-wheel, B, in order that when desired the power of the rider may be employed to aid the motor in propelling the cycle or to start the motor; an automatic clutch can form part of the gear between the pedal shaft, E, and the trailing-wheel, B, so that the latter may be allowed when driven by the motor to over-run the pedal shaft, but cannot conversely be over-run by it.

For the operative connection of the motor shaft, D^1, with the trailing-wheel, B, it is preferred to dispense with a chain and to employ worm or helical gearing. In the drawing the motor shaft, D^1, is provided with a worm, D^2, gearing into a worm-wheel, G, fixed on one end of an intermediate shaft, G^1, carried by the stay, C^4; the other end of this intermediate shaft has secured on it a bevel pinion, G^2, which operates the trailing-wheel, B, by acting on

Fig 2·



a bevel-wheel, B^2, fixed to the rear wheel huh. If desired, worm or helical gearing may be employed instead of the wheels, G^2, B^2, or helical gearing may be used in place of the worm, D^2, and worm-wheel, G.

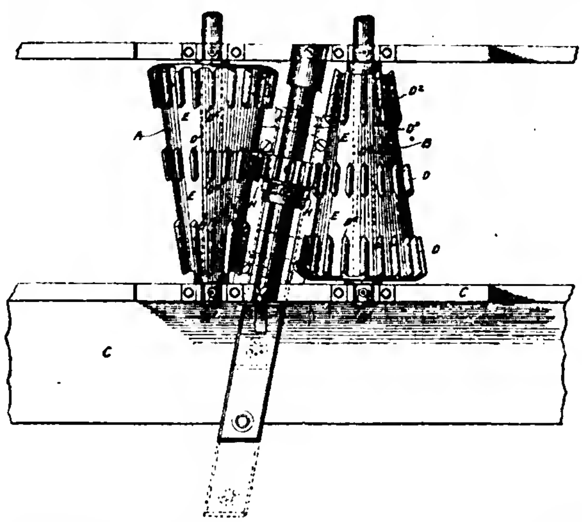
The battery, H, for the igniting spark and the carburetter, J, can be disposed upon any convenient part of the frame, the tubes heing arranged in any preferred manner.

12,360. Variable Gearing for Vehicles Driven by Motive Power. Frank Frederick Wellington, 100c, Queen Victoria Street, and Edwin Percival Allam, 14, Hatton Garden, London. June 5th, 1896.

This invention refers to improved means whereby the speed of motor-driven vehicles may be readily varied or regulated.

Two conical drums, A, B, are employed, one of which is the driver and the other the follower; these conical drums, A, B, are mounted on parallel shafts, A^1, B^1, carried in bearings on any suitable framework, C, and the drums are arranged so that the major diameter of one drum is opposite to the minor diameter of the other drum.

Upon these drums any number of series of teeth, D, D^1, D^2, are formed, at regular intervals apart, circumferentially around the drums, and these teeth extend lengthwise in the direction of the axes of the drums, A, B. Each tooth upon the drums is formed



with parallel sides, or nearly so, and with the ends of the teeth tapered or pointed as at D^x. The several series of teeth, D, D^1, D^2, around the drums are separated by spaces, as at E, E.

Between the two drums is a toothed pinion, G, so toothed as to be capable of engagement with either series of teeth on the drums, and free to revolve upon an axis parallel to the sides of the conical drums, A, B. Such pinion, G, is carried, say, upon a collar or sleeve, G^1, free to be slidden laterally by a forked slide, H, or by other convenient means. The width of the pinion, G, is less than the space or spaces, E, E, between the series of teeth, and, moreover, the ends of the pinion teeth are also tapered or pointed as are those upon the conical drums, A, B.

By thus constructing or forming the teeth upon the drums and upon the pinion, the latter can be slidden from engagement with one series of teeth and brought into engagement with another set, and the relative speed of one of the conical drums (such as the follower, B) thereby varied, the tapered end formation of the teeth permitting a smooth transference of the teeth of the pinion from one series of teeth to another upon the conical drums. The separation of the series of teeth, D, D^1, D^2, by the spaces, E, E, enables us to start or stop the motion of the follower, B, at any time by but a small motion of the pinion, G.

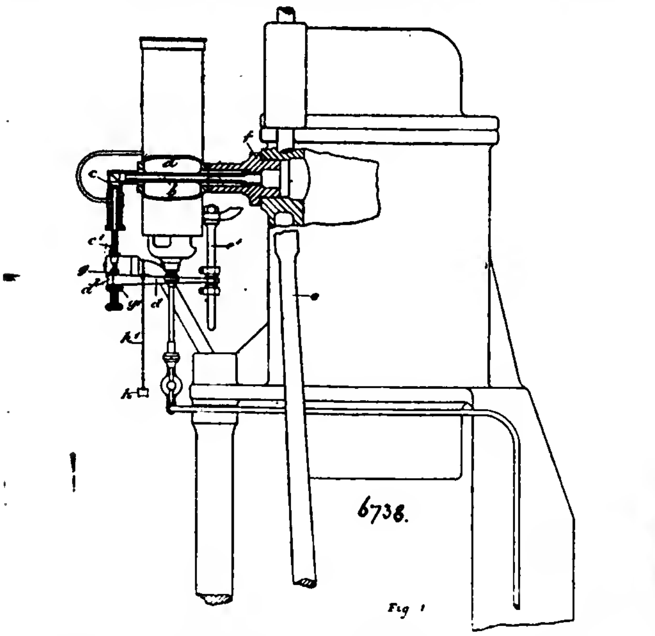
It is proposed in practice to provide an oil-containing bath or case for the gear to run in.

In such variable speed-gearing the tapered end formation of the teeth promotes a smooth and certain transference of the pinion from one set of teeth to another, while the teeth so formed present a sufficient length of bearing surface to render the construction applicable where the ability to withstand wear and tear is a consideration, as in motor-driven vehicles; while in this connection the spaces between the series of teeth, permitting of ready stopping and starting, is also of the utmost importance.

6,738. Igniting the Working Charge in Hydrocarburetted-air Engines. William Dent Priestman and Samuel Priestman, Holderness Foundry, and Harold Richardson, 51, Walmsley Street, Kingston-upon-Hull. March 27th, 1896.

This invention relates to motor-engines operated by the combustion of hydro-carbon vapour mixed with air; and consists in an improved method of and apparatus for igniting the working charge.

Across the chimney, *a*, of a heating lamp is arranged a tube, *b*, which is open at one end to the working cylinder and is provided at its opposite or outer end with an air admission valve, *c*. The movements of this valve are controlled by suitably timed mechanism,



regulated in such a manner that a small portion of the charge is allowed to escape while compression of the charge in the cylinder is taking place, or until the crank has arrived at or beyond the dead-centre. While the air-valve remains open, the charge is not ignited and pre-ignition is guarded against; but so soon as the valve closes, ignition and combustion ensue. The valves, *c*, are opened and closed by means of a lever, *d*, operated from a convenient moving part of the engine through the intervention of a connecting rod such as *e*, and arm, e^1. The open end of the tube, *b*, is inserted in a plug, *f*, which is screwed into the side of the cylinder; packing, consisting of layers of asbestos and iron, being employed to prevent the radiation of heat to the cylinder. In order to regulate the timing of the valve or valves, *c*, so as to render the ignition of the charge earlier or later, adjusting screws, *g*, are provided, and thumb-nuts, g^1, the former, *g*, of which screw through bosses, d^1, d^2, on the lever, *d*. By thus regulating the timing of the air-valve in starting, premature ignition of the charge and reversal of the engine are avoided. For the purpose of holding open the valve, *c*, of one of the igniters, in a double-cylinder engine, we provide a distance piece, or wedge; same being conveniently connected to the engine by means of a chain, h^1. At the time of starting the engine, this wedge is inserted between the lower extremity of the valve stem, c^1, of one of the air valves and the upper extremity of the adjusting screw, *g*, pertaining thereto; its function being to hold the valve open until the piston has effected a small portion of its stroke by reason of the compressed air which passes into the cylinder before the valve closes. The wedge becomes displaced almost immediately the piston moves, the valve closes and the charge is fired, whereby impulse is given to the piston.

11,491. Internal Combustion Engines. Major Henry Capel Lofft Holden, Royal Arsenal, Woolwich. May 27th, 1896.

This invention relates to improvements in the construction of internal combustion engines, the working piston or pistons of which are actuated by the explosion of a mixture of volatilised or gaseous hydro-carbons and air in suitable proportions.

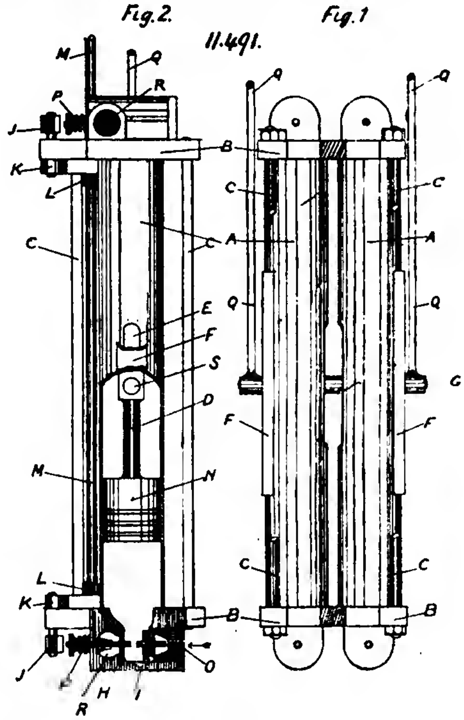


Fig. 1 is a plan of an engine.

Fig. 2 is a part elevation and part section of one of the cylinders.

The engine is constructed of two pieces of metal tube, A, A, preferably of steel.

Each end of the tubes, A, A, forms a working cylinder so that each tube comprises two working cylinders, and thus the two tubes, A, A, together comprise four working cylinders.

In each of the tubes, A, A, are two pistons, one at each end of each tube.

One of these pistons, N, is shown in the sectional view in Fig. 2.

The piston, N, is rigidly connected to another similar piston, similarly situated at the other end of the tube, by the piston rod, D, which rod has a hole, S, through the centre of its length at right angles to the axis; through this hole the crosshead bar, G, passes.

This crosshead bar, G, also passes through the piston rod connecting the two pistons in the other tube.

In order that the crosshead bar, G, may move backwards and forwards in the tubes, A, A, a slot, E, is cut in each side of each of the tubes, A, A, of the same width as the diameter of the crosshead bar, G.

To the outer ends of the crosshead bar, G, which ends project beyond the tubes, A, A, on either side, are attached by bearing sleeves the two connecting rods, Q, Q, which are attached to the crank or cranks of the main shaft of the engine in the usual manner and for the usual purpose of rotating it.

In order to exclude dust or foreign substances from the tubes, A, A, which form the working cylinders, segments of tube, F, may be arranged so as to cover the slots, E, E, and to work backwards and forwards with the crosshead bar, G, which passes through them.

The outer ends of the tubes, A, A, are closed by suitably shaped blocks of metal, B, B, in which are situated the inlet valves, I, and the exhaust valve, H.

The ends of the tubes, A, A, are bedded in the blocks, B, B, in such a manner as to obtain a suitable joint to withstand the pressure caused by the explosion and the aforesaid ends may be screwed or shrunk into recesses in the blocks, B, B, or may be, as shown in the figures, held in position by two or more tie rods, C, C, passing through holes in the blocks, B, B, and holding the whole system of tubes, A, A, and blocks, B, B, firmly together.

In Fig. 2 is seen a section through a part of the block, B, showing one of the four sets of exhaust and admission valves. The exhaust valve, H, is normally kept closed by the action of the spring, P, except at such times as the valve is forced downwards and off its seating by the pressure of the arm, J, which arm, J, is itself actuated in a manner to be hereinafter described.

By the opening of the valve, H, the waste gases after the explosion and working stroke are allowed to escape from the working cylinder into the passage, R, and thence to the external air.

The admission valve, I, is situated opposite the exhaust valve, H. It is held normally closed by the action of gravity or by means of a light spring as is the usual custom, or by the combined action of gravity and a spring.

The valve, I, is lifted by the partial vacuum produced by the movement of the piston, N, on its forward stroke and the vacuum so produced draws in the necessary explosive mixture from the source of supply through the passage, O, which is connected to the source of supply by means of pipes in the usual manner.

On the return of the piston, N, the valve, I, is closed and the explosive mixture compressed into the space in the tube, A, behind the piston, N, and between the piston, N, and the block, B. As the piston moves forward again the compressed mixture is fired by one or other of the well-known electrical or mechanical means in common use for this purpose, such as the electric spark, heated tube or wire.

The levers, J, J, are mounted on short shafts or arbors journalled in the blocks, B, B, and they carry also the pieces, K, K.

The pieces, K, K, embrace and are actuated by the cams or eccentrics, L, L, mounted on the shaft, M, in such a manner that when M is rotated the ends of the levers or arms, J, J, are raised and depressed, thereby actuating the exhaust valves, H, H.

The shaft, M, is journalled in the end blocks, B, B, and is carried beyond one of them in the direction of the crankshaft to which it is attached through the intermediary of gear wheels or equivalent devices in such a manner that its angular velocity is only one-half that of the crankshaft actuated by the connecting rods, Q, Q.

The rotation of the shaft, M, by the crankshaft of the engine at only one-half the angular velocity of the latter thus causes the exhaust valves, H, H, to be opened in the proper succession and at the right moment.

The engine works on the Otto or four cycle, which is well known, and since the four cylinders work in succession to one another then it follows that the crosshead bar, G, and through it the connecting rods, Q, Q, are continuously acted upon by a working stroke in either direction.

9,337. Valvular Arrangements for Petroleum and like Engines. Count Albert de Dion and Georges Bouton, Puteaux (Seine), France. May 2nd, 1896.

This invention relates to improvements in valve arrangements for petroleum and like engines, and has for its object to enable petroleum and other combustible to be withdrawn from a reservoir and fed into the engine cylinder in such a manner that both its quantity and its quality or composition remain uniform during the whole time that it is desired to keep the operation of the motor uniform without, however, employing any accessory parts or devices whose action is apt to prove unreliable.

The figure is a longitudinal section of a slide valve arrangement for charging the explosion chamber of a petroleum motor.

A is the slide valve and A^1 is the recess therein for carrying the successive charges of petroleum. B is the chest or casing in which the said valve works, and C is the valve rod or spindle which works in a stuffing box, D, in the ordinary manner, and has its inner end supported in a guide or socket, D^1.

Integrally with the valve casing are cast two cylindrical projections, E, F, each provided with an external screw thread. Through the projection, E, is formed a passage, E^1, communicating at one end with the petroleum reservoir (not shown in the drawing) and at the other end with a longitudinal groove, G, in the slide face of the valve casing, B.

The projection, F, is also provided with a passage, F^1, which forms at one end of the valve ports, and is enlarged at the other end, where it is provided with a valve seat, f, for a suction valve, $f^\times$, which is mounted on the rod, f^1, and held lightly up against its seat by means of a spring, f^2, acting against a collar, f^3, on the said rod. A cap or union, F^2, screwed on the projection, F, serves to keep the seat, f, in place, and is provided with a screw-threaded projection or nipple, F^3, having a passage, F^4, whereby communication is established between the suction valve, $f^\times$, and the explosion chamber of the motor.

Another screw-threaded projection is provided in which is a passage extending to the slide face, and forming a second admission port, $I^\times$, therein. This passage serves to admit the air necessary for the explosion, and communicates with an air inlet pipe traversing the explosion chamber, the supply of air for each explosion being thus heated during the interval between successive explosions.

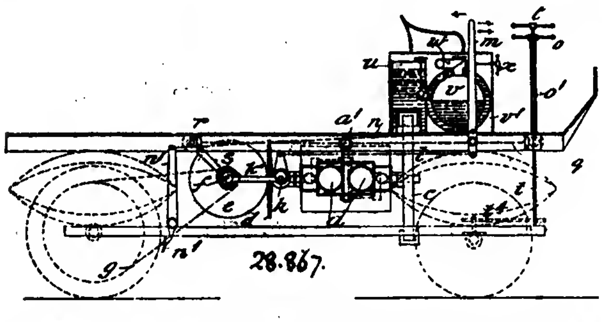
The passage, E^1, in the projection, E, is constantly in communication with the petroleum reservoir during the working of the engine, such communication being controlled by a suitable valve (not shown) at the will of the driver. By reason of the pressure within the reservoir, the petroleum passes through the passage, E^1, into the space around the valve, A, and also into the longitudinal groove, G.

28,867. Motor-van. Johann Geisenhof, Landsberg, Germany. December 16th, 1896.

The motor, a, is constructed as four-cylinder motor, and the cylinders are so arranged that each pair lies parallel to the other, and that both pairs stand opposite one another in such a manner that the four pistons operate upon a common crank shaft, which is provided on the front with a fly-wheel.

The transmission of force from the motor to the carriage wheels is effected through the disc, d, upon the shaft, and by the friction disc, e, touching it first, to the shaft, f, and from here, by means of chains and chain-wheels, g, to the carriage wheels. The disc, d, and friction disc, e, are so regulated and combined with the brake lever that the removing of the disc and the braking of the carriage wheels is effected by hand in one single operation. The disc, d, is movable, with its hub on the axle, and held from revolving thereon by a feather. In front of the disc, d, upon the non-rotating axle, h, lies a pressure-roller revolving thereon. This bipartite axle surrounds a hub of the disc, d, and is journalled at the ends by means of vertical carriers as well as horizontal arms, k, and serves for moving the disc, d, forwards and backwards. The rotation of the same by means of the shaft is therefore not disturbed by the axle, h, lying transversely to it. Its forward and backward movement is effected by means of the eccentrics surrounding the latter axle and the rod, l, connected thereto, which is fixed at the front to the brake lever, m. If the latter is pulled a little in the direction of the arrow, the rod, l, and the eccentrics are pulled or turned forwards, and the axle, h, with the rollers, is thereby pressed back so that it presses the disc, d, strongly on the friction disc, whereby the revolution is communicated to the same and thus to the wheels of the car; however, when the lever, *m*, is pressed forwards in the direction of the two arrows, the rod, *l*, and the eccentrics are moved back, and thereby the axle, *h*, is moved a little forwards, so that it pulls the disc, *d*, by means of the friction of its hub sleeve, from the friction disc and stops the transmission. This movement of the disc, *d*, is extremely small, and is sufficient to effect communication or interruption between *b* and *f*. On the brake-lever, *m*, above its turning point is fixed also the brake-rod, *n*, for the carriage brake, n^1, which thus, on the displacement of the lever, receives a movement which is opposite to that of the rod, *l*, and which while pressing disc, *d*, on roller, *e*, pulls the brake back, but on withdrawing the disc, *d*, from roller, *e*, it presses the brake on the carriage wheels. It is thns possiblo to give any degree of brake pressure and also to suddenly stop the carriage. One can, however, also change at pleasure the velocity of the motion, and this is effected by turning the wheel, o, correspondingly. The latter is fixed upon the tube, o^1, which at the underpart engages, by a bevelled gearing, with a shaft. From the latter, the motion is transferred to the shaft, *q*, and from the latter to the screw spindle, *r*. On the latter engages the arm, *s*, which forks the hub of the friction-roller, *e*, without hindering it in its rotation.

In the seat case lies the cooling water receiver, *u*, which at the under part is recessed semi-circularly, and under which is placed the fly-wheel, *c*, of the shaft, *b*, provided with paddles, so that the water is continuously cooled, and renewing on account of evaporisation is



not necessary for a long time. Next to this receiver is the receptacle, *v*, for benzine, petroleum, or the like materials developing explosive gases. It is surrounded with a jacket, v^1, and between the latter and reservoir, *u*, is a communication, so that the benzine receiver is surrounded by water from the cooler for the motor. This offers the advantage that the benzine or the like is previously warmed by the water always considerably warmed by continual cooling of the motor, and hereby a better and securer evaporisation is effected.

From the receiver, *v*, the tube, *w*, provided with a valve, leads to the motor, and by means of the handle, *x*, the valve can be regulated from outside at pleasure. The tube connection with the motor, the lighting which takes place in the chambers, *z*, and all the other organs necessary for a motor, which are already generally sufficiently known in the construction of motors, are not indicated in the drawing, and it may only be mentioned that in consequence of the above-described arrangements in this carriage, when the stoppage is only a short one, one can after having separated discs, *d* and *e*, let the motor continue to run free, or one can put it out of operation for completely stopping the working by closing the valve, *w*.

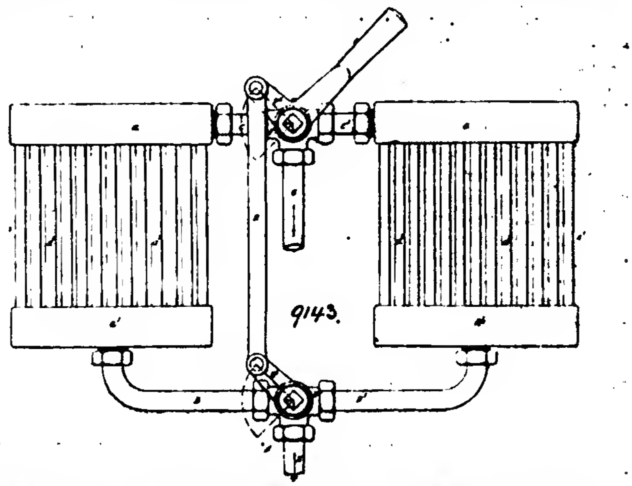
9,143. Motor-driven Vehicles. John Bradley Carse, 64 and 66, Wabash Avenue, Chicago, Illinois, United States of America. April 30th, 1896.

This invention relates to road vehicles driven by gas or oil or like internal combustion engines which require the working cylinder to be kept cool by water circulating in a jacket.

The drawing shows two reservoirs with their communication pipes constructed in accordance with this invention.

A, A^1, are the two reservoirs, B, B^1, are the outlet pipes leading therefrom, and C, C^1, are the inlet pipes. The pipes, B, B^1, are coupled by a three-way cock, D, to which is connected the pipe, E, leading to the cylinder jacket, and the pipes, C, C^1, are similarly coupled by a three-way cock, F, to which is connected the pipe, G, leading from the cylinder jacket. The plugs of the cocks, D, F, are furnished with short arms, D^1, F^1, which are connected together by a link, H, so that the cocks are opened and closed in unison. J is the handle for operating the cocks. Each of the reservoirs, A, A^1, may be conveniently made of upper and lower boxes, *a*, a^1, connected together by tubes, a^2, so as to expose a large surface to the cooling action of the atmosphere. The water entering the top box, *a*, passes down through the tubes, a^2, into the lower box, a^1, and in its passage is rapidly cooled.

The action is as follows:—By turning the handle, J, the reservoir, A, for example, may be placed in communication with the cylinder jacket, and the communication between the reservoir, A^1, and the cylinder jacket cut off, so that only the water in the reservoir, A, will be available for cooling purposes. When this water becomes unduly



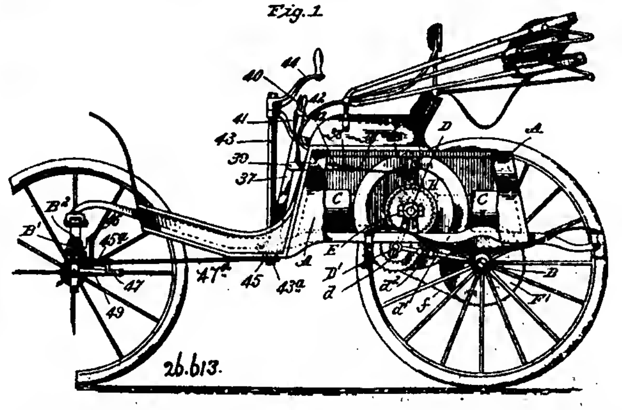
heated, the handle, J, is turned so as to reverse the connections, thereby placing the reservoir, A^1, in communication with the jacket, while communication between the reservoir, A, and the jacket is shut off. The water in the reservoir, A, is then cooled by the contact of the atmosphere with the tubes, a^2, so as to be ready for further use by the time the water in the reservoir, A^1, becomes too hot. The reservoirs are thus used alternately. If there are more than two reservoirs, they are used in turn.

26,615. Motor Vehicles. James Frank Duryea, 70, Montrose Street, Springfield, Massachusetts, United States of America. November 24th, 1896.

This invention relates to motor vehicles, and has for its object improvements in the driving mechanism.

The body, A, is supported on suitable springs on the axles, B and B^1. B is the driving axle, and B^1 the forward axle of the carriage.

Fig. 1



On each end of the forward axle is hinged, on a vertical bolt, a short stud for the reception of the hub of the wheel of said vehicle; said stud has a swinging movement in a horizontal plane, which movement is imparted thereto as follows:—

A short horizontal arm, 49, projects rearwardly from the said stud, which arm is by a rod connected to the forked lever, 47, which is secured to a sprocket-wheel, 45^a; said sprocket-wheel is rotatably supported on a yoke, 46, which is clamped to the forward axle, B^1.

A sprocket-chain, 47^a, engages said wheel, 45^a, and a similar sprocket-wheel, 45, on the lower end of the steering-post, 43^a, within the tubular support, 43. The upper end of said steering-post is provided with a crank-arm, 44, whereby it is rotated, and through the connections above described the forward wheels of the vehicle are turned on their pivots.

Suitably supported on the frame of the carriage, and at right angles to the axles thereof, is a suitable motor; said motor is preferably a gasolene motor, though any suitable motor may be used.

In the drawing said motor is represented by C, and shows two oppositely located cylinders connected directly to a crank on the end of the driving-shaft, D (see Fig. 1), which shaft is supported on suitable bearings, E, on the frame of the carriage, and is parallel with the driving-axle, B, thereof.

A counter-shaft, D^1, parallel with shaft D, is supported in bearings at the extremities of the arms, d, which arms depend from the main shaft, D, and have a swinging motion thereon.

A rod, d^1, having a loose connection with each end of the counter-shaft and the rear axle, is made in two parts, said two parts being united by a suitably threaded nut, d^2, by which the distance between said counter-shaft and said driving axle is regulated.

On one end of said counter-shaft a sprocket-wheel is secured, and on said driving axle another sprocket-wheel, F^1, is secured, a sprocket-chain, f, engaging both of said wheels.

The tension of said chain, f, is regulated by means of said nut, d^2, on the rods, d^1.

By means of suitable connections (described in the specification) between the driving-shaft, D, and its counter-shaft, D^1, varying speeds are imparted to said counter-shaft, and through said sprocket-wheels and chain to the driving axle, B.

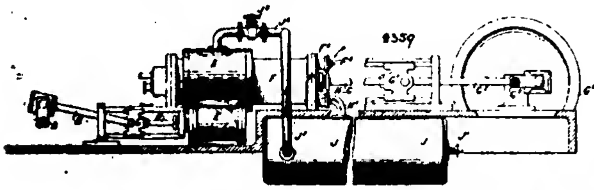
The means by which the said elbow-levers of the various clutch mechanisms are operated to drive the carriage forward or backward consist of a series of cams rotatably secured to the bar, L, on opposite sides thereof, one of said cams being provided for operation on the end of each of the said elbow-levers.

Each of said cams is provided with a spirally grooved hub, around which a chain, 34, is passed, which hubs are all in a line on one side of the bar, L, and said chain being supported on sheaves located on said bar, L, and on sheaves located on the frame of the carriage, whereby said chain is disposed in a horizontal quadrilateral form. The said chain, 34, is made endless, and has secured to any convenient part thereof a lever, 38, which by its opposite end has a pivotal engagement with the operating lever, 37, whereby, by the reciprocating movements of said operating lever, movement may be imparted to the said chain, 34, by which movement the cams may be rotated in either direction, because of the engagement of said chain, 34, with the spirally grooved hubs of said cams.

8,359. Motor-Power Apparatus for Propelling Vehicles and Boats. John Malcolm MacDonald, 2, Victoria Mansions, Westminster, London. April 21st, 1896.

A is the main driving shaft from which motion is transmitted to, say, the wheels of a vehicle, this shaft, A, forms the crank shaft of the compressed-air engines of which B B are the connecting rods, C C the crossheads, D D the piston rods, and E E the cylinders. Located

Fig. 1.



above the cylinders, E, E, is arranged the cylinder, F, of an explosive engine such as an oil-engine. The minor details of this engine are not specially illustrated as these do not differ from such engines as are ordinarily constructed and the cycle of operations are as is usual on the Otto engine. The piston rod, G, passes out of this cylinder through a packed gland, F^1, at the forward end of the cylinder which is provided with a cover, F 2, while the usual cycle of operations such as the indrawing of the explosive vapour, the compression, ignition, &c., take place at the rear of the piston. In its rearward motion the piston draws in atmospheric air into the forward end of the cylinder by means of an air inlet valve, F 3, on the cover, F 2, and the next forward motion of the piston forces the air therefrom by an outlet valve, H, and pipe, H^1, into a reservoir, J, which should be fitted with a suitable safety valve, such as J^1. From the reservoir, J, the air is conducted by a pipe, such as J 2, to a jacketted chamber, K, surrounding the cylinder, F, of the explosive engine, the pipe, J 2, being fitted with a stop-cock, J 3, and reducing or other valves as required (not shown in the drawing) are fitted in the air-conducting pipes if required or found necessary.

The piston rod, G, of the explosive engine is connected to a cross-head, G^1, having a connecting rod, G 2, operating a crank shaft, G 3, on which is or are mounted a fly wheel or wheels, G 4.

From the jacketted chamber, K, the compressed air is conducted to a valve chest of compressed-air engine cylinders, E, the valves of which are operated by eccentrics mounted upon the crank shaft, A. The motion of the crank or driving shaft, A, is communicated to the wheels of a vehicle or to the propeller or paddle shaft of a boat, in any usual or convenient manner.

The jacketted chamber, K, is preferably somewhat narrowed internally towards that part where the air passes out to the valve chest by plates for the purpose of bringing the air into more intimate contact with the walls of the hot cylinder, F.

5,682. Rotary Motors. William Phillips Thompson, 6, Lord Street, Liverpool; Wilhelm Eduard Marx, Halle, Germany. March 3rd, 1897.

A fixed flat disc, a, mounted on a suitable base, is provided with concentric rings, b and c, and with a concentric core, d. In the concentric interstices, e and f, thus formed there engage two concentric rings, g and h, of a revoluble flat disc, k, which is mounted eccen-

Fig. 1.

trically to the flat disc, a, and fixed on a motor shaft, i. This disc, k, is so eccentrically mounted relative to the flat disc, a, that the concentric rings, g and h, come in contact in one direction with the inner or outer surface of the concentric rings, b and c, and core, d, of the flat disc, a. In this manner there are formed between the rings crescent-shaped working chambers, e, e^1, f, f^1. Plates, m, are arranged radially movable side by side in the rings, g and h, the length of which plates is equal to the width of the concentric interstices situated between the rings, b and c, and the core, d. These plates which are movable in the rings have for their object to divide the crescent-shaped working chamber into two parts—one for the expansion, and the other for the discharge. The plates, m, act thus in the manner of a piston. As the rings of the two flat discs stand eccentrically to one another, the various working chambers alternate, and there is simultaneously an always varying endwise reciprocation of the two plates.

The mode of working is as follows :—

The high-pressure steam is conveyed in the direction of the arrow by means of a feed-pipe, y. It passes through the inflow passages into the working chamber, f, presses against the plates, m, and causes a rotation of the flat disc, k, and shaft, i, in the direction of the arrow, p. When the affected plates, m, come behind the discharge passage, 4, the expanded steam passes through the passages, 4 and 6, into the working chamber, f^1, where it acts in a similar manner. In the meantime, however, fresh steam flows into the working chamber, f. The further expanded steam in the working chamber, f^1, passes through passages, 7, 8, 9, into the working chamber, e, acts there by means of its expansion, passes through passages, 10, 11, and 12, into the working chamber, e^1, and after it has been expanded almost to atmospheric pressure escapes through a passage, x. The motor revolves, therefore, in the direction in which the steam enters. The motion of the motor is a constant and even one. The expanded steam engages on an always increasing radius, so that an equal pressure takes place on all parts.

6,067. Gas and Oil Engines or Motors, and Carriages Propelled Thereby. Frank Herbert Briggs, of 6, Park Crescent, Torquay, Devon. March 18th, 1896.

This invention has for its object improvements on the invention set forth in Application No. 16,079 of 1895.

Fig. 1 is a sectional view of the engine through the cylinders, and a sectional view at right angles to the above through the vaporising part, which is shown broken off from the other portion at the bottom.

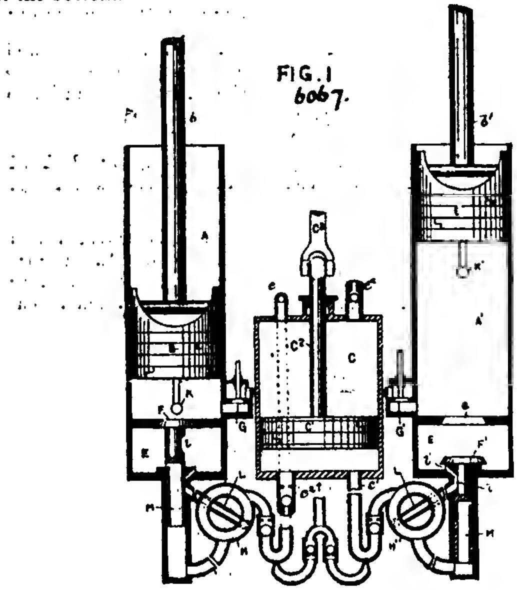


Fig. 2, a vertical section through the vaporiser and parts connected therewith.

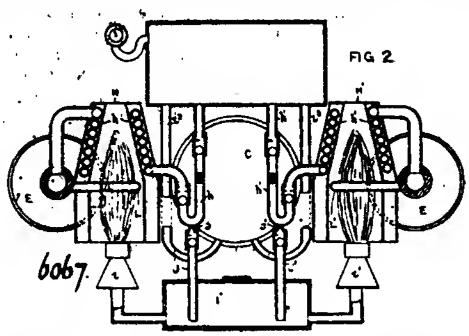
Fig. 3, an elevation of the valve actuating gear and other parts showing one form of mechanism.

Fig. 5, a plan of the engine as applied to a road carriage.

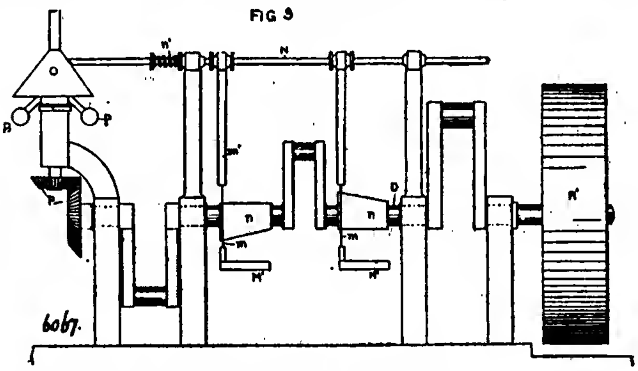
Fig. 11, a modification of the governor and valve actuating cams when these are placed on a counter shaft instead of the main shaft.

Fig. 13, sectional elevation of guiding handle and accompanying parts.



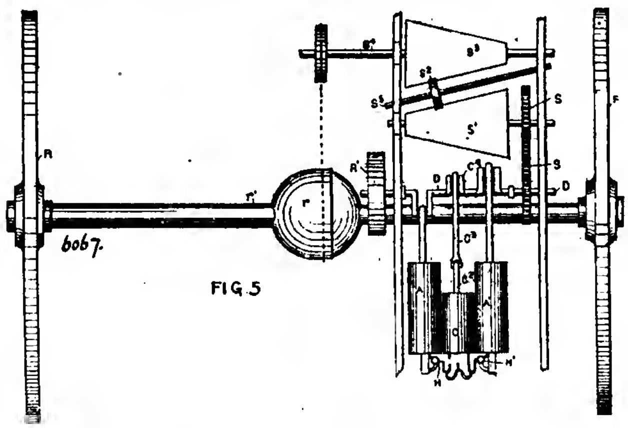
Referring first to Figs. 1, 2, 3, and 5, A, A¹, are two working cylinders, B and B¹ pistons of same with piston rods, *b*, *b*¹, pivotally connected to them as shown. C is a third cylinder enclosing a piston, C¹, and forming the pump. This is connected by a piston rod, C², and connecting rod, C³, with the central crank, C⁴, of crank shaft, D, Fig. 3. This cylinder, C, as shown in Fig. 1, hereinafter described, can be made single acting or double acting. It is used for supplying air and compressing the charge. E and E¹ are chambers immediately below or behind the cylinders, A, A¹, in which the ignition and explosion of the charge takes place. These communicate with the working cylinders, A and A¹, by means of orifices capable of being closed by the mushroom valves, F, F¹. G, G¹, are the exhaust valves, H and H¹ are annular conical vaporising chambers, Figs. 1 and 2, in which the oil and air circulate through tubes, *h* and *h*¹, the air being forced into tank, I, through pipe, *i*², by the pump, C, and under some circumstances hereafter set forth it is supplied by tank, I.

The tubes, *i*³, communicate with the opposite ends of the pump, C, so that compressed air is being forced through one of them all the time. In Fig. 1 the tank, I, is omitted, and the pipes, *i*², are broken away. The pipe, *i*², which supplies air and oil to the left-hand vaporiser, H, communicates with the outlet, *c*, of cylinder, C, while



the other pipe, *i*², which supplies air and oil to the vaporiser, H¹, communicates with outlet, *c*¹, at the opposite end of the cylinder, C. The cylinder, C, is provided with a valved air inlet, *c*², at each end.

The chambers, H, H¹, are heated by the flames of lamps, *i* and *i*¹, fed from tank, I¹, with oil. Oil from tank, I¹, passes through pipes, J and J¹, to the little nozzles, *j* and *j*¹, in bends in pipes, *h*, *h*¹, the air from pump, C, passing through the pipes, *h*, inducing the oil to issue in a spray form from nozzles, *j*, *j*¹, to be mixed with the air and carried to the vaporising chamber, H or H¹, where it is vaporised, and from thence it enters the bottom of chamber, E or E¹, as the case may be. Ball or other valves prevent action in a contrary direction, as shown in the drawings. K and K¹ are projecting pins or tappets on the pistons, B, B¹. L and L¹ are



ignition tubes projecting into the flame of lamps *i* and *i*¹, and communicating with the ignition chambers, E, E¹, respectively through ducts, *e*.

The mode of action of the parts is as follows:—

Assuming that the working piston, B¹, has just reached the end of its forward stroke, the exhaust valve, G¹, opens and allows the exhaust gases to escape. The pressure of the air from the pump, C, entering the tubular extension of the ignition chamber, E¹, at once forces the valve, F¹, on to its seat, *e*; the gas still exhausting, the piston, B¹, continues its inward or return stroke until it comes near the end. In the meantime the chamber, E¹, has been filled by the compressed air and gas vapour from the vaporising chamber, H¹, and has been shut off from cylinder A¹, by the valve, F¹. The tappet, K¹, now strikes the valve, F¹, and pushes it down to the position shown in the right-hand side of the drawing in cylinder A¹, and at the same moment connection is made with the ignition tube, L¹, by means of the notch or port, l, in the stem of valve, F^1, connecting the ignition chamber, E^1, with the small ignition duct, l^1. (The notch, l, is shown plainly in the left-hand side of Fig. 1 where the valve, F, is shown closing the chamber, E^1, from the ignition tube, L.) Ignition being caused, and at the same time or just previously to it the exhaust valve, G^1, being closed, an explosion takes place, and the piston, B^1, is caused to perform its working stroke, during which the operation above described will be repeated in connection with the other working cylinder, A, namely, the driving out of the residual products of the previous combustion, and the forming of a charge ready for firing when the piston reaches the end of its instroke. It

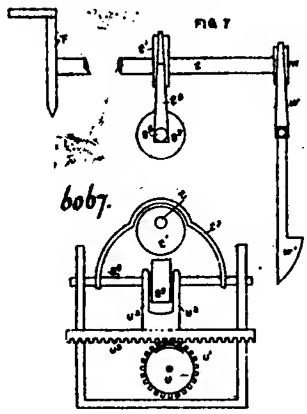


FIG. 9.

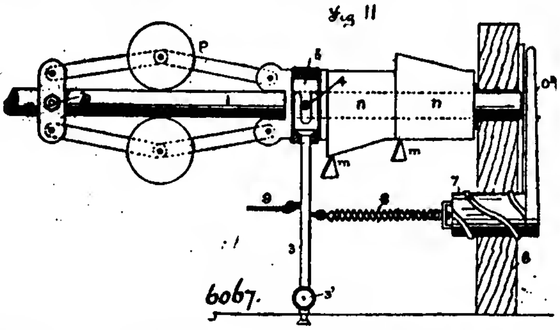
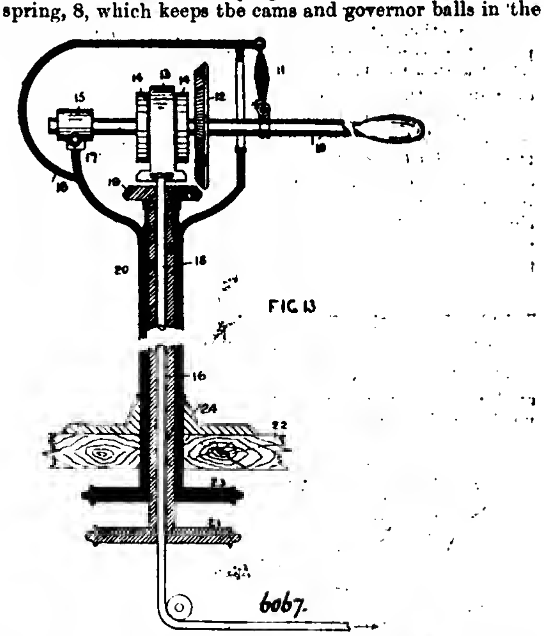
will thus be seen that as the pistons work alternately, there is always a compressed charge stored up ready for firing, and thus the engine can be automatically started without having to rotate the shaft by hand as in other arrangements. By the above arrangement two explosions are obtained at every revolution. When either of the pistons, B or B^1, alternately reach the end of their respective cylinders after performing their working stroke, the exhaust valves are again open, the valves, F or F^1, are closed on their seats by the pressure of the air from the pump, and the air enters freely through the hollow part, M, of the stem of the valves, F or F^1. The various valves set forth in the drawings in pipes, h, &c., allow the air and gas to go forward, but prevent their return. The firing device may, instead of the heated tube, L, already described, be any other



suitable device, such as the ordinary electric sparking apparatus. In some instances I may do without a vaporiser altogether, spraying the oil direct into the explosion chamber. The exhaust valves, G and G^1, are operated by the cam motion set forth in Fig. 3. In this M^1 is the valve lever; m, a knife edge or thin part of the connecting rod connecting the valve rod, m^1, with shaft, N; n, n are conical or partially graduated cams on the main shaft, D. By pressing the shaft, N, longitudinally in its bearings, the connecting rods, m^1, and knife edges, m, are brought on to a smaller portion of the cams, until when they get to their smallest diameter, there is no motion in the knife edges, consequently the valve is not actuated. Instead of the shaft, N, moving longitudinally, the connecting rods, m^1, or the cams, n, n, can be made to shift on the shaft; n^1 is a spring for bringing the shaft, N, back to normal position. For the purpose of stopping or starting the motor, a handle may be coupled to the shaft, N, or the cams, n, n, so that by pulling this handle and sliding the shaft, N, or cams, n, n, longitudinally, the knife edges, m, are brought to the smaller portion of the cone cams, n, thus stopping the engine. The shaft, N, is (or sliding cams or their equivalent are) linked to the governor and has any suitable device, such as slotted bearings for the connecting pin to allow for the small angular motion of the bell crank, a spring puts a resistance on the governor, and by regulating this resistance, any required resistance can be obtained, and thus the governor regulated to any required speed.

1, Fig. 11, is the counter shaft, which is revolved by a bevelled gear-wheel at its left-hand end gearing to another bevelled gear-wheel fixed on the axle. Its position is parallel to the cylinders, and at right angles with the main crank. Fixed to this shaft is a ball governor, P, by a set screw, p, the right-hand end of which is attached to two conical cams, n, n, these two cams, along with the right-hand end of the governor, are capable of being slid horizontally along the shaft, 1, but are prevented from revolving round the shaft, 1, by a key and keyway. 3 is a forked rod hinged at 3^1 to the base plate and its forks fitting round two studs, 4, which project from a loose collar, 5, which fits in a groove in the right-hand end of the governor, P. 6 is a standard from the base plate, with bearings for shaft 1, through the lower part of 6 is a hole tapped with a thread into which is screwed plug, 7, between this and lever, 8, is a strong spring, 8, which keeps the cams and governor balls in the



position shown in drawing, the end section of cam rods are shown at m and m, the valve connected with the left-hand cam being open, and that connected with the right-hand cam being closed. 0^3 is a pointer attached to the plug, 7, passing over a dial on which the number of miles or revolutions per hour is marked. The action of the governors on the cams is as follows:—The pointer, 0^3, being set at a given figure on the dial and clamped with any convenient locking device if desired, causes a given amount of tension to be put upon the spring, 8, and the forked arm, 3, so that the cams are held in the position shown until the speed of the engine revolving the governor balls increases to such an amount that the centrifugal force overcomes the spring, 8, and draws the cams, n, n, towards the left, thus regulating the opening at the valves, and in that way the speed of the engine. Should the speed of the engine be so great as to draw the narrow end of the cam on to the knife-edged valve rods, m, m, then the valves would not be open at all, and the engine would come to a stop. 9 is a swivel and rod connected with the steering gear, and is used when the steering handle falls to stop the engine instead of rising.

The steering, stopping, starting, and speed regulating gear is shown in Fig. 13. On the handle, 10, is first a spiral spring, 11, second a bevelled gear-wheel, 12, a loose collar, 13, running between two guide flanges, 14, and a bearing, 15, which is swivelled to the outer case, 16, by a bolt, 17, this is to allow of an up and down motion of the handle, 10. To the loose collar, 13, is swivelled a rod or wire rope, 18. 19 is a bevelled gear-wheel which is attached to a tube, 20, at the lower end of this tube is a sprocket-wheel, 21. The outer case, 16, descends beneath the carriage floor, 22, and ends in sprocket wheel, 23, it is kept in place and made to revolve in bearings, 24, which is screwed to floor, 22, of carriage.

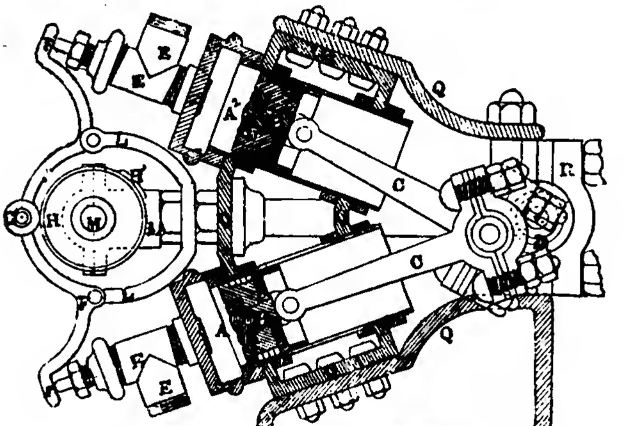
Referring to Fig. 5, R, R, are the carriage wheels, r, the differential gearing whereby each wheel is able to go at a different speed from the other, R^1, fly-wheel, S, S, gearing for driving cone, S^1, from the shaft, D. A friction-roller, S^2, drives the cone, S^3, by friction from S^1. The axis of the friction-roller, S^2, revolves in the adjustable bearings, and the said roller is pressed down against the surface of the cones, S^1 and S^3, by a spring. Shaft, S^4, is connected with the axle, r^1, of the vehicle by any suitable gearing, such as sprocket wheel and chain, as shown in drawing.

Referring now to Figs. 7 and 9, T is an end crank on shaft, t, t^1, is an eccentric on this shaft. By turning this shaft, therefore, the yoke, t^2, is raised. This yoke carries in bearings the shaft, S^5, on which the friction-roller, S^2, of Fig. 5, runs. By turning this crank, T, round therefore, the roller, S^2, can be raised out of gear with cones, S^3 and S^1, and thus the engine cut off from the driving-wheels, R, of the carriage. In order to increase or lessen the speed, the friction-roller, S^2, is drawn towards one or other end of the cones, S^3 and S^1. This is effected by a hand-wheel, not shown, on shaft, U, driving the gear-wheel, U^1, and rack, U^2. Projections, U^3, on this rack push the pulley, S^2, longitudinally on shaft, S^5.

The method of supporting the autocar on the engine, so as to prevent uncomfortable vibration, consists of two springs on each wheel with a bar between. On this bar the engine is supported, and on a spring the carriage body itself is suspended either directly or by a C-spring. The result of this arrangement is that the spring being interposed between the engine and the road, the shocks caused by the irregularities of the road are taken off the engine to a further considerable extent, and a spring being also interposed between the road and the carriage and also between the engine and the carriage, the shocks of the road are further deadened by this spring, and the vibration of the engine is also cut off to a considerable extent from the carriage occupants.

7,609. Explosion-Motor. Alphonse Edouard Tavernier, 23, Plato Road, Brixton, London, S.W. April 10th, 1896.

The object is to produce a gas or petroleum-engine, working by explosions in the best possible conditions, and to obtain in such machines the possibility of regulating at will the speed of rotation.



7609.

FIG. 1

The four cylinders, two of which, A, A^2, are shown, are fixed in a special box of sheet iron, Q.

In every cylinder is a piston, B. This piston is composed of three parts. One part receives the special segment of this piston, another keeps the said segment in place. The third part is the segment itself. This segment is composed of a steel wire of a square section, which is rolled so as to form a spiral spring. The three pieces are kept in place by a bolt and a nut.

Every piston has a connecting rod, C, the connecting rods of two opposite pistons acting on the same baring of one of the cranks of the crank shaft. To each cylinder is fixed two valve-boxes, E, E, one has for object the alimentation of the detonating mixture in the cylinder, the other valve-box is on the contrary for letting out the foul gases produced by the combustion of the detonating mixture in the same cylinder. The valves in the valve-boxes are worked by the levers, F. Each lever, F, has a friction roller, G, this roller turning on the drum, H. The drum, H, turns with the machine at a speed of the half of the speed of the crank shaft. On this drum, H, are disposed in the required positions cams, H^1. These cams acting on the friction rollers, G, bring, by the aid of the levers, F, the valves to open. Springs properly disposed keep the valves closed, and the levers, F, must overcome this resistance to open the valves.

The valve-boxes are of two different sorts. The valve-boxes serving for the alimentation are connected two by two by the tubes, these tubes being in communication, through an aperture covered by a wire gauze, with the interior of box, Q.

Each cylinder has fixed to it the two valve-boxes, E, E, and also a small detonator. The detonator is composed of a recipient in which are fixed two small insulating pieces in porcelain or steatite. These insulating pieces are traversed by a wire of platinum, and small nuts on these platinum wires form the electric terminus of the apparatus. The detonators are communicating with the interior of the cylinder on which they are placed, the upper part being shut by a screw.

In the middle of the drum, H, is a part in ebonite, and with the assistance of electrodes and contact pieces, this part forms the electric distributor to the detonators. By the help of a source of electricity and this distributor an electric spark is produced at the proper moment between the platinum wires of each of the detonators. The source of electricity employed may be a small magneto or dynamo put in motion by the machine itself, or an accumulator.

If the machine is burning petroleum or any other liquid hydrocarburet, this liquid is stored in a special apparatus. Methods of cooling the cylinders and changing the speed of the machine are described.

Printed Copies of the above Specifications Published may be obtained by forwarding 1s. for cost of each copy and postage to Messrs. Herbert Haddan and Co. Applications not yet Published.

THE ENGINEER AUTOMOTOR COMPETITION.

IN response to the offer of the proprietors of *The Engineer* of prizes amounting to 1,100 guineas for the best self-propelled vehicles, the following firms announced their intention of competing, and paid the deposit money :—

CLASS A.

For the best mechanically-propelled vehicle constructed to carry, including the driver, four or more persons, the total weight, when fully loaded, not exceeding two tons, a prize of 350 guineas will be given.

The Electric Motive Power Company (Limited), 16, Elm Street, Gray's Inn Road.

The Electric Motive Power Company (Limited), 2nd carriage.

Middleton Crawford, 37, New Oxford Street, W.C.

The London and Glasgow Motor-Car Syndicate, 11, Queen Victoria Street, E.C.

New and Mayne (Limited), Palace Chambers, Bridge Street, Westminster.

Clement Richardson, 128, Stephen's Green, Dublin.

G. F. G. Des Vignes and Co. (Limited), Orleans Works, Teddington.

John I. Thornycroft, Eyot Villa, Chiswick Mall, Chiswick.

The Dorset Iron Foundry Company (Limited), West Quay Road, Poole.

E. J. Pennington, Bramlea, Hersham Road, Walton-on-Thames.

W. J. Perrett, The Laurels, Romford.

W. H. Barker, 37, Haverstock Hill, N.W.

William Baines, 5 and 6, Great Winchester Street, London, E.C.

John Fielding, Upton Saint Leonards, Gloucester.

The McDonald Patent Battery Syndicate, 4, North Saint David Street, Edinburgh.

The Clarkson and Capel Steam Car Syndicate (Limited), Deverell Street, Great Dover Street, S.E.

J. Irving Courtenay, 4, Great Winchester Street, E.C.

Douglas Neale, 21, Rutland Square, Edinburgh.

Roots and Venables, 100, Westminster Bridge Road, S.E.

Higgins, Bessemer, Nicholson, and Co., 127, Brixton Hill, S.W.

The Romiley Engineering Company, Hatherlow Wharf, Romiley.

Henry Sharp, 43, Broadway, Deptford.

Brindley, Naylor, and Wilson, 5, Waterloo Road, North, Wolverhampton.

Ridley James Urquhart, 6, Clayton Square, Liverpool.

Stevenson and Shovelton, 23, School Lane, Liverpool.

H. K. Hales, cycle agent, Burslem.

Walter Jno. Hubert Jones (J. Truman and Co.), Gloucester Works, Smithfield Passage, Birmingham.

The London Motor-Car Works Company (Limited), Albert Mills, Beavor Lane, Hammersmith.

CLASS B.

For the best mechanically-propelled vehicle constructed to carry either one or two or three persons, the total weight, when fully loaded, not exceeding one ton, a prize of 250 guineas will be given.

The Electric Motive Power Company (Limited), 16, Elm Street, Gray's Inn Road, W.C.

James Morton Hall, 102, Dale Street, Lancaster.

J. Holt Thomas, West View, Hopwood Lane, Halifax.

New and Mayne (Limited), Palace Chambers, Bridge Street, Westminster.

Atkinson and Philipson, Northumberland Carriage Factory, Newcastle-on-Tyne.
E. J. Pennington, Bramlea, Hersham Road, Walton-on-Thames.
W. J. Perrett, The Laurels, Romford.
Greengrass and Docking, 62, Dingwall Road, Croydon.
William Baines, 5 and 6, Great Winchester Street, E.C.
The Electric Construction Company (Limited), Bushbury, Wolverhampton.
G. Stanton, 335, Strand, W.C.
The McDonald Patent Battery Syndicate, 4, North Saint David Street, Edinburgh.
The Clarkson and Capel Steam Car Syndicate (Limited), Deverell Street, Great Dover Street, S.E.
Douglas Neale, 21, Rutland Square, Edinburgh.
The Steam Carriage and Wagon Company (Limited), Homefield, Chiswick.
The Dorset Iron Foundry Company (Limited), West Quay Road, Poole.
The Lancashire Steam Motor Company, Leyland.
The Prince Motor Syndicate (Limited), 147, Leadenhall Street, E.C.
The Clarkson and Capel Steam Car Syndicate (Limited), Deverell Street, Great Dover Street, S.E.
Douglas Neale, 21, Rutland Square, Edinburgh.
The Liquid Fuel Engineering Company, East Cowes, Isle of Wight, and 20, Abchurch Lane, E.C.
The Romiley Engineering Company, Hatherlow Wharf, Romiley.
Merryweather & Sons (Limited), Greenwich Road, Greenwich.

Fig. 1a.

Roots and Venables, 100, Westminster Bridge Road, S.E.
Eccles and Sugden, 75, Queen Victoria Street, E.C.
William Henry Dugard, Vulcan Mills, Bridge Street West, Birmingham.
The Yeovil Motor-Car and Cycle Company (Limited), Yeovil.
J. F. Stilwell, Royal Pier Hotel, Weston-super-Mare.

Class C.

For the best mechanically-propelled vehicle constructed to carry, in addition to the driver, not more than one ton of goods or parcels, the total weight, when fully loaded, not exceeding two tons, a prize of 250 guineas will be given.

Herbert John Dowsing, 24, Budge Row, Cannon Street, E.C.
New and Mayne (Limited), Palace Chambers, Bridge Street, Westminster.
Enock Bros., Coombe, Dartmouth, Devon.
Clement Richardson, 128, Stephen's Green, Dublin.
J. F. Stilwell, Royal Pier Hotel, Weston-super-Mare.
Stevenson and Shovelton, 23, School Lane, Liverpool.

Class D.

For the best mechanically-propelled vehicle constructed to carry, in addition to the driver, five hundredweight of goods or parcels, the weight, when fully loaded, not exceeding one ton, a prize of 150 guineas will be given.

The Clarkson and Capel Steam Car Syndicate (Limited), Deverell Street, Great Dover Street, S.E.
Roots and Venables, 100, Westminster Bridge Road, S.W.

Supplemental Class.

For the vehicle, whether passengers or goods, propelled solely by a motor actuated by the vapour of oil or spirit, having a lower specific gravity than 0·8, or a flashing point lower than

73° Fah., Abel's test, and constructed to satisfy the requirements of any Act of Parliament, and the rules to be made thereunder for the time being respectively in force, which, in the opinion of the judges, best satisfies the purpose for which it is built, a prize of 100 guineas will be given.

Herbert John Dowsing, 24, Budge Row, Cannon Street, E.C.
Herbert John Dowsing, 24, Budge Row, Cannon Street, E.C. (2nd).
M. Tod and Son, Devon Engine Works, Dunfermline.
Alfred Cornell, Tonbridge, Kent.
William Baines, 5 and 6, Great Winchester Street, E.C.
T. Coulthard and Co., Cooper Road, Preston.
J. F. Stilwell, Royal Pier Hotel, Weston-super-Mare.
H. K. Hales, cycle agent, Burslem.

The necessary power is obtained through a two-crank compound tandem horizontal steam-engine, A, having two high-pressure cylinders, placed on two low-pressure cylinders of large area. The whole of the engine working parts have very large bearing surfaces, and are thoroughly well lubricated by running in oil contained in the case. In order to prevent as little water as possible finding its way into the steam cylinders, the valves are placed below the centre line of the engines and so allowing of proper drainage. Owing to the high revolution of the engines it is necessary to gear it down by toothed wheels (no chain gear being used) contained in the case, *a*, which transmits the power to the driving shaft, *b*. On each side of this shaft are steel pinions gearing into a large internal gear, *d*, which is attached to the spokes on each of the rear wheels. This gear-

FIG. 1.—"LIFU" STEAM VAN (Plan).

Of the above firms seven only appeared at the Crystal Palace with automotors, viz., the Liquid Fuel Company of Cowes (1); Messrs. Roots and Venables (2); the Electric Construction Company of Wolverhampton (1); the Yeovil Motor-Car Company (1); the Electric Motive Power Company (1); Mr. Holroyd-Smith (1); and Mr. Cornell (Arnold Carriage, Benz System) (1).

Taking these exhibits in order, the motor van of the Liquid Fuel Company was unquestionably, from the utilitarian point of view, a wonderfully perfect machine, and deservedly gained special commendation from the judges. We illustrate it in the figures on pp. 344–349:—Fig. 1A is a side view; Fig. 1 is a plan; Fig. 2 a longitudinal sectional elevation; and Fig. 3 a rear transverse section. As will be seen, the van is of the ordinary four-wheel type, having doors at the rear. The body of the van is about 10 feet by 4 feet 3 inches by 5 feet, and is carried by springs in the ordinary way.

wheel, *d*, is encased in a patent dust-proof case, through which it is impossible for any dust or grit to find its way. The engines when running at 600 revs. are capable of indicating about 12 horse-power, and weigh, with feed-pumps, about 155 lbs. The carriage wheels make one revolution to 8½ revs. of the engine. When necessary, as when climbing a hill, steam can be admitted direct into the low-pressure cylinders by the valve, A 2; on ordinary occasions the engines are worked compound. The exhaust from the steam-engines passes into the exhaust box, C, then into the funnel, B, where the steam is consumed by the gases from the furnace as they escape up the funnel. The boiler feed pumps, J, draw their water from the water tank, W. The main boiler feed pumps are placed beneath the front seat, and are run off the main engines by means of a shaft and gearing by which the speed of the pumps is reduced.

A separate steam pump is also placed beneath the seat, to be worked only when the engines are not running. The boiler, B (which is separately illustrated in Figs. 3A and 3B), is placed immediately behind the front seat, and is of ample size, to allow of easy steaming. The boiler is of the water tubular type, and the steam pressure carried is 250 lbs per square inch. Its chief peculiarity is a patent detachable tube joint, by means of which all the small generating tubes are connected to the upper steam drum and the lower water drums. Any tube can be taken apart for inspection and replaced within a few minutes. The steam drum is of Elmore copper, and the small generating tubes of solid drawn copper. Ordinary petro-Company's patent liquid fuel burners, *j*.

In this carriage the fuel (petroleum) is carried in a strong copper tank placed under the floor beneath the front seat. The oil is forced into the burner by means of an air pressure in the tank not exceeding 10 lbs. per square inch. A few strokes of the hand air-pressure pump, H, placed alongside of the driver on his right is sufficient to maintain the necessary pressure. The fire is regulated by the oil valve, P, and is also automatically controlled by a small automatic valve, which is opened or closed by the steam pressure according to the rise or fall of the pressure in the boiler. Should the pressure in the boiler rise then the valve shuts off the supply of oil to the burner or *vice versâ*. The

Fig. 2.—"Lifu" Steam Van (Longitudinal Sectional Elevation).

We illustrate this burner in Figs. 4 and 5, the former being a plan of the generator and the latter a section; it will be seen that the oil is forced through a series of passages in a chamber, which is heated by the flame from below. In this way the oil is gasified and passing down through the vertical tube reaches the conical burner, from whence it issues as a powerful and intense flame of great volume. The amount of oil-gas emitted, and consequently the volume of the flame, being automatically regulated by the needle valve in the cone which is actuated by the steam pressure.

This burner is extensively used in oil launches and yachts, and seems to us well suited for steam barges on canals.

whole of the arrangements are quite under the control of the driver, who sits on the front seat with the steering handle, D, in his left hand, which is connected to the two front wheels. The front wheels are placed on pivot axles which are connected together by a rod crossing and joining the two levers on the pivots which is again joined by a universal joint beneath the carriage to the steering handle, D. On the driver's left is the steam valve, A 1, giving steam to the high-pressure cylinders, and the valve, A 2, giving steam to the low-pressure cylinders. E is the reversing lever, and G is the hand brake, while the foot brake is shown at F. It will be seen that all operations are immediately under the control of the driver.

The Bushbury electric dog-cart (Fig. 6, p. 319), manufactured by the Electric Construction Company, Wolverhampton, from the design of Mr. A. Blackburn, M.I.C.E., is one of the neatest, best-appointed vehicles for private use that we have seen for some time. As will be gathered, it presents an exceedingly elegant appearance, and it is difficult at first sight to see how it is propelled, nothing savouring of mechanism being visible save a casing under the body of the car. This vehicle is designed to carry two persons seated side by side. The motive power is derived from accumulators, which, under ordinary conditions, hold sufficient charge to carry it from 20 to 25 miles at an average speed of 9 to 10 miles an hour. The total weight, including accumulators, is about 14 cwt.

The accumulators, which are of the Faure-King type, number 40 in all, and are carried in four boxes, each containing 10 cells. They are manufactured by the E.P.S. Company. The total weight being about 5 cwt.: the total capacity is 40 ampère hours at a discharge rate of 5 ampères, or about 28 ampère hours at a discharge rate of 15 ampères. The cells can be charged in about seven hours from a 100 volt circuit. Terminals are provided for enabling this to be done without shifting the cells. These cells supply current to a double pole series wound motor, which has a drum wound armature with Eickemeyer coils. The current delivered by the cells is 10 ampères at 80 volts, and at 700 revs. the commercial efficiency or the ratio between the current supplied and the work performed is about 80 per cent. The motor is suspended beneath the footboard by a flexible attachment to the footboard, and the motion of the armature spindle is transmitted to the sprocket driving wheels by means of a Renold pitched chain. The driving wheels are carried on an axle which is in two parts, united by a differential bevel gearing. The sprocket wheel is 20·5 inches diameter, the driving wheels 39 inches diameter, and the steering wheel 45 inches diameter. All these wheels, excepting, of course, the sprocket, are solid rubber tyred and fitted with ball bearings. The gauge is 4 feet 6 inches and the length of wheel base 5 feet 6 inches.

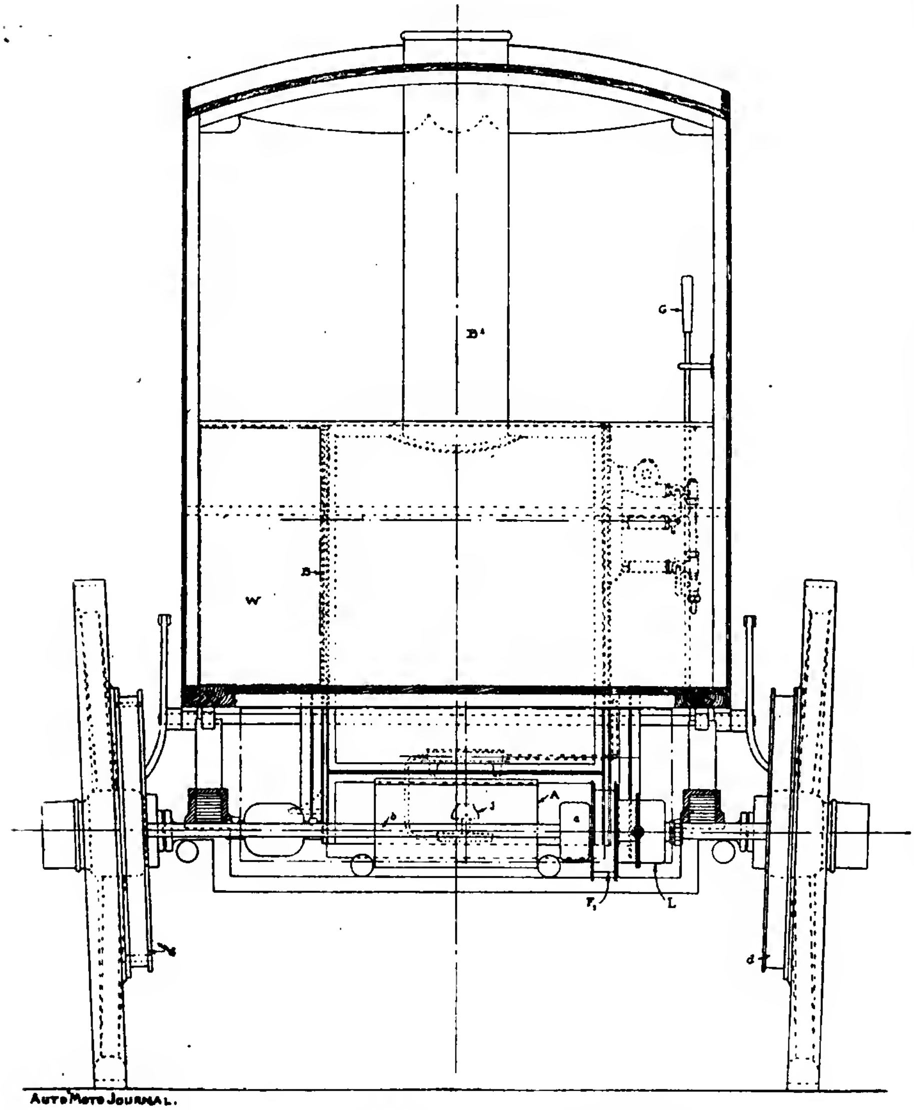

Fig. 3.—"Lifu" Steam Van (Rear Transverse Section).

The front wheel is steered by means of ordinary reins, and when the wheel is locked, owing to the peculiar method of attachment, it is thrown out of perpendicular, thus greatly adding to the stability when turning.

The switch gear is placed under the driver's seat, and consists of a reversing and controlling switch, the former actuated by a vertical lever on the right hand, and the latter by means of a sliding contact seat, having four positions, viz.:—(1) off; (2) two parallels of 20 cells in series in circuit with the motor; (3) 40 cells in series in circuit with the motor; (4) 40 cells in series in circuit with the motor, but with a resistance in parallel with the magnets.

Thus three speeds are provided, practically corresponding to the paces of a horse, viz., walking, slow trot, and fast trot. An electric brake enables the speed to be checked when descending gradients, and in addition there is a hand brake actuated by the foot, capable of bringing the car to a stand within a distance of a few feet.

It will thus be seen that the cart will do about as much work in the day as one horse for every day in the year, but by having a spare set of accumulators it will do as much as two horses.

A person using a car of this description, and living within a few miles of an electric supply station, could easily at small cost, say not more than 3*d.* per unit, arrange for charging his accumulators, which could be sent and returned by rail. Most electric lighting companies using continuous current would gladly entertain any chance of increasing their day load. We have no doubt that the Bushbury Car will be largely patronised by medical men and country residents of limited means, for whom it seems very suitable.

Messrs. Roots and Venables, of Westminster Bridge Road, London, entered two vehicles, the one a four-seated Petro dog-cart, and the other a Petro tricycle. The general appearance of these is shown in Figs. 7 to 12 (pp. 350-354).

Dealing with the dog-cart first (Fig. 7), Fig. 8 is an elevation and Fig. 9 a plan. The great merit of the motor designed by and brought to a considerable degree of perfection by this firm is that ordinary petroleum, which can be purchased anywhere, is used as the source of power. The motor is a twin-cylinder one, giving off 3·2 brake horse-power at 510 revs. The cranks are placed opposite each other, thus ensuring good balance. They are enclosed in a chamber partly filled with lubricant, and there is thus no risk of heated or warm bearings from mud and dust attaching to the working parts. A silent-running chain connects the crank-shaft to a countershaft, on which are keyed the friction clutches. These clutches drive either of two chain wheels, which are connected by chains and chain wheels directly to the axle. The method of governing is that of operating the exhaust valve and the oil feeder simultaneously and by the same mechanism, by which means a clean exhaust is obtained; and the construction of parts surrounding the vaporiser and igniter relatively to one another ensures complete combustion. The method of governing was only arrived at after many years of experiment. The automatic burner for

Fig. 3a.—Back View, showing "Water Back."

heating the ignition tube enables the motor to run continuously as long as it is supplied with oil, without any attention whatever.

There is an automatic feed delivery for each working stroke, and the function of the governor is to cut out feeds of oil according to the load. The cooling water for the cylinders is forced through the jackets, it then traverses the whole of the upper tubes of the frame and then by half the lower tube to the water tank, thence by the other side of the lower tube of the frame back to the pump. This enables a much less quantity of water to be carried, the tubes owing to this surface forming a very efficient cooler.

There is only one countershaft, which not only drives the axle directly, but also operates the valves and carries the governor. It has been found by experiment that it is preferable to have the driving countershaft directly over the axle rather than placed horizontally with it, and to have an intermediate stiff spring, because in meeting with a large obstacle, such as a brick, the driving wheel, if the car is going at a slow speed with but little momentum, is suddenly checked, and the chain may snap or shear a tooth off the wheel; in this car the chain slackens to reduce the jar, slack in the chain is easily taken up, and the chain can always be kept tight, it also runs more smoothly, and the power is conveyed through the clutches more evenly and steadily.

The steering of the car can be done at full or slow speeds with the finger and thumb, and is always positive.

No gear wheels are used anywhere in the motor, all driving being done by chains in order to reduce noise.

Fig 3b.—Front View, showing Furnace.

One valuable advantage possessed by this motor is that it can be quickly started from "all cold."

The mechanism of this firm's Petrocycle (Figs. 10, 11, 12), is similar to the foregoing, the motor in this case being however but of 1½ brake horse-power. There are, however, important differences in the arrangement for cooling the water. The water tank is placed on one side of the frame to balance the fly-wheel on the other. The cooling water is conveyed from the tank through the tubular frame of the car, and passes through a coil of pipe surrounding the fly-wheel, and is thus cooled by the air given off at the periphery by rotation. The ignition tube is first heated by a separate lamp, which is removed or extinguished as soon as the engine is started. The tube is afterwards kept hot by means of an automatic burner.

The special features claimed for this motor are:—The tubular frame for conveying and cooling the jacket water, and the coil round the fly-wheel for cooling the latter; the automatic burner; the method of making the same governor govern both the oil feed and the exhaust valve; the disuse of gear-wheels, all the driving being by chain and chain-wheels; the construction of the ignition tube relatively to the port and combustion space, thereby enabling complete combustion to be obtained.

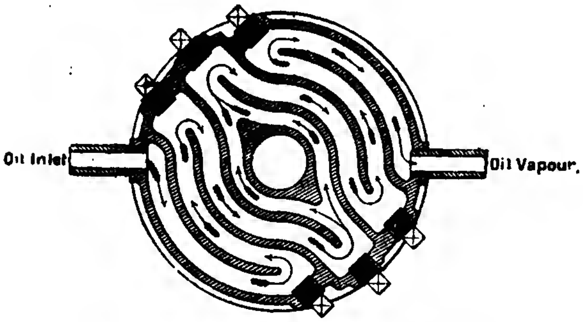

FIG. 4.—PLAN OF "LIFU" GENERATOR.

The Yeovil Motor Company's car (Fig. 13, p. 355) is a neat and compact dog-cart, suitable for two persons, and with room for a portmanteau.

It is driven by a two-cylinder Petter patent petroleum-engine, working on the Otto cycle and using ordinary petroleum. The cylinders are arranged side by side, and fire alternately. The explosions are effected by means of two ignition tubes, the foot lever is held down, and the back of the belt pressed on to a pulley fixed on the intermediate shaft. A brake is held on the fly-wheel by a spring to control the engine when the

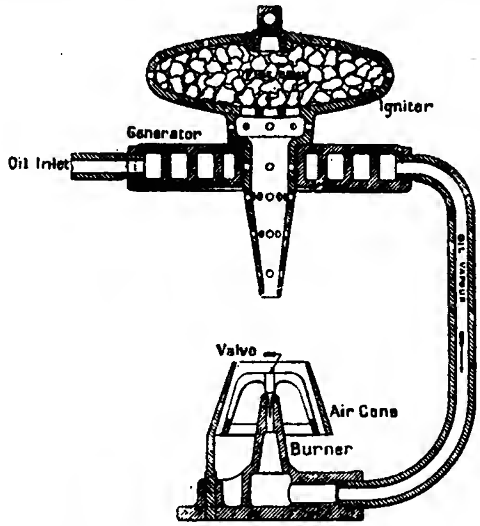

FIG. 5.—SECTION OF "LIFU" BURNER.

carriage is at rest. When the carriage is in motion this brake is held off by a hand lever. Two pairs of ordinary carriage

FIG. 6.—BUSHBURY ELECTRIC DOG-CART.

heated by a single blow lamp. The air inlet valves of the motor are operated by the suction of the piston, the exhaust valves by means of levers driven by chain gearing from the crank shaft. The motion is taken from the crank shaft to an intermediate shaft by means of sprocket wheels and chains, reducing the speed in the ratio of 2·8 to 1. A friction disc on the intermediate shaft is made to grip the chain wheel by lateral pressure applied to the end of the shaft by a hand lever. The intermediate shaft drives on to the rear axle by either one of two chains, the one gearing in a ratio of 12 to 32 and the other of 6 to 36, providing fast and slow speeds of 10 and 4 miles respectively. A square clutch on the intermediate shaft between these two chains throws either one of them into action. The rear axle drives one only of the rear wheels of the carriage. The reversing motion is taken from the crank shaft by a belt. This belt drives a loose pulley carried on a foot lever. When reversing, the friction clutch for forward driving is released

brakes are applied to the rear wheels, and the reversing motions provide a strong additional brake in case of emergency.

The Holroyd-Smith benzoline motor phaeton (Fig. 14, p. 355) is an ingeniously constructed machine possessing many elements of originality. As befits a pioneer in electric tramway traction worm-gearing is employed. Why, it is not very apparent; the absence of drawings makes it somewhat difficult to describe this motor at length, but we may say the engine is a twin cylinder, one giving off about 2½ to 3 brake horse-power, and it is placed longitudinally, the motion of the shaft is transmitted by toothed gearing and a worm to the driving axle. To each cylinder is fitted a silencer consisting of a cylinder fitted with baffles. Another feature is the coil water cooler. The method of carrying the car on a double framing and the wheels on ordinary springs combined with spiral springs working in a kind of horn plate no doubt has advantages, but we failed to appreciate them. The fuel capacity of this motor is, we understand, about five gallons, sufficing for a run of 60 miles at a speed of about 10–11 miles per hour on the level. The total weight being about ·75 ton.

The next motor (Fig. 15, p. 356) is entered by Mr. Cornell. Owing to our inability to obtain drawings or even much information concerning it we must be content with the briefest description. We understand that light oil is employed in an ordinary Otto cycle engine having electric spark ignition. Neither this motor nor its performances call for any special notice.

Another motor-car was entered, viz., a handsome Victoria, by the Electric Motive Power Co., but was withdrawn from the competition. We give a general view in Fig. 16 (p. 357), and Figs. 17, 18, 19 (pp. 358–360) are respectively a plan, transverse section, and elevation, showing details of the motor and gearing.

of some half-a-dozen vehicles instead of 70, as was anticipated some months ago. During last month the manufacturers with one accord began to make excuses, and the plea generally put forth was inability to complete their machines in time, so that there must be at least 50 motors of different design scattered about in the "shops," and no doubt we shall hear of them in the coming bye-and-bye.

Speaking generally, all the vehicles showed merit and advances on former performances. Although the judges have not deemed it necessary to carry out the programme yet the performances are distinctly encouraging, and those who competed have no reason to feel unduly depressed at their non-success in capturing any part of the *kudos* (not to mention the more material money) that was offered by *The Engineer*. One word in conclusion. Much, and we think undue, importance was attached to the

FIG. 7.—ROOTS AND VENABLES' PETRO DOG-CART.

The power for propelling the carriage is obtained from 32 Epstein (120 ampère hour) cells. A two brake horse-power series motor is geared to the driving wheels through double reduction spur gear, flexible couplings allowing for the play of the springs on the carriage. The resistance switch is worked by a to-and-fro movement of the steering handle. The steering wheels are centrally pivoted so as to enable them to be turned with the minimum of effort. The brake is an ordinary foot brake.

As regards the trials in the Crystal Palace these duly came off in the presence of the judges on May 27 and 28, and on the latter date were summarily terminated by the posting up of the following official pronouncement:—"The judges have decided that they cannot award a prize to any of the cars exhibited. It will, therefore, not be necessary for the trial run to Birmingham to take place. Although the judges cannot see their way to award any prizes, the steam car of the Liquid Fuel Engineering Company, and the Bushbury electric car of the Electric Construction Company are highly commended."

Thus then the competition resolved itself into an inspection question of offensive smell emitted by the motors, and during the trials the smell of partially consumed petroleum was very pronounced, especially at starting and stopping. Whether these fumes are more objectionable or offensive than the fœcal emanations of a horse is, of course, a matter of taste. We prefer the petroleum, because we *do* know what that is; but no one, not even a sanitary expert, can say what *may be* in the latter. At the worst, the petroleum involves a deposit of pure carbon in the air passages; the other means the absorption of millions of microbes, which may be anything from anthrax to glanders, in any case they are cadaverous, and set up ptomaines in the system. At present there is apparently a prejudice in favour of the retention of horse manure, and we are not disposed to quarrel with those who prefer to put their trust in chariots and horses rather than in automotors. Thus *The Engineer* competition.

Fig. 8.—Roots and Venables' Petro Dog-Cart (Elevation).

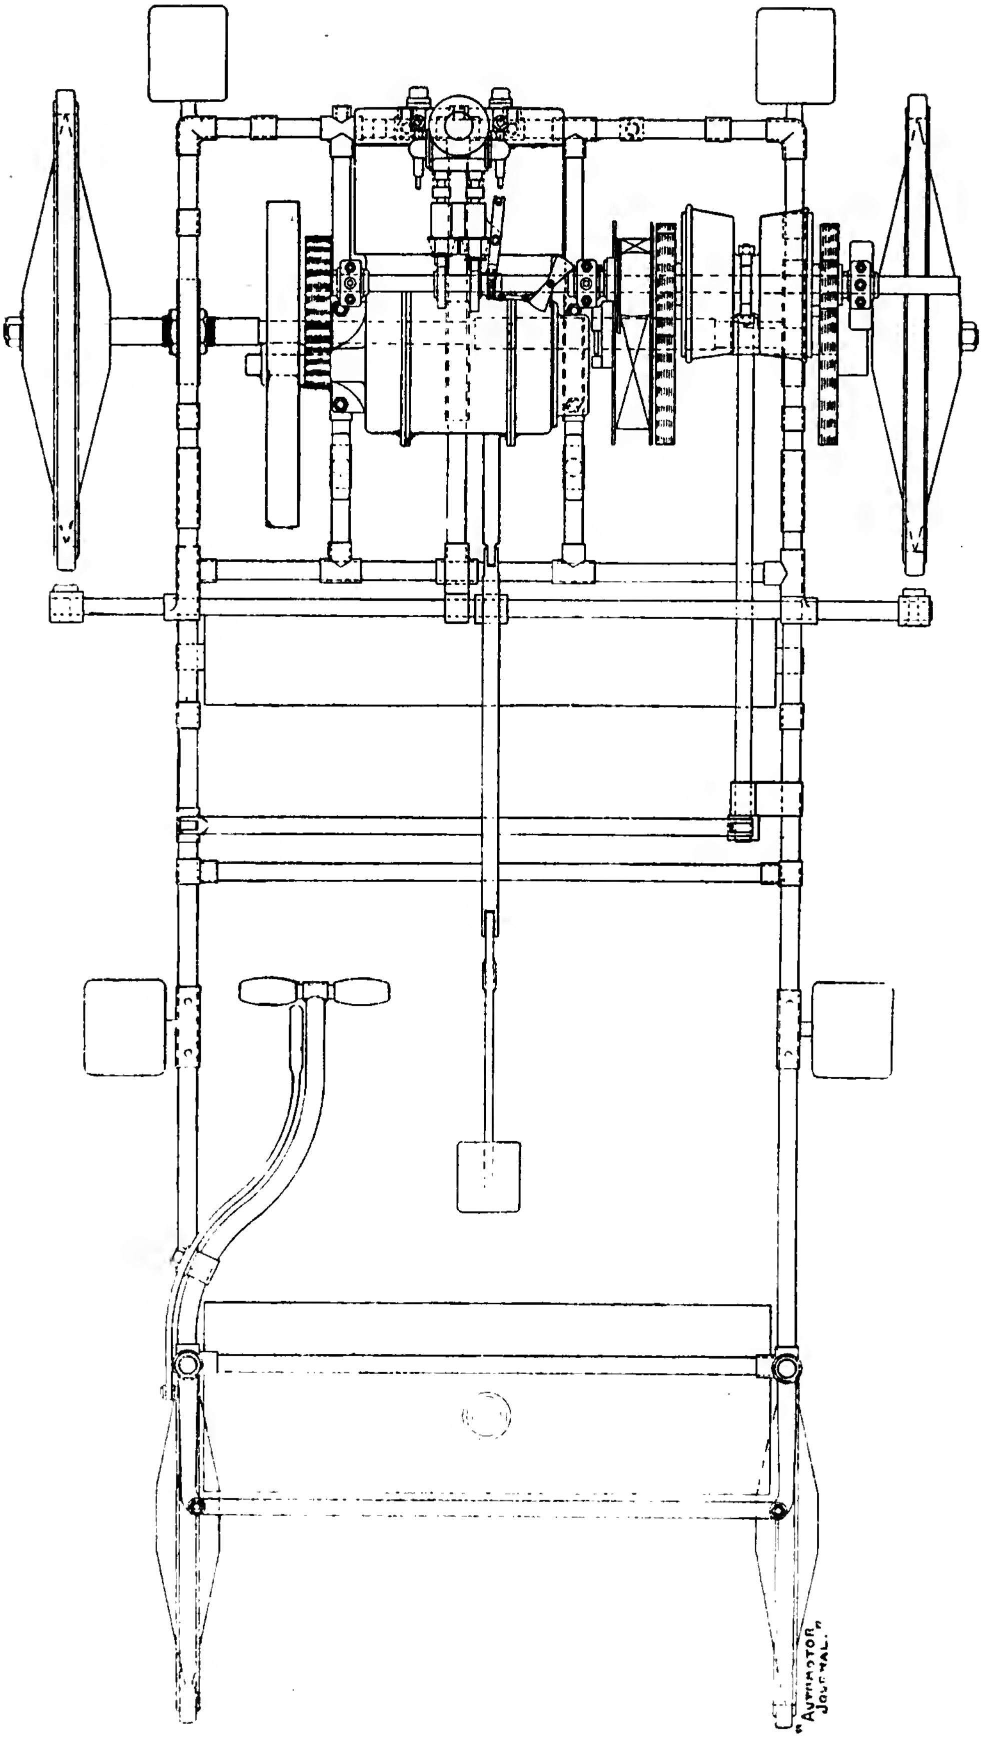

FIG. 9.—ROOTS AND VENABLES' PETRO DOG-CART (Plan).

THE PRESS ON THE MOTOR-CAR COMPETITION.

THE failure of *The Engineer* Motor-Car Competition has naturally been much commented on in the Press, and confidence in the future of the horseless vehicle is, as a consequence, much shaken. It has been very generally assumed by writers in the non-technical Press that no reliable automotors are at present manufactured in this country. We are told with wearisome iteration that the industry is (of course) "in its infancy." The air of profound wisdom with which this bald platitude is trotted out by scribes in the daily Press is not a little ludicrous. On inaccurate premises and with that general all-round knowledge of nothing in particular which distinguishes the ordinary non-technical journalist, conclusions are formed and opinions uttered which are repeated *ad lib.* by that shining light the "Man in the Street"; and in all societies one hears the before-mentioned "wheeze" delivered as though it were some Delphic Oracle. With the daily Press—always so woefully at fault where mechanical matters are concerned—we need not concern ourselves any more than to deplore the inaccurate and misleading opinions which have been expressed as a result of *The Engineer* competition fiasco. The technical Press, we regret to observe, is apparently also disposed to draw erroneous conclusions, and it would seem that the automotor is regarded much in the light of the *mauvais sujet* of the highly respectable and extremely well-connected engineering family, and is, one would think, doomed to bring the grey hairs of its sponsors with sorrow to the grave.

The Engineer is naturally grieved at the failure of its well-intentioned efforts to make the automotor a respectable member of society. Says our contemporary :—"The motor-car has yet to be made. It may be that it has not as yet been invented. This we say with a full appreciation of what has been done in France. It must not be forgotten that what will satisfy our French neighbours will not at all satisfy public opinion in this country, which is much more exacting. And then after all comes the question—are motor-cars wanted? Will there ever be so full a demand for them that money can be legitimately made out of their manufacture? There are not lacking those who assure us that the motor-car has been slain by the tramcar and the bicycle. Time alone can settle the question. The world may rest assured that if a motor-car is really needed it will in time be produced."

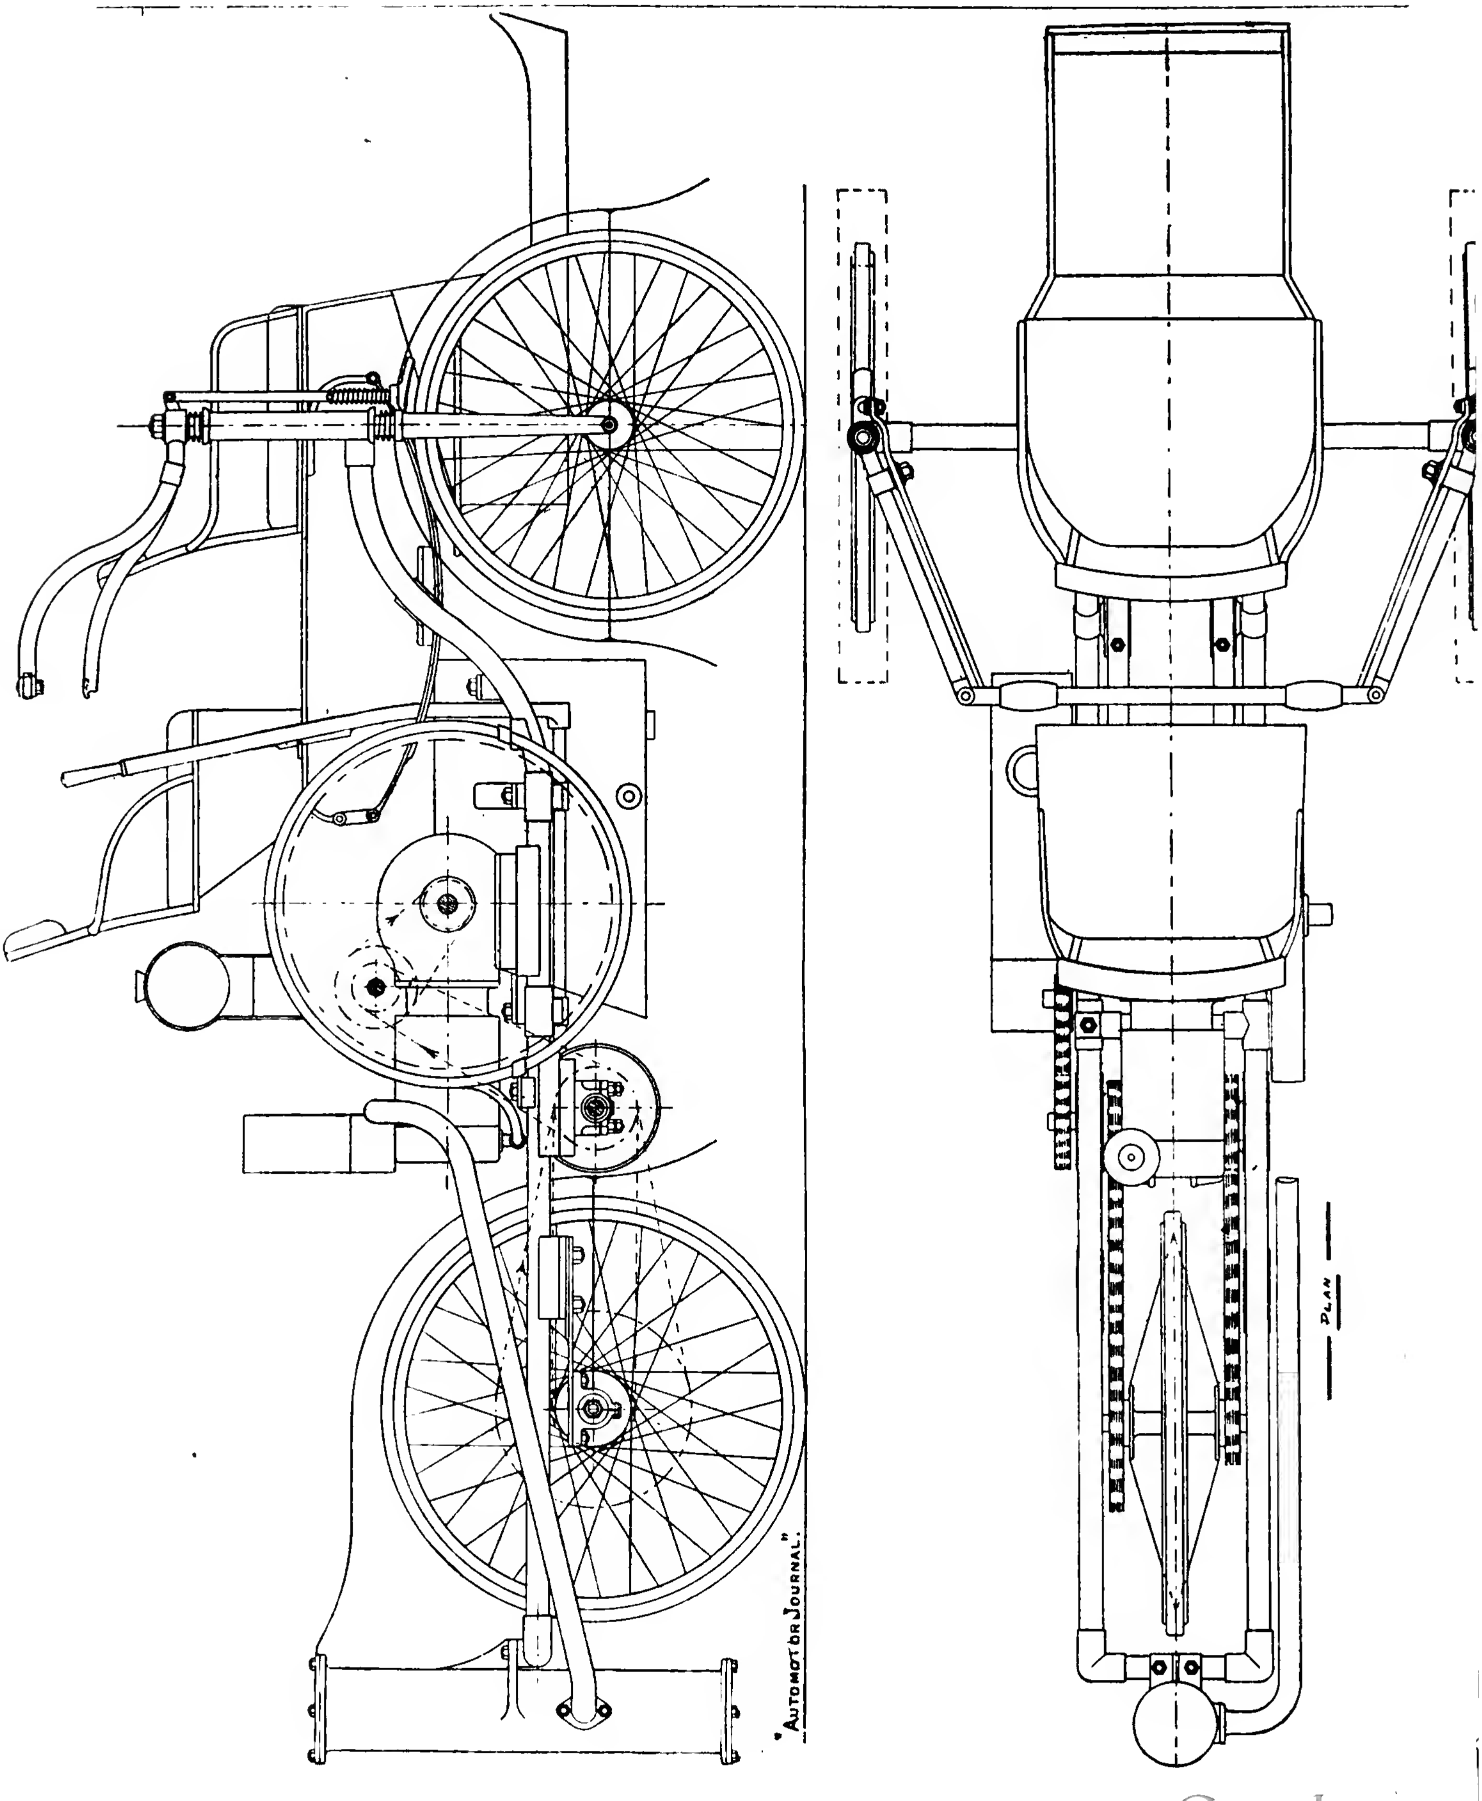
How truly moral! In an earlier part of the same article it complacently washes its hands of the business thus :—"One result of our essay has been satisfactory. It has cleared the air. It has placed the world in possession of facts concerning the motor-car industry in this country. There is at present no such industry. There is no such thing as a thoroughly satisfactory self-propelled vehicle. If a motor-car of the kind existed it would have been submitted for competition."

Engineering quite endorses all this and goes a little bit better. It casts aside the severe air of the technical critic and becomes positively facetious :—"It must be always remembered that a locomotive with steering gear added is not a motor-car, even if petroleum take the place of coal and also of water."

FIG. 10.—ROOTS AND VENABLES' PETROCYCLE.

Perhaps our contemporary will kindly explain what *is* a motor-car? *Engineering* then continues :—"The motor-car of the future must be able to compete with the horse, not only in his capacity for speed but also in economy of keep and attendance. For years the problem has been studied in relation to tramways, and, speaking generally, it has ended in failure. A tramcar generating its own motive power without nuisance either to passengers or public, and running economically in comparison with horse-traction, yet remains to be produced. The motor tramcar is, however, an easy problem compared with the motor-carriage or omnibus, and it will be a very considerable time before it attains the dignity of constituting an industry. As an instrument of sport, affording plentiful chances of sudden death from collision, upset, and explosion, the spirit-car will satisfy the aspirations of any reasonable man, but it is just these capabilities which put it out of court as a commercial vehicle."

It is not often that our two elderly contemporaries agree, but



"Automotor Journal."
Plan

FIG. 13.—THE YEOVIL MOTOR COMPANY'S DOG-CART.

FIG. 14.—THE HOLROYD-SMITH BENZOLINE MOTOR PHAETON.

when they do their unanimity is wonderful. Despairing of a friendly and sympathetic word we turn to the *Electrical Review*, only to find that it too has not a good word for the automotor. The *Review* naturally may reach the same conclusion as any other paper, but it must get there quite "on its own," or it would not be the *Review*. Says it :—"Our contemporary (not us but *The Engineer*) has made in the aforesaid ponderous leader a few good points. First, that it is obvious that the motor-car industry of this country is practically non-existent. No one will gainsay this so long as they admit that vehicles using petroleum spirit were properly excluded. The exclusion of this class from the competition practically assured the *status quo* of the 1,100 guineas. At the present time the spirit engine is the only motor that has effected much. True it smells, it can only creep up hills, it vibrates, it is noisy, and so on, but it is a success, and it was ruled out, and being so negatives the claim made by *The Engineer* that the best England can do at present was to be seen at the trial." And again :—"At the same time, while not agreeing with *The Engineer's* methods or mode of reasoning, we may agree that the motor-car is yet to be made. Not merely as a machine is it far from perfect, but as a carriage it is equally imperfect. Tied down to the exterior appearance of the horse-drawn vehicle, and apparently, also afflicted with the fear of the older locomotive men that drove them to adopt low centres of gravity, the motor-car men of to-day put their passengers as near the road as possible. Why cannot they place them well above the ground with a clear view over the hedge rather than into the ditch, and thereby find machinery room below him, so escaping at once from the thraldom of the old design, and the necessity of cramping their machinery into the narrowest possible space."

With very much of this we cordially agree, and makers of automotors would certainly do well to depart from the traditions of elderly carriage makers, and endeavour to imitate a Post Office van as little as possible. It is evident that the automotor car is not liked by our contemporaries. It has been weighed in the Press balance, and has been found wanting in some respects, and hence it is consigned by the technical Pecksniffs to everlasting damnation. Fortunately the automotor has its admirers, and is not quite such an outcast as our contemporaries seem to think, and is, in fact, being quietly perfected and improved. We should, however, like to see an automotor designed by our contemporaries. Since no automotor at present meets with their critical approval, why not give the world the benefit of such superior knowledge?

It was certainly rather rough for *The Engineer* to declare that they did not believe that any motor-car industry properly so called is carried on at Coventry for other than Company-promoting purposes. Mr. H. Sturmey, the Acting Chairman of the Daimler Motor Company, promptly requested the retractation of this (if false) very damaging statement; *The Engineer* refuses to do anything of the kind, and no doubt more will be said about the matter in a very different place. Mr. Harrington Moore, of the Motor-Car Club, likewise feels grieved at the utterances of *The Engineer*, and writes our contemporary to pass no rude remarks about the Daimler Motor and the Coventry industry. In this case, too, *The Engineer* is not disposed to accommodate Mr. Moore. Really, it would seem that this unfortunate Competition is producing very untoward results.

FIG. 15.—CORNELL OIL CARRIAGE (BENZ SYSTEM).

The Bollée Motette.—Some satisfactory running has been done lately by the Hon. C. S. Rolls on a Bollée tandem tricycle, including two runs from Coventry to Cambridge, a distance (by the route taken) of about 90 miles, which were accomplished without any serious trouble with the mechanism. The machine is a racer, fitted with a cylinder of extra large diameter for high powers, and seems to have given considerable satisfaction.

Indiarubber—Erratum.—By a clerical error the price of indiarubber per ton was stated by us in our article dealing with this in our May number as £16 10*s*. It is palpable that this should have been £216 10*s*.

SOME DISADVANTAGES OF THE HORSE.

We are all familiar with the usual plea urged in defence of betting and horse racing, viz., that it encourages the breed of horses. And to this noble end thousands of people devote their time and money, from office boys who steel petty cash and postage stamps, to the mechanic who "'as 'is little bit on"; and from prosperous business men and shopkeepers to noble members of the Beerage and the Peerage, who sit upon magistrates' benches and dispense good advice to delinquents upon the evils attending betting, &c. We are not, however, concerned with the ethics of those who, in various ways, are interested in horses, but we wish to point out that from a purely business point of view the horse is, notwithstanding all that its admirers may say to the contrary, about the most expensive means of locomotion that can be devised. It has been truly remarked that the great advantage of the horse is that it gives employment to such a large number of trades. It does indeed. In the good old days—we don't know precisely when these were—but it does not matter, there was usually work for all that wanted it. Nowadays the inevitable and proper tendency is to lessen the amount of toil and save the expenditure of energy—which means money—in every possible way. The extinction, or rather the

Fig. 16.—Electric Motive Power Company's Victoria.

disuse of the horse for any but purely luxurious purposes is a scientific certainty; just as the disuse of sails for marine propulsion is. Sailmaking is practically an extinct art in this country, and is confined to the yachting port; so it will be with the horse, that noble but nervous animal will be used for hunting, racing, and circus riding, and such like luxurious purposes. Our present object is, however, to point out a few reasons why it can hardly be deemed sound economy to purchase a horse for business purposes. Leaving aside the first cost, there is the food, which must be regular in supply, sufficient, and of good quality; the stable must be a building which conforms to sanitary laws, which means it must be well drained and ventilated, well supplied with water—in short, in all but a fireplace and bedding it must be as well built as the master's house. All this involves money, and the services of a groom. We then have to consider that a horse is just like a woman — never continuously well; this means the "Vet." and his fees, or it may mean, in addition, the loss of the beast. Much more might be said on this head. Another trade is the harness-maker, which again involves the leather-maker, or tanner; then we have the farrier who supplies the shoes, without which the horse, in all developed countries, would be of little use. If, as recently, the farriers go out on strike the locomotion that depends upon horses becomes paralysed. The horse is indeed the hub or centre of a wheel of employment; if one spoke is damaged the whole thing upsets. Of course the master or owner pays for everything; every business man knows that the less the number of subsidiary trades he employs the greater are his chances of success. Thus the great objects of the employers in such trades as shipbuilding, engineering, iron and steel making, mining, &c., is to reduce as much as possible their dependence upon other trades, and to make their own industry simple and self-contained. Similarly the horse, inasmuch as it involves the employment of so many other trades, is bound to be replaced by the motor-car. Even in their present state of development it is much cheaper to maintain a motor-car for light business purposes than a light horse-drawn van. The former requires no stable—a tarpaulin thrown over it gives ample protection against the weather; it will run at a cost of less than 2*d.* per horse-power hour, this including fuel and wages.

FIG. 17.—ELECTRIC MOTIVE POWER COMPANY'S VICTORIA (Plan of Motor).

Apart from the disadvantages inherent in the employment of animals for power purposes we have to consider the objections to the use of horses in crowded cities. In our leading article we have referred to the disgusting and offensive fœcal emanations of the horse. In streets this nuisance is much more serious, and it requires a large army of sweepers to prevent our cities from becoming immense cesspools. It is only by the most vigorous sanitary precautions in such towns as London, Liverpool, Manchester, &c., that outbreaks of fever and other diseases are avoided. For humane reasons too the use of the horse in towns is to be in every way deprecated. The slippery condition of our streets in wet or damp weather involves the sacrifice of thousands

FIG. 18.—ELECTRIC MOTIVE POWER COMPANY'S VICTORIA (Transverse Section, looking from Rear).

of horses, and this alone constitutes an expense which might well be avoided. In the City it is a common sight to see the traffic stopped because half a dozen horses have fallen. We have ourselves seen no less than five horses down in Cheapside at one time, of which three were dead or dying from fractured pelvis. Only last week a most painful sight to thousands of people was witnessed in Kensington High Road. Three horses had fallen; they had evidently split their pelvis and were dying an agonising death—plunging and kicking in a way most distressing to behold. These horses were not "old crocks," such as one sees falling down from sheer exhaustion, but were fine animals owned by firms of the highest repute, one being owned by Messrs. Gilbey, who have done so much for the horse. We estimated that these three horses represented at least £200. Indeed we can't go to the City in wet weather without meeting convincing proof of the unsuitability of horse for traction purposes.

THE CREWE AUTOMOTOR TRIALS.

[BY OUR SPECIAL COMMISSIONER.]

As soon as the development of automotors began to make decided progress, about two years ago, the Royal Agricultural Society of England saw the possibilities these motors possessed as forming a cheap means of conveying produce and what not to market, and they therefore decided to offer prizes for vehicles specially designed for traction purposes. The trials of the cars entered for competition were arranged to take place at Crewe on June 10th, and thither our Special Commissioner duly journeyed on the day previous.

On Arriving

at the Station Hotel, from the yard of which the run was to start, hopes of good things were raised by the fact that the house was full, a number of gentlemen interested in or connected with automotors staying there, while Mr. Clarke, the Secretary of the Royal, had booked rooms for a party of seven, including

The Judges,

who were three in number, and included Sir William Anderson, K.C.B., F.R.S., of Erith, Kent; Bryan Donkin, Esq., of London; and F. W. Webb, Esq., C.E., of Crewe.

Although there was, therefore, a goodly smattering of people interested in the trials, it was not very encouraging to learn that so far none of the vehicles had put in an appearance, and in fact it was no easy matter to gather any information from the "inhabitants," who, strange to say, seem to take but little interest in the matter. A little persistence, however, proved

Fig. 19.—Electric Motive Power Company's Victoria (Elevation through Motor).

Towing an Electric Motor-Car.—A somewhat novel sight was witnessed in London recently when the Hon. C. S. Rolls, with his Peugeot phaeton, towed an electric four-seated car weighing nearly a ton, which had exhausted its current, from Chelsea to Mansion House, City, without a hitch, maintaining on the level a speed but very little below the normal speed of the former vehicle. This performance does great credit to the Peugeot car considering the weight of the towed vehicle.

successful in so far as to learn that it was intended to make a run of 50 miles out and 50 miles back in the direction of Derby, and that the judges and other spectators were to follow the vehicles in wagonettes. The advisability of this step will be apparent when it is remembered that the vehicles in the chief class were not intended for passengers, and therefore offered no accommodation; while, on the other hand, it would hardly have been fair to burden them with additional weight in excess of the load enjoined by the rules of the competition. Such, in brief, was the position up to evening, when neither the prospect nor the weather was very propitious. Later on the first arrival put in an appearance in the form of the motor-wagon of the

LANCASHIRE STEAM MOTOR COMPANY,

Leyland, Lancashire, which was entered in the 1st class, viz., substitutes for light spring carts, the prizes offered being £100 and £50. There were no entries for the 2nd class, of heavier vehicles. In an interview with the firm's courteous Mr. Spurrier I was able to learn the following particulars concerning their motor, which had come a journey of close on 50 miles to be ready for the start at 9 o'clock next morning. The van is four-wheeled, with steel tyres, and the body is of greater capacity than was to be expected. It is roofed with sheet metal, and so constructed that all the rain falling on it is collected and passed to the water-tank. The condenser is situated on the roof, consisting of a number of brass tubes indented on the Rowe system. Liquid fuel is used for steam raising, the boiler and the firing arrangements being special patents which are the property of the firm. The boiler and engine are placed in the front of the van, the former being a vertical multitubular boiler, the 84 tubes being of copper, and the shell steel. The engine is a vertical compound, of the marine type. The tubes and copper firebox present a total heating surface of 50 square feet. The connection with the engine is made by a steam dome, which thoroughly dries the steam and prevents priming.

The crank shaft revolves in one direction only, and is connected with a second motion shaft with clutch gearing, which gives three changes of speed, and also reverses. From the second motion shaft the power is conveyed to a third shaft, on which the driving-chain pinions are fixed, and the compensating gear. Powerful pitch chains convey the power to the road or driving wheels. The boiler, engine, and gearing are so disposed that the weight on the steering wheels are kept constant, and as the clutch levers, &c., are all in front one man can easily attend to the car. Steam can be raised in a few minutes, and any ordinary petroleum lamp oil can be used. The partition which separates the boiler and engine from the car does not restrict the rear view of the driver. The oil and water are carried in a cylinder under the van. The cost of running has been found, from a number of experiments, to be about one penny per hour. The weight of the car and driving plant is 26 cwt. The speed ranges from three miles per hour uphill to six on the level, averaging, as a rule, five miles an hour.

THE ROUTE

as officially announced, was as follows:—Start from station opposite Crewe Arms Hotel, past Wheelock to Sandbach. Bear to the left from Market Place at Sandbach, along Congleton Road, bear to the right at the fork a mile out, opposite a house with pink may and rhododendrons in the garden. On arriving at Congleton turn to left at Lion and Swan, then to right, and again to the left where four roads meet, taking the Buxton Road hill, passing Buglowton. At the Yew Tree Farm keep to the left until the Macclesfield-Leek Road is reached, then turn to right, and after passing Rushton bear to the right where the signpost points to Leek and avoid the old road. Pass Hanging Gate publichouse, and straight on to Leek. Pass Leek Church and turn to the right down Market Place. At the bottom turn to left and bear to the right along Ashbourne Road, passing New Carlton. In middle of Ashbourne turn to the right where four roads meet. Take the one to Derby, bearing slightly to the left until the five-milestone from Derby is reached. Turn round and return by the same route to Crewe.

The following morning it was found that no other car had arrived for the competition so that only one out of the three entries put in an appearance. A Daimler car, however, had arrived from Coventry with a party to witness the run.

By nine o'clock steam was up and things shaping well for a start, but it was 10.25 before the judges had made their inspection and weighed up the load, which in this case was 12 cwt. It then transpired that the trial run had been shortened to Leek. By 10.30 we were off, the party including, among others, others, Mr. Shrapnell Smith (Secretary, Self-Propelled Traffic Association, Liverpool); Mr. Coulthard and Mr. Tomlinson (of Preston); Mr. Samuelson (Banbury), Mr. Courtnay (Engineer to the Royal Agricultural Society), while a number of others followed on bicycles. About three miles out some trouble was experienced by side slipping which rather upset the steering, these three miles having been accomplished in 30 minutes. At Wheelock Canal Bridge there was a remarkably sharp hill culminating in the high crest of the bridge itself. On sighting it there was a flutter in the judge's wagonette and many thought the rise would prove too severe a test. It was pleasing, therefore, to see that the hill and bridge were taken very nicely with only a reasonable slackening of the speed, and apparently with far less effort than by the horses and cyclists. The six miles to Sandbach were made in the hour. Practically speaking all there was to see had been seen, and certainly the van appeared at its best when hill climbing.

An hour and a half were lost owing to slight accident with the steering gear, so that the trial was eventually restricted to the journey to Congleton and back, the *average* speed attained having been 6½ miles per hour, which shows that the Company had not exaggerated their claims in the first instance.

In making a mental survey of the whole we feel that before criticising in any way it is only fair to explain that the van was largely an experiment. The general system was a step in the right direction, and power had not been sacrificed for speed, as the hill tests proved. The steering gear seemed the most unsatisfactory part, as it could hardly be said by an impartial critic that the van was always under perfect control. It is, however, an open question whether this was so much due to the steering gear as to the side slip of the steering wheels. Although it is known that the wear and tear on rubber tyres on the *driving* wheels with heavy vehicles is excessive considering their cost, still we venture to suggest that the addition of rubber tyres to the two steering wheels would do much to overcome this difficulty of side slipping. In the matter of emitting smoke or visible vapour it is at present almost impossible to attain perfection, and although on the whole the van was satisfactory in this respect, there is still room for improvement, before the regulations of the Board of Trade can be said to be fully complied with. As a whole, however, the firm are to be congratulated on having produced a van which, as an experiment, is a success and gives good hope for the future.

Lastly, we would venture to suggest that if the automotor industry is to be fostered it will be well for those getting up competitions to bear in mind that people interested in these trials like to know a little about the probable arrangements, and that courtesy costs nothing. If those who take an interest are to be always treated as in the case of the Crewe trials, there is every prospect of their ardour flagging away to nothing.• This may not greatly concern the organisers, but it is not fair to the competitors, who would thus lose half the benefits that should accrue from their competition. In the present case as only one van ran it could scarcely be considered a competition, and so the judges decided that no prize should be given.

LAW REPORTS.

Reid v. Hooley and Rucker.—The Appeal of the Defendants dismissed.

The action commenced against Mr. Hooley and Mr. Rucker by Mr. Reid for damages consequent on his having subscribed for 125 shares in the Grappler Pneumatic Tyre and Cycle Company (Limited), as to which he alleged conspiracy between the defendants, on June 2nd came before the Master of the Rolls and Lords Justices A. L. Smith and Chitty, the defendants appealing from the decision of Justices Grantham and Wright, sitting as a Divisional Court, and refusing to strike out the plaintiff's statement of claim as not showing reasonable ground of action.

Mr. Bigham, Q.C., and Mr. W. Graham were counsel for the appellants; and Mr. Carson, Q.C., appeared for the respondent plaintiff.

Mr. Graham, in stating the case for the appellants, pointed out that the plaintiff's statement of claim alleged a conspiracy by the defendants to spread a rumour that they had purchased the Grappler Pneumatic Tyre and Cycle Company, in consequence of which the £1 shares of that concern, which at one time were as low as from 1*s.* 9*d.* to 4*s.* each, went up to £4 each. By causing this rumour to be spread, the statement of claim went on to say, the defendants had sought to benefit themselves and to cheat and defraud the public by their purchase of shares. For the purposes of carrying out this conspiracy the defendants (the claim went on) purchased shares in the Company, and caused it to be publicly known that they were negotiating for the purchase of the undertaking, and ultimately, by an agreement dated May 12th, 1896, they purchased the undertaking for £385,000, a provision being contained in the agreement enabling the defendants to cancel the agreement and to refuse to complete it on paying £25,000. The statement went on to say that the price thus agreed to be paid was absurdly exaggerated and had no reference to the real value of the Grappler Company, nor had the defendants any intention of carrying out the purchase or of paying more than the £25,000. In further pursuance of the said conspiracy, it was likewise charged, the defendants caused a letter to be written by their solicitors to the *Irish Times* stating that the negotiations for the purchase were then completed.

Lord Justice Smith remarked that what was said was the defendants told a lie, and that they never intended to act upon the agreement.

Mr. Graham said the statement went on to say that, it having become publicly known, as defendants designed it should be, that this Company had been bought, so absolving the concerns it had been thought desirable to amalgamate, the price of the shares of the Grappler Company rose to £4 or thereabouts, the defendants never completed the purchase, but sold the shares they had acquired at a profit far in excess of the £25,000 they had agreed to pay as a forfeit; and plaintiff claimed that he had suffered damage, consequent on the publication of the alleged purchase by the defendants, through the purchase of 125 shares.

The Master of the Rolls: Suppose they prove all this?

Mr. Graham said his clients were not to be responsible to everyone who chose to believe what he read in a newspaper, and on it to go and gamble in shares on the Stock Exchange. The fact was that plaintiff, having found out by inquiries one half of the agreement, and not having discovered the other half, now wanted to base an action upon it.

Lord Justice Smith: You only told him one-half.

Mr. Graham: We told him nothing.

Lord Justice Smith: Oh, yes, you did.

Mr. Graham: Well, all we said was that we had entered into an agreement, as we had. We said nothing about terms; but plaintiff found out things through friends of his connected with the Company. If things leaked out, the defendants were not liable to people who chose to act upon such information.

Lord Justice Smith: Why did you instruct the solicitors to write that letter to the *Irish Times*?

Mr. Graham said because it had been represented, in connection with a £5,000,000 scheme then being talked about, that the defendants had not obtained the whole monopoly so long as this Company was outside, and it was written to show the defendants had concluded an agreement acquiring this particular property.

Without calling on Mr. Carson for the plaintiff in support of the judgment below, affirming his right to proceed, the Master of the Rolls said they had heard a wondrously innocent and plausible comment on this innocent transaction, but he was too old to adopt it. Because, after all that Mr. Bigham had stated, it came to this:—I cannot deny that this statement of claim suggests an ill-looking fraud, but it is not clear enough—it is not sufficiently specific. All this Court had to do was to take the statement of claim, and see whether it disclosed a cause of action. It said that the defendants invented transactions with the aim of running up the shares, and then they intended to sell to people who could be induced by these representations to buy; that they never intended to pay £385,000, but they did intend to pay and actually had paid £25,000, and had put into their pockets the difference they had received over this amount on the figure to which the shares went up. Was it not obvious that their intention in suggesting the £385,000 was that they might cheat the public? It was all very well to look and talk so innocently about a transaction of that kind. They had to look out for dupes, and the statement of claim said that they had an eye not only on the public generally, but on this particular plaintiff, and that it should come to his notice. And why? That he might give an advanced price, and then they would pay themselves the £25,000, and, pocketing the difference, leave the plaintiff with a dead loss. That was what was stated, and whether or not it was true and formed a false or fraudulent statement was the point to be decided on the trial of the case. It seemed to him there was no colour or ground for striking out the statement of claim, and that the appeal ought to be dismissed and the way left open for the trial.

Lord Justice Smith said he was of the same opinion. Whether the allegations could be proved or not was not the question for this Court, and he was not saying whether it was true or not; but he had no doubt there was no foundation for saying that the statement did not disclose reasonable cause of action.

Lord Justice Chitty said he agreed. He, too, thought the appeal failed, and that the statement sufficiently disclosed reasonable cause for bringing the action.

The British Motor Syndicate.—Lanchester and Others v. Richter and Another.

In the Queen's Bench Division of the High Court of Justice on June 1st, Mr. Justice Wright tried the above case. In his opening Mr. Walter, who appeared for the plaintiffs, said:—The action is brought for infringement of letters patent No. 5,479 of the year 1890. It relates to motors and gas-engines and to the apparatus for starting same. As your lordship knows, these motors have a cylinder somewhat similar to the cylinder of an ordinary steam-engine. In an ordinary gas-engine there is a cylinder with a piston, and in lieu of the piston being brought forward by the pressure of steam generated from water, as in an ordinary boiler, the motor is worked by the explosion of an explosive mixture of oil—petrol—and air; it may be not only gas and air, but also petroleum vapour and air, and any other explosive mixture of air and some body that will burn. Great difficulty has been experienced in starting these motors, especially where the engines are of any considerable size, and your lordship sees the reason of it is this, that when the engine comes to rest there remains in the cylinder of the engine either a mixture of the burnt gases from the last explosion, or more generally of air, and with an engine with a fly-wheel weighing some tons or several hundredweight, great difficulty has been experienced in starting the engine on account of the fly-wheel having to be turned round by hand or by an auxiliary starting engine in order that a proper explosive mixture may be introduced into the cylinder. This is a device for obviating those difficulties, and it shortly consists of this: Mr. Lanchester discovered that by boring a hole into the cylinder and inserting therein a very simple piece of apparatus which I will shortly describe to your lordship, and passing gas into the air contained in the cylinder, the gas and air as they mix in the cylinder would pass out from the opening which he provided, which was furnished on the outside of the flame. As the gas and air pass through, when the proper mixture of gas and air had been attained within the cylinder, the flame which passed out through the opening, and which was lit by the jet outside, indicated the proper and precise moment when the explosive mixture was within. The gas, of course, was passed with a certain pressure into the cylinder and was passing out with a certain pressure. All that was necessary was to provide really a tap in the apparatus to close the gas admission, and the result of doing that was this: It enabled the rate of flame transmission, the combustion of the gas—which was going on outside—to pass back through the mixture of gas and air into the cylinder, and there meeting the flame it exploded instantly, and forced the piston forward so that it rose, and there was no necessity at all to turn the fly-wheel. That really is the apparatus, and it is of a very simple kind. The defendants had done absolutely the same. I will ask Mr. Dugald Clerk to explain that there are practically no differences at all. In both cases there is the hole in the cylinder, in both cases the gas is allowed to go into the cylinder and work the apparatus by passing out, forming the explosive mixture, and when the explosive mixture has obtained the proper proportion the thing is forced back. The thing enables the use of two things; it enables the operator when he has a proper explosive mixture to start an engine of any size, and it has immense value. Messrs. Crossley, amongst others, are licensees, and they put a very large number of these on to their engines. It is of great importance to my clients; I shall have to call Mr. Lanchester, who will speak to having seen exactly the same thing manufactured by the defendant as his.

Mr. Dugald Clerk was then called and deposed:—I find here a self-starting arrangement in which gas is injected into air already present in a cylinder. That gas mixes with the air in the cylinder, and that mixture flows out at a jet shown in the drawing marked 5. The nozzle is screwed into the cylinder with a clear passage from the outer gas flame. For the purpose of igniting the mixture that flows from the cylinder by the nozzle 5 in the space 2, there is a little check valve which is shown separately at Fig. 4. That check valve has a groove at the bottom surface which leaves a clear way by No. 25 between the nozzle 5 and the cylinder. When the mixture flows through that valve it is a weak mixture; first, air only appears, because the gas shown in the cylinder at 10, Fig. 6, displaces air first and then mixes with the air to form the explosive mixture. As that explosive mixture is formed, more and more gas goes out from the nozzle 5, and ultimately an explosive mixture passes through that nozzle. Now, if you allow too much gas to enter the cylinder in Fig. 6 then you get a mixture, by what we call over-dosing, which is not explosive at all. One of the objects of the inventor is to find the exact point where you get the proper mixture. Whenever you touch the flame 5, turning the proper way, you turn off the tap 11, and in turning that tap off you diminish the rate of flow of the gas from nozzle 5. Now, the reason why the flame does not go through the nozzle 5 while the gas is flaming into the cylinder is this: that though flame propagates itself from an explosive mixture at a certain velocity, if you cause the mixture to flow too freely, then the flame, of course, produces a flame, and does not go back. If you check that velocity the flame goes back into the cylinders. Mr. Lanchester has taken advantage of that to check his velocity by taking off the tap. The moment he does that he causes an explosion, and the little valve, Fig. 4, is then thrown up by the explosion.

After further evidence his Lordship found for the plaintiffs, and granted a certificate of validity, made an order for injunction, for an inquiry as to damages, for delivery up of the infringing article, and for costs of the action and for destruction of all infringing apparatuses.

Furiously Driving a Motor-Car.—At the Kenilworth Divisional Sessions, on May 26th, Alphonse Deniot was charged with furiously driving a motor-car in Leek Wootton, Kenilworth, and other places, under three summonses. The Bench dismissed the second case, but convicted in the first and third. The defendant was fined £5 in each case, and the costs of six witnesses and solicitors' fees, the total amount of the fines and expenses being £16 4*s.* 6*d.*

Alleged Furious Driving.—Mr. John Stirling, of Hamilton, Scotland, was summoned at Leeds, under the Locomotives and Highways Act, for having unlawfully driven a motor-car along Victoria Road, Headingley, at a furious pace. A police-constable, named Sunley, said that on the evening of May 10th he saw the defendant and three other men in a motor-car going down the road in question at a speed of about 14 miles an hour. For the defence it was contended that the car could not be driven more than 12 miles an hour, and that on the occasion in question there was no danger to the public, owing to the width and quietness of the road. The case was dismissed, but the magistrates suggested that motor-car drivers ought to regulate their speed to suit the locality.

Obstruction.—Mr. Edward Mines was summoned for leaving a motor-car in the street at Liverpool, and thus causing an obstruction. The police officer stated that the car was left standing in Lord Street on the afternoon of the 13th ult., while defendant was inside a shop. It was there about 40 minutes, and attracted a large crowd. Defendant's excuse was that he had gone to get his lunch. A fine of 5*s.* and costs was imposed, the Bench remarking that people had no right to go shopping on motor-cars!

What is a Proper Warning?—At Brighton, on the 25th ult., Mr. Chas. F. Monk was summoned for not giving proper warnings of the approach of his car. The defendant had run against an elderly flower-seller named John Welch, breaking five of his ribs and lacerating his head and hand. The patient had been in the infirmary for a fortnight, and would have to stay there another month. The defence was that the accident was unavoidable, as Welch turned in the road just as the car reached him. The magistrates held that the car had been negligently driven, and inflicted the maximum penalty of £5 and costs. It was agreed that the car was going at 10 miles an hour, and the Justices declared that that speed was excessive in a town, whatever might be the case on a country road.

The American Electric Motor-Car Race.—Mr. A. Shippey thus describes the performances of the Riker car at the recent trials at Providence, R. I.:—In the first heat the Riker car, with only 40 storage cells, did the five miles in 15 minutes and 1 second. In the second heat with the same cells the car did the space in 13 minutes and 6 seconds, and in the third heat the five miles were done in 11 minutes and 28 seconds. He is informed that the Morris-Salom people in the first heat used 49 cells to drive their motor, or a pressure of about 18 per cent. over and above the actual voltage of the motor used by them, which battery power was increased to 55 cells in the second heat, being an increased pressure of E.M.F. of about 30 per cent., and still the Riker car came in with flying colours. The third and final heat was not fairly run, because it is said that the Morris-Salom people increased their battery power to 60 cells, being a pressure of about 40 per cent. over the actual voltage of the motor used by them. Mr. Shippey says his firms are having constructed at one of the largest carriage builders in London a specimen parcels van, an electric phaeton, and an improved electric cab employing 1½-2 and 3 kilowatt Riker motors, which vehicles will be driven by the new Woodward multipolar traction cell, but for the present he will leave the merits of both systems for other experts to report upon, which they will be invited to do after the vehicles are finished and ready for working on the thoroughfares of the metropolis.

NOTICES.

Contributions and articles likely to prove of interest to our readers will receive due attention, but in all cases the name and address of the writer must be given, not necessarily for publication.

All matter intended for publication should reach us not later than the 10th of each month. Stamped envelope must be sent if the manuscript is required to be returned. The Journal is published the middle of each month.

All Advertisements should be sent to the Advertising Department, F. King and Co., Limited, 62, *St. Martin's Lane, London, W.C., where Advertising Rates may be had on application.*

The Annual Subscription is 7s., including prepaid postage to any part of the world. Single copy 7d., post free.

Cheques and Post Office Orders should be made payable to F. King and Co., Limited, *and crossed London and County Bank; otherwise no responsibility will be accepted.*

SPECIAL NOTICE.

The Automotor and Horseless Vehicle Journal *can be obtained from all* Messrs. W. H. Smith and Son's *bookstalls, and the following Agents:—*

London: Pottle and Sons, 14 and 15, Royal Exchange, E.C.
Wholesale: Brett and Co., 5, Pilgrim Street, Ludgate Hill, E.C.
Birmingham: J. McCann, 37, Union Street.
Manchester: John Heywood, Deansgate.
Newcastle-on-Tyne: C. C. Ross, 35, Side.
Paris: Homère Moreau, 97, Rue Nollet.
Victoria (Australia): Phillips, Ormonde, and Co., 169, Queen Street, Melbourne.

When any difficulty is experienced in procuring the Journal from local newsvendors, intending subscribers can obtain each issue direct from the Publishing Office, by forwarding remittance of 7s. for 12 months' subscription, post free (or at the rate of 7d. per copy).

The Automotor and Horseless Vehicle Journal.

A RECORD AND REVIEW OF APPLIED AUTOMATIC LOCOMOTION.

JUNE 16th, 1897.

ANSWERS TO CORRESPONDENTS.

H. B. N. and Co. (Brixton).—Much depends upon the purpose for which the petroleum burner is required. We should recommend a Rusden and Eeles burner for large furnaces. Wurstemberger and Co., München, make a good burner, as do Moeller and Coudrup, of 78, Fore Street, London.

Vox (Chelmsford).—We know nothing of the firms in question and could hardly advise on the matter. On page 34 of the "Automotor Diary" for 1897 we give a list of reliable firms and consulting engineers engaged in the motor industry.

A. W. B. (Knighton).—We do not supply newspapers, but the address of *La Locomotion Automobile* is 7, Faubourg Montmatre, Paris.

E. H. (Stony Stratford).—The address of the Motor-Car Club is 40, Holborn Viaduct, E.C. (C. H. Moore, Esq., Secretary), and the Self-Propelled Traffic Association is 30, Moorgate Street, E.C. (Secretary, Andrew W. Barr, Esq.).

GIÖVIK STÖBERI (Norway).—(1) You should communicate with any of the following firms :—New and Mayne, Palace Chambers, Westminster ; Daimler Motor Company, 219, Shaftesbury Avenue, W.C. ; E. J. Pennington, Motor Mills, Coventry ; Great Horseless Carriage Company, Coventry ; C. Oppermann, 2, Wynyatt Street, Clerkenwell, E.C. ; Anglo-French Motor Carriage Company, Digbeth, Birmingham ; &c., &c. (2) Desired form for signature has been duly forwarded you.

S. STREET (Northampton), W. H. PICKARD (Walton), J. POTTER (Dublin).—The address of M. Serpollet is 13, Boulevard Malesherbes, Paris, and for England all information can be obtained from G. Hopkins, Esq., 30, Parliament Street, London, S.W.

MORGAN AND CO. (Tamworth).—The address of Atkinson and Philipson is 27, Pilgrim Street, Newcastle-on-Tyne, and that of Thornycroft and Co. (the Steam Carriage and Wagon Company), Homefield, Chiswick.

W. A. M. (Stantonbury).—We can only suggest your writing direct. We are glad to know that you are satisfied that you have obtained a successful motor, and should you prove it by practical tests, you would have no difficulty in getting a first-class firm to take up its manufacture.

W. J. P. R. (Falmouth).—(1) The addresses you require are :— M. Serpollet, 13, Boulevard Malesherbes, Paris ; The Woleseley S. S. Machine Company, Alma Street, Birmingham ; and E. J. Pennington, Motor Mills, Coventry. (2) Your regular stockbroker can procure you what you want, in all cases at a very considerable discount. The published quotations are to a large extent nominal.

E. W. (Brighton).—We think it will be some little time before Serpollet steam carriages will be made in England, although a special Company has been formed, we believe, for the sole purpose of utilising the system on tramways. No doubt carriages will follow. The French factory, we understand, is so full of orders that you would experience difficulty even in getting one direct from France.

THE MOTOR-CAR COMPETITION.

BY the time these lines are in print everyone concerned will be fully aware that the competition promoted by our contemporary, *The Engineer*, has proved abortive ; there has been no competition. Nearly two years ago, or, to be exact, on July 5th, 1895, our contemporary offered prizes to the amount of 1,100 guineas for the best self-propelled road vehicles which fulfilled certain conditions. These conditions were drawn up by three engineers of the highest professional standing. In deference to the wishes of manufacturers and engineers the trials were postponed from the date of trial originally fixed till the early days of the present month, when five automotors out of seventy-two entries put in an appearance, and on examination by the judges none were found to come up to the standard of excellence laid down by them. The projected trials were, therefore, abandoned, and it has gone forth to the world that British engineers cannot yet solve the problem of horseless traction. We, no less than our contemporary, regret the result, and no amount of special pleading on our part, even supposing we were disposed to indulge in it, can alter the facts of the case. We would, however, ask the unbiassed reader to carefully bear in mind what these facts are.

On referring to the conditions of the competition published in our supplemental number on 28th ult. it will be seen that the points of excellence to which the judges would give particular attention to included—

(*a*) Distance run without taking or receiving supplies of fuel, oil, gas, electrical or chemical materials or electrical current, or of any agent employed for actuating the motor. Freedom from stoppages for repairs, adjustment, or for oiling, or any other purpose or cause.

(*b*) Suitability of design and excellence of workmanship, not only of the actuating machinery but of the carriage.

(*c*) Safety.

(*d*) Simplicity, durability, accessibility, and facilities for repairs, absence of offensive smells, and of excessive vibration.

(*e*) Time occupied in getting to work and ease of starting.

(*f*) Speed—up to 10 miles per hour—and hill climbing.

(*g*) Completeness of control by, and certainty and decision of, steering and steering gear, and efficiency and durability of brakes and brake gear.

(*h*) Weight of carriage and motor machinery and appliances.

(*i*) First cost and — to a limited extent — the cost of working.

(*j*) General efficiency.

How long, may we ask, did it take to bring the railway locomotive to attain anything like the above degree of excellence? And even in the latest types of locomotives is there much evidence of "simplicity" in, say, a "Webb" compound, fitted with Joy's or Walchaert's gear? Is a locomotive free from "offensive smells"? Or even go further, does the fœcal matter of horses constitute a particularly grateful and sweet-smelling savour that a motor should be damned because at times it may emit the fumes of unburnt petroleum? Is a locomotive, too, so free from vibration? Is it perfectly "safe"? Does it not at times "jump the track," and do not sparks from it set fire to hayricks? While, is not the shriek of its whistle in towns one of its most objectionable features? Does it not, too, require a most expensive roadway, and is it not a most wasteful and uneconomical heat-engine? Do we, therefore, ostracise the steam locomotive? Not a bit.; because it is a general, if imperfect, public convenience. Similarly, we cannot reprobate the motor-car because it does not at present possess those points of excellence which are only partially attained in the steam locomotive. In both, the question is not—Is this a perfect machine? but, Shall I, as a trader, obtain any advantage in using either in preference to horse-drawn vehicles? If public opinion is so tolerant of the frailties of the steam locomotive, surely we ought to regard with a benevolent and forgiving spirit the lapses from the path of strict mechanical rectitude (as expounded by our contemporary's judges) of the younger and, therefore, immature motor-car in the sure hope that with greater experience existing imperfections will be remedied, and any tendency that may be evinced by the motor-car to prance wildly and unrestrainedly about the country, a danger and a nuisance to the public, will be eradicated under the chastening influence of the law. Naturally enough the collapse of *The Engineer* competition has been received with a chorus of cacaphonous concatenation by the Press of "We told you so," "There is no practical road locomotive," "The horse is still the best motor," and so forth and so on. It is, of course, useless to tell those who thus jump at conclusions that there has been no competition ; but to argue, as does *The Engineer*, that because there has been no competition, *therefore*, there is no motor industry in this country, is not only illogical but utterly at variance with the truth. We could mention at least a score of firms of repute engaged in the design and manufacture of motor-cars intended not so much for pleasure purposes as for the requirements of trade. At least three firms have evolved motor-carriages for commercial uses which, in spite of their not complying with all the conditions of *The Engineer's* competition, are yet in every way practical machines. We refer to the carriages of Messrs. Thornycroft, of Chiswick, and those of the Liquid Fuel Company, of Cowes, and of Messrs. Atkinson and Philipson, of Newcastle. So far as our observation goes, we should say that the principal and only serious objection to each is that a skilled driver is necessary; or perhaps we should say that some intelligence and knowledge of machinery is requisite on the part of the driver. We believe this remark applies to the handling of automotors of every description, including locomotives. No doubt this was felt to be a sound argument against the use of the early locomotives, just as the probability of "coos" getting on the track was an absolutely convincing clincher urged against their use. The public, however, required locomotives, and was content to take the risk of the stranded "coos." Similarly, if it wants automotors—and it does want them badly—it will not mind a few imperfections, and there will be no lack of competent drivers.

Our contemporary also asserts that "there is no such thing as a thoroughly satisfactory self-propelled vehicle." As we have before intimated that there is no such thing as a thoroughly satisfactory railway locomotive, we need not further labour the point. We might, however, say that there is no thoroughly satisfactory battleship or lifeboat; it all depends upon the point of view. Ruskin, we think it was, called the locomotive a "devil," or something equally expressive. This, no doubt, is very shocking to the feelings, say, of Mr. Aspinall or Sir F. Bramwell, who regard that motor as the triumph of mechanical engineering. Be this as it may, we—all of us—may rest assured that the demand for cheap internal transport must be met, and the automotor van is the only possible solution for crowded cities. In its present state it may not be "thoroughly satisfactory." What is? It can be improved. In the meantime we must take it as it is, so long as it enables us to effect a saving in the cost of transport. It has taken over half a century to produce a fairly satisfactory locomotive; but to evolve an almost perfect dynamo did not require fifteen years. With so much cultivated intelligence at work on the automotor, as we know is the case, we may reasonably expect that within a very few years the drastic conditions of *The Engineer* competition will be more than satisfied.

We sympathise with our esteemed contemporary over the failure of its well-intentioned plans, but considering the very short time that has elapsed since the legal restrictions affecting the industry have been withdrawn it would seem hardly reasonable to expect all at once the evolution of the "thoroughly satisfactory" automotor. We would say to our contemporary: Make your conditions a little less rigid and try again in a year's time.

We would specially direct the attention of our engineering readers to the advertisement which appears in the present number, in which £100 is offered for working drawings of a steam tractor. Without, of course, divulging the name of the firm advertising, we may say it is one of high standing, and the designer who succeeds in gaining this prize will also probably establish a valuable connection.

FIRE-ENGINES.

One of the features of the Jubilee proceedings will be a Review of the Fire Brigades by the Queen at Windsor. One hundred Brigades will attend, and the total force will be 1,000 men, 66 engines, and 127 horses. As a review or exhibition of an inefficient, uneconomical, and very costly method of road traction it will be no doubt interesting. As showing how lamentably slow we are to adopt better methods, it may be mentioned that when the Queen was about a quarter of a century younger the fire engines of that time differed but little, if at all, from the present accepted type, and they were then as now drawn to the scene of their employment by horses with the usual accompaniment (as now) of vociferous and raucous cries rendered necessary by the noise made by the sledge-hammer action of the horses' feet. When this review takes place we are afraid that Her Majesty will be horribly bored by the ancient spectacle. While on this subject we would ask, How is it that the London County Council, as the principal fire extinguishing body in the country, still adheres to horse traction? Is it in accordance with modern ideas of Municipal Progress that an inefficient and costly system should be maintained when a better one is at hand? Or is it that the technical talent employed by the L.C.C. is not so conversant with what is being accomplished in the matter of road traction as is desirable? Accepting as we do the *dicta* of such distinguished authorities as Sir David Salomons and Mr. Worby Beaumont, we cannot understand how it is that at the close of the nineteenth century a light steam pumping plant has to be dragged about by horses, and this by a municipal body which is supposed to be "smart" and "up to date." As our remarks will no doubt be read by many members of the L.C.C. we will amplify them in order to show what might be effected. In each fire station we would place a "thermal storage" plant; this would merely be a moderately large low-pressure boiler, that would suffice for all purposes of lighting, heating, and cooking for the station and the staff. The fire-engines would consist of a water-tube boiler of the Yarrow or Thornycroft type, supplying steam to a suitably designed engine, which could act either for locomotion or pumping. Under idle conditions the boiler would remain empty; on a "call" being received, hot water would be injected into it and the fires started: the fuel being of course petroleum. In a few minutes, or at any rate in not more time than is at present taken to "start the wagon," there would be steam sufficient to propel the engine at a speed of not less than 10 miles per hour. The engines would of course be fitted so as to work either as simple expansive engines or compound. As the steam pressure increased so would the speed, and on arrival at the scene of the fire we should have a pump ready for work actuated by a motor necessarily about twice as powerful as the present ones. As regards weight this should be certainly less by 25 per cent. than the most modern fire-engine (weight of horses included in the latter). The first cost would be greater by perhaps the same amount, but the annual cost of maintenance would be ridiculously small. Of course in this, as in all similar problems, Kelvin's "Law of Economy" applies, and our proposition is a matter of unquestionable demonstration. Those then that will take part in the Jubilee Fire Brigade Review may reflect that they are by no means exhibiting an "up to date" show. For our part we would just as soon see an exhibition of four-wheeled cabs, and should derive about as much instruction from the one as from the other. Notwithstanding the absence of anything like scientific progress on the part of the Fire Brigade of the L.C.C., which is all the more to be regretted as it deters other municipal bodies from advancing with the times, it is satisfactory to know that in the United States horse haulage for fire-engines is being abandoned in favour of self-propelled vehicles. Since the foregoing was written we have had the advantage of a conversation with a leading manufacturer of fire-engines who assures us that he has had several inquiries from municipal bodies for automotor fire-engines, fire-escapes, &c. Some experiments are also being carried on at Croydon under the local authorities with motors, &c., for this purpose. So after all some progress is being made in replacing the noisy, excitable, nervous, sledge-hammer horses by other and more efficient means of locomotion.

THE DAGNALL MOTOR.

This motor, which we illustrate below, is of considerable interest, the designer, Mr. Dagnall, departing from ordinary practice in several important points of detail.

He considers the use of *variable* speed gear a mistake, and in place provides a motor which will run at a variable speed, and develop, under all conditions of running, sufficient power for the work.

His calculations of the power required are not based on the horse-power developed by the engine, which on consideration will be seen to be inaccurate, but on the tractive force necessary to propel the carriage, which he finds to be one-third of the weight of the car (720 lbs. per ton) under the worst working condition.

His engine is therefore constructed to develop great power on emergency, while it may be regulated to produce any power from zero to the maximum without the use of the ordinary hit-and-miss governor device. The motor derives its power from ordinary lamp oil, and runs at the moderate speed of 300 revs. per minute.

No flame burners for heating or igniting are used, as he considers a lamp burning on the carriage far more objectionable and dangerous than even motors using light oils.

We hope to illustrate the motor fully at an early date.

The Dagnall Motor.

We regret to announce the death of Mr. Joseph Ruston, head of the well known Lincoln engineering firm of Ruston, Proctor, and Co. He represented Lincoln in Parliament as a Liberal in 1884 and 1885, but split from the party on Home Rule and retired. His decorations were the Cross of the Legion of Honour and the Order of Osmanieh.

BUSINESS NOTES.

The London Motor Van and Wagon Company have opened a showroom at 86, Chiswell Street, E.C., and are ready to take orders for immediate delivery.

Barges Propelled by Electric Motors.—The Clayton Foundry Company have received the order from Messrs. Lever Brothers, of Port Sunlight, to supply two motors of the enclosed type, of 40 horse-power each, to be driven from accumulators, for a cross-river barge.

An interesting example of the enterprise of Manchester business men was, according to the *Manchester Courier*, given last week in that city, when Mr. J. Burgess, the proprietor of Sutton and Co., the well-known carriers, launched a motor van on the city. The van is a light one, and was run as an experiment, with a view to its general adoption. It is constructed to carry half a ton. It proceeded through the principal streets of the city, thick with traffic, at a comfortable pace; and in the hands of Mr. G. Foster Pedley, of the Daimler Motor Company, proved of easy guidance through the congestion as any horse, while more obedient to the touch, and not at all restive. After going through the town, it set off, through the country, to Cheadle Hulme. It took the country roads at a more rapid pace, getting up to 12 miles an hour, and running quite as easily, though iron-tyred, as the average four-wheel cab. The motion was easy, the speed good, and the steering perfect. Mr. Burgess occupied a seat in the car, and tested its utility for parcel delivery purposes. All experiments, such as sudden stoppages, were highly satisfactory. If when in regular use the van proves as successful it will undoubtedly revolutionise the parcel delivery business. It is a Daimler car, and has been built at Coventry. It travelled by road from Coventry—a distance of 109 miles—in 13 hours, exclusive of stoppages for refreshments. The van is driven by a four brake horse-power Daimler motor. A supply of oil sufficient for a run of 60 miles is carried. Messrs. Sutton intend to make a general use of motor power for the locomotion of their vans, which will mean the retirement of 230 horses in Manchester alone.

LONDON can hardly be regarded as behind Manchester in using motor-vans practically. Messrs. Carter, Paterson, and Co. have now for some little time been using several light express parcel vans for town delivery. They look exceedingly neat and business-like as they glide along amongst the general traffic, and as far as we can see, horses absolutely ignore their presence. One thing we can personally vouch for, whether it be chance or otherwise, since this firm has been using these motor vans they have secured several regular and important deliveries which hitherto have been in the hands of other carriers.

MOTOR-CAR DESIGNS.

THE Worshipful Company of Coach Makers and Coach-Harness Makers' regular Exhibition of Prize Drawings is now on view at their Hall, in Noble Street, near the General Post Office; the principal prize offered, we are pleased to see, being in Competition No. 4, for designs of a self-propelled Light Motor Pleasure Carriage, to convey two or four persons—side elevation —half-front—and half-back—on two or more sheets of paper, of a uniform size, 2 feet 6 inches by 2 feet—scale 2 inches to the foot—details of mechanism 6 inches to the foot. The copyright of any new design gaining a prize remaining the property of the winner of such prize.

1st Prize.—The Company's Silver Medal and £20, given by the Worshipful Company.

2nd Prize.—The Company's Bronze Medal and £10, given by the Worshipful Master (Col. John Wm. Lee).

Although it is very satisfactory to note that these competitions are only open to British subjects, it is very disappointing to find the drawings sent in are not of sufficiently novel a character to justify the judges (composed of the Master, Wardens, and the members of the Company's Standing Committee), in awarding a prize to either of the two competitors. Messrs. Joseph and William Graham (aged 17 and 20), of Gateshead, send in a smart-looking four-wheeled electric dog-cart, which is provided with special facilities for steering and turning. In the elegant design for a vehicle of the wagonette type by Mr. Matthew W. Henderson (aged 21), also of Gateshead, all suggestion of the motive power to be used is absent, which is a drawback, as the very essence of a design should be to provide for the special machinery, &c., with which it is intended to propel the vehicle. This competition, however, is a move in the right direction, and no doubt next year, with the same inducements held out by the Company, there will be a much greater number of entries, including, we hope, some drawings of sufficient merit to carry off both prizes offered. It is curious to note both the present competitors hail from the same town, and are associated in business with Messrs. Atkinson and Philipson, the well known carriage builders of Newcastle-on-Tyne.

THE BAZIN ROLLER BOAT.

IN an article in our last number dealing with this vessel, we expressed grave doubts as to its fulfilling the expectations of its designer. Since then the trials have taken place, and the result is as we anticipated. Instead of the 30 knots, but 12 were obtained.

NOTES OF THE MONTH.

"VAGABOND," the well-known north-country journalist, is hardly, to judge from his writings, the kind of person to indulge in very optimistic views or one likely to pour himself out in fulsome panygeric on any new thing. He has, however, recently devoted his attention to the very excellent automotor carriage designed and built by Messrs. Atkinson and Philipson, of Newcastle-on-Tyne, and has recorded his experiences in the *Newcastle Daily Chronicle* of the 24th ult. We are glad to learn from such a distinguished layman that the automotor in question meets with his warm approval. "Vagabond" displays quite a critical appreciation of the whole problem of horseless traction, and does not attempt to minimise the disadvantages or to unduly appreciate the merits of the subject. If all or most critics would display the same judicious attitude as "Vagabond," manufacturers of automotors would have little cause for complaint. We should say that the motor-car upon which "Vagabond" made a pleasant run was intended to compete in *The Engineer* competition, but after completion it was found slightly in excess as regards weight. It has, however, been most thoroughly tested on the steep gradients of Newcastle and its vicinity, about the worst district for either horse or horseless traction that we know of, bar parts of Wales and Scotland; and has given every satisfaction to the inhabitants of a town all of whom are, not even excepting the ladies and children, expert critics in machinery, and if a motor-car will suit Newcastle it will suit any town. We congratulate Messrs. Atkinson and Philipson, and also their engineers, Messrs. T. Toward and Co., on their success, and we hope to have the duty of recording many similar successes.

LAST month we drew attention to a proposed race that was being inaugurated by the *Irish Field*. We have not heard anything further of the matter, and it would be interesting to know whether the projected race is to be abandoned. Really, we think, after *The Engineer* fiasco, that competitions which *do not* turn out to be competitions in any sense of the word are useless, and only serve to hinder the development of the use of motor-cars.

AUTOMOTOR-cars, if not vehicles plying for hire, are now allowed to enter the Royal Parks just as other private carriages are.

THE automotor has penetrated to Arran, N.B.

IN the prospectus of Messrs. Thomas Tilling (Limited), of South London, it is stated that "the directors do not at present contemplate the adoption of motor-cars for any portion of their business, but power has been taken in the memorandum of association which will enable them to introduce any present or future automatic inventions when, if ever, they may become of practicable utility." Messrs. Tilling have a stud of 3,386 horses.

A FEATURE of the Petersfield election was the employment of automotors in the shape of traction engines for the conveyance of the "free and independent" electors to the poll. An automotor is at all times an instructive object, and its presence in a country village has a distinct educational value; we are, however, not aware that it has ever before been used for the propagation of great political truths or falsehoods as the case may be. It would be interesting to know the opinions of leading politicians as to the moral influence of an automotor in swaying an election.

ONE of the most interesting processes carried out in Nature's laboratory is the manufacture of petroleum. How this is accomplished is as yet unknown to us. Mendeleef, the great

Russian chemist, thinks petroleum of mineral origin through the chemical interaction of steam upon metallic carbides, assumed to exist at great depths. Engler has recently demonstrated experimentally the artificial production of hydrocarbons of the paraffin series in the destructive distillatiou of animal fats under pressure. This interesting fact greatly strengthened the view of many chemists, that natural stores of petroleum had their origin in the decomposition of animal remains under peculiar heat and pressure conditions. Sadtler now supplements the work of Engler by demonstrating that petroleum hydrocarbons are produced in the destructive distillation, under pressure, of linseed oil, a product of vegetable origin. The results obtained by Sadtler, therefore, would permit the conclusion that native petroleum was derived from the decomposition of vegetable remains, and reopens the whole question.

AN air pump worked by the motor is being introduced for the purpose of inflating the tyres of motor-car vehicles. We also hear that carbonic acid gas is to be tried for this purpose. The former seems to us to be the preferable method, as in the latter it would be necessary to carry about a tube of the compressed gas—not a desirable thing to entrust to the average driver to handle, because of the great weight of the flask and the risk of fracture uuder pressure.

OXILIN is the name of a new substitute for indiarubber. It is said to be impervious to mineral oils and a temperature of 400° F., while its cost is low.

USERS of motor-cars will be interested in learning that, as the result of numerous tests, the best paint is graphite paint. Professor Spennrath, director of the Technical School of Aix-la-Chapelle, lately won the 2,000 dollars prize offered by the Society for the Advancement of the Industrial Arts for the best essay on protective paints. The prize was not won simply by theoretical demonstrations, although the professor furnished scientific reasons also, but by most carefully conducted practical experiments with various pigments and oils, extending over several years' time. The results demonstrated that a properly-made paint of graphite and boiled linseed oil is the most suitable for protecting structural ironwork, roofs, &c., exposed to the destructive agencies of heat, cold, storms, &c.

A MR. GUATTARI proposes to increase the efficiency of steam boilers by adding to the water a liquid composed of carbonic acid gas and ethene chloride, better known as "Dutch liquid." The carbonic acid gas is generated in the ordinary way in a suitable closed receiver, which is provided with a stoppered mouth by which the Dutch liquid is introduced. The proportions which are found suitable are :—Water, 28 litres; whiting, 7 kilogrammes; acid, 2 litres; ethene chloride, 140 grammes. The resulting compound gas passes off through a pipe (provided with a check valve) and is injected into a saturator filled with water. The water saturated with two or three times its own volume of the compound gas is forced by a feed pump into a steam boiler. Here it is evaporated and does work in a steam engine, from the exhaust of which it passes into a surface condenser, wherein condensation takes place without separation of gas. The condensed solution is then forced back by an air pump into a receiver at atmospheric pressure, from whence it is pumped again into the saturator. We should like to see this process in operation or to hear of reliable tests having been made of it.

"ANTI-TRAM," writing to the *Morning Post*, strongly advocates the employment of motor-carriages. He says:—It is to be hoped that the accession of the motor-carriage may in some ways reduce the frightful plague of tramways, which, having bought their way into all Continental towns, are rapidly making the roads impassable for other vehicles. How far one form of traffic has a right to monopolise three-quarters of the road to the utter detriment of thousands of other vehicles of every description is a question too long to discuss. They have bought their way, and money is a vehicle that runs smoothly. They have taken possession of the roads, which ought to be free to everyone, under pretence that it is for the good of the public. It may be good for the company; it is certainly no good for carts, cabs, fiacres and carriages, &c. The sooner the motor-cars come into force and open the roads again to the public the better. All success, say I, to the motor-car. I have personally no objection to trams in their own place, but I do contend that they have no right to place rails on the crown of the causeway. In their own place, with roads adapted for them, they may be useful enough.

A LOCOMOTIVE of a novel description has recently been constructed at the Baldwin Locomotive Works, for the New City branch of the New Jersey and New York Division of the Erie Railroad, running from Nannet to New City, a distance of about four miles. The Erie Company runs a few trains between the terminal points every day, but the passenger and freight traffic is very light, and the company felt the requirement for a motor-car which will do the work that is now being done by a locomotive, a baggage and smoking-car combined, and a passenger car, which, altogether, require the services of five men. The motor has been built according to the plans of the Kinetic Power Company, and weighs 13 tons. The length over all is 26 feet. It resembles in appearance an ordinary street-car, and has a seating capacity of 20. The driving wheels are 31 inches in diameter. A preliminary test showed that in running a distance of 20 miles but 30 gallons of water were used. According to the *Railroad Gazette* the water is carried in a tank beneath the car body, but enough space is left in this tank for the accumulation of a small amount of steam. Before leaving the car-house the water in the tanks is heated until the pressure of the steam is about 200 lbs., but the steam is used in the working cylinders at a much lower pressure. In order to keep up pressure a fire in a small fire-box is kept burning in one end of the car in order to generate a constant supply of steam, keeping the pressure in the tank from 150 lbs. to 200 lbs. per square inch.

AT the recent Royal Society soirée, Sir A. Noble, K.C.B., showed an apparatus for ascertaining the duration of an explosion, pressure developed, and rate of cooling of products of combustion. The apparatus in which the explosion takes place was not shown, as it is too weighty. It is a cylinder into which the explosive is inserted and closed up. The chamber, however, is not entirely filled. Into its mouth is screwed a powerful pressure-gauge, comprising a piston and coiled spring. Connected with this piston is a lever which moves a pencil over a "card" on a large rotating drum. By aid of a chronometer and another pencil seconds are marked on the paper, and by this means there is prepared a diagram in which the two elements are time and pressure. To check this diagram a second is made on a smoked cylinder. In this the line is not continuous, but a succession of dashes are made by the pressure-gauge lever moving over electric contacts, and so setting a series of electro-magnets into intermittent operation. To minimise the effects of inertia, the pressure-gauge can be set not to move until eight or nine tons has been attained. A number of curves were shown during the evening. In these the pressure required a perceptible fraction of a second (cordite being the explosive) to reach the maximum, and several seconds to fall to about one ton, when it remained stationary.

THE well-known Paris correspondent of the *Daily Telegraph* writes to his paper on the prospects of motor-cabs in Paris. He says:—"Although the public does not seem to take very kindly to the idea of starting motor-cabs, the manager of the Company which is assuming the initiative in the matter is extremely sanguine as to the result of the bold experiment. In all likelihood, electricity will ultimately be adopted exclusively by the Company in preference to petroleum, but each is to have a fair trial. As for the objection that the present drivers will be unable to hold their own under the new system, the manager makes light of it, and says that in the course of three or four days the men will be quite in their element with the motor-cabs, models of which, by the way, were to be seen at the Cycle Exhibition held at the Palais de l'Indnstrie some time ago. There is one decided advantage in the contemplated change, and that is that the pleasure of a lounge in the streets of the gay capital will not be marred by the spectacle of the brutal treatment to which cab-horses are so frequently subjected."

FOR crass ignorance of law and a bucolic attachment both to the "whisky of their forefathers" and old-world ideas and prejudices, commend us to the provincial magistracy. Puffed up with the importance of affixing the shibboleth "J.P." to their names, they as a rule administer after a fashion the common law of the land. For "drunks and disorderlies" and slight "assaults" these magistrates, usually an illiterate class of persons, may fulfil their part with more or less—usually less—ability. *Truth* has for many years found the provincial magistrates an unfailing source of interesting copy. Their ways, their sentences, and their prejudices really form a complete branch of human science. It seems that it will also be our duty to discuss the Great Unpaid, because the prejudice and absolute illegality that many of them exhibit in their dealings with motor-cars is fast becoming a public scandal, and unless these ignorant J.P.'s manifest a little less prejudice and a good deal more justice we shall have to bring the matter before the notice of the Lord Chancellor. Even J.P.'s can be removed, and, as Koko says, "I have known it done." A gross instance of the prejudice with which many of these J.P.'s regard the automotor has lately occurred in Liverpool (see our Legal column), where a magistrate told a defendant that he had no business to go shopping in a motor-car. It makes one positively boil to read such an insolent observation, and we trust that the defendant will use every means to obtain an apology. The case ought to be brought to the notice of the House of Commons, the Lord Chancellor, and the Home Secretary.

COMPRESSED air is to be tried on the Manhattan elevated line, the Hardie system being adopted. In general appearance the machine much resembles the ordinary steam locomotive. The space usually occupied by the boiler, however, is taken up by the storage tanks for the air and by the reheater. On this locomotive the air is stored in 36 tubes of Mannesmann rolled steel; they are 9 inches in diameter and of varying lengths, from 13½ to 21 feet. The charging pressure is 2,000 lbs. per square inch. The air is led from these tanks through the reheater, in which water is stored at an initial temperature of 350° F., and after passing through three reducing valves is admitted to the cylinders at a pressure of 150 lbs. The working cylinders are 13½ × 20 inches. The American Air Power Company, which controls the Hardie patents, has erected a compressing plant for charging. The locomotive has been delivered, and is now undergoing its trials. We shall probably refer to them in our next issue.

Automotors for Small Boat Propulsion.—In our present number we give excerpts of some interesting and instructive papers that have recently been contributed to the Institution of Civil Engineers and the Institution of Naval Architects. The standing of these bodies is guarantee enough of the excellence and soundness of the views expressed. We would particularly direct the attention of canal-boat owners to the advantages of the steam turbine. We can speak of this motor from personal experience, having worked one of the earliest ones.

REVIEWS OF BOOKS.

"Manuel Pratique du Conducteur dAutomobiles." Par PIERRE GUÉDON, Ingénieur, Chef de Dépôt principal de la Traction mécanique à la Compagnie Générale des Omnibus de Paris, et YVES GUÉDON, Ingénieur civil. Préface de M. EMILE GAUTIER, Directeur de la *Science Française*. (J. Fritsch, 30, Rue du Dragon, Paris.) Price 5 francs.

WE have in this work an excellent treatise on automotors by two writers who are in every way well qualified for their task. In the first part, which treats of steam motion, all the best types are fully illustrated and described in some detail. The authors are apparently not very conversant with motors of types other than those usually met with on the Continent. Thus in the present section the Dion et Bouton, the Serpollet, the Weidnecht, the Bollée, Le Beant, and Scottie systems are dealt with, but nothing is said about the varions British types of steam automotors. Surely such distinguished engineers as the writers of this work must be conversant with our water-tube boiler practice? After describing each motor, the authors devote considerable space to a discussion of the tractive data, and much useful information is given under this head. This is followed by a discussion of the advantages of the compound engine and the method of calculating power; our authors state that the greatest *practical* effort of a machine such as a steam-motor is only 63 per cent. of the theoretical. We should suppose that this is rather too high an estimate. The second part contains an equally well-written account of gas-engines, and singularly enough the patents owned by the London Gas Traction Company come in for a good deal of description. The authors, after discussing the *pros* and *cons*, conclude that gas traction is very suitable under certain conditions. No other system than that of the Gas Traction Company is described. In the third part petroleum motors are exhaustively dealt with, and our authors evidently think that there is a future for petroleum. All the well-known French oil motors are described, but nothing is said about the British oil-engine. We do not think that our French friends will deny that Priestman, Tangye, and others, have done a good deal to improve the oil-motor. We see no reference either to the Capitaine motor. A very short chapter suffices for electric motors, but only one or two types are described, and we fear the authors are hardly aware of recent advances in the direction of reducing the weight of cells and improving them generally. The electric motor described can hardly be said to represent the best practice. This chapter is succeeded by a very useful one on motor-car accessories; in this one learns French practice as regards constructive details of wheels, tyres, &c. There is a good account of petroleum, and how to test it, and the book concludes with a list of the duties levied on automotors by the various Continental States. Altogether, the work is well written, and is indeed a high-class one in every respect. We have perused it with pleasure and can recommend it; the illustrations are good, but might be better, and we should have preferred them on a larger scale.

"Aggenda du Chauffeur." Édité par *La France Automobile*.

THIS is a handy little pocket-book, arranged as a kind of "log," in which to record motor-car performances. We think something similar might be produced for use on this side of the Channel.

An Essay on Motor-Cars.—A schoolmaster, having set his class the task of writing an essay on motor-cars, found one scholar (the son of a horse-trainer) had excelled for brevity. It ran as follows:—"Motor-cars is beastly things, and stinks." He said he had not written more, as his father told him the less he knew about them the better.

President	Sir DAVID SALOMONS, Bart.
Secretary	ANDREW W. BARR, Esq.
President of the Liverpool Centre	The EARL OF DERBY, G.C.B.
Hon. Local Secretary	E. SHRAPNELL SMITH, Esq.
Semi-Official Journal of the Association	THE AUTOMOTOR AND HORSELESS VEHICLE JOURNAL.

Motor Vehicle Exhibition and Competitive Trials.

IT will be remembered (*vide* report in THE AUTOMOTOR for May) that last month the Liverpool Branch of the Self-Propelled Traffic Association announced their intention to organise an Exhibition of Motor Vehicles, to be held some time in the spring of 1898, by which time there is reasonable ground to expect that makers of both light and heavy types will be in a position to take part.

We now have pleasure in announcing that the preliminary arrangements in connection with the above will be ready for publication by the end of June. Persons desiring to be provided with copies of same are requested to apply to Mr. Shrapnell Smith.

The Objects of the Self-Propelled Traffic Association.

IN a letter to the *Manchester Guardian*, Mr. Shrapnell Smith, the Hon. Local Sec. of this Association, says:—"Sir,—I must take exception to the statement to the effect that this Association proposed to run vehicles in opposition to the Ship Canal. This branch of the Association has been organised for the 'scientific investigation of self-propelled vehicular and locomotive road traffic,' and has no intention of entering as a body upon any commercial undertaking whatever."

Royal Agricultural Society's Trials.

MR. SHRAPNELL SMITH had arranged for the vice-presidents and members of the Liverpool and District Centre to visit Crewe on the occasion of these trials, but on reaching the Station Hotel on Wednesday afternoon, the 9th instant, he learnt from Mr. Frankish (Chairman of the Implement Committee) that only one car was likely to take part in the run.

Under the circumstances, it was thought advisable to cancel all arrangements, which was accomplished by the despatch of a batch of telegrams to the members who had signified their intention of following the trials on the Thursday. On the latter occasion Mr. Shrapnell Smith represented the Association. Naturally, much disappointment has been felt and expressed in Liverpool and Manchester that these trials have not served to produce a vehicle suitable for heavy traffic, but, at the same time, it is known that the problem is engaging the attention of many engineers, and it is hoped that before long something tangible will be evolved.

THE DANGERS OF HORSE TRACTION.

FEW situations are more dangerous than that of being in a vehicle drawn by restive horses. In spite of his docility and other good qualities the horse is yet one of the most nervous of animals, and when excited by fear, or in any

way alarme

and another, it is feared, will have to be killed. As the season advances such accidents will become numerous—at least judging from the experience of former years; with motor-cars they would be impossible. In this respect—not to mention others—the motor is unquestionably the safer mode of travelling.

THE POPE MANUFACTURING COMPANY'S ELECTRIC PHAETON.

WE have received from the Pope Manufacturing Company, of Hartford, Conn., U.S.A., a description of their Electric Phaeton, which, we understand, has already become very popular in the States. Unfortunately, the motor-car industry in America, as with us, has had to suffer from the injudicious booming of crude and unsuitable types of motor-cars, and hence it is only by combining the best design and workmanship, together with handled with ease and safety by anyone who is not altogether devoid of common-sense. The battery can be readily charged from any 110-volt circuit. The total weight of the car complete is 1,900 lbs., and one charge suffices to traverse a distance of from 30 to 35 miles, at speeds of from 10 to 12 miles per hour. The cost of this motor-car complete is, we understand, 3,000 dollars. It is interesting to note, and it may be taken as a guarantee of excellence, that this car was designed by and under the superintendence of Mr. H. P. Maxim, the son of the well-known ordnance engineer who resides on this side.

DOIGS OF PUBLIC COMPANIES.

Standard Weldless Tube.

The statutory meeting of the Standard Weldless Tube and Cycle Components (Limited) was held on May 17th.

The Chairman (Colonel Lewis Vivian Lloyd) gave an outline of the work which had been done since the registration of the Company. He stated that since the issue of the prospectus Chillingworth's patents had been all assigned to the Company, to the satisfaction of the patent agents and the solicitors of the Company. The business of the Standard Tube Company, carried on by Mr. J. W. Fitter, had been taken over by the Company, and more land had been acquired on the other side of the canal at a small rental. The existing works were in full operation, and they had a considerable number of customers, among which might be mentioned the Birmingham Small Arms Company, Messrs. W. Heath and Company, and Messrs. W. Bown (Limited). With reference to Chillingworth's foreign patents, the Company had been approached by certain persons who were desirous of purchasing these, and negotiations were pending in respect of the American, French, and Belgium patents at very satisfactory prices. The board had secured from Mr. Chillingworth a very valuable patent for the manufacture of the hubs, which was not set forth in the prospectus as part of the purchase.

The "Clyde" Cycle and Motor-Car Company (Limited).

The first general statutory meeting of the above Company was held at the Bell Hotel, Leicester, on June 2nd, Mr. J. F. L. Rolleston, J.P., Chairman, presiding, who explained that the meeting was held in conformity with the Act of Parliament. The Company had every prospect of paying substantial dividends. The works were in full operation, and overtime had been resorted to for months to enable them to cope with the orders on hand. Shares had only been issued for an amount of capital which could be usefully employed.

Leather-Shod Wheel Company.

The statutory general meeting of the Leather-Shod Wheel Company (Limited) was held on May 28th, under the presidency of Mr. C. N. Baker, who said:—This is a meeting called for the purpose of complying with the Act of Parliament, and hardly sufficient time has elapsed to let you know much about the prospects of the Company. All I can tell you is that we have taken a factory at Bow. We have got the engines there, but the necessary machinery for manufacturing the leather-shod tyre is being made abroad, and we hope to receive it and get it in its place in the factory in the course of next month. Meanwhile, I may tell you that in order to keep the factory at work and make some profit we took an order for some 200 cycles, which we are manufacturing there. But, of course, this will not interfere with our other business. I hope that at the end of our first year we shall be able to show you that we can make a profit; at all events, I have every hope that the tyre itself will turn out a great success. Personally, I should very much like to see all our omnibuses and cabs fitted with noiseless leather tyres, which are more durable than indiarubber. I certainly am of opinion that the tyre will meet a great want, and be a great success. We have received a great many sample orders from various railway companies, carriers, and various firms, and as soon as we get the necessary machinery to manufacture them these will be supplied. The machinery that we require no English firm would make, and therefore we had to get it abroad.

Mr. Thurston inquired the amount of capital taken up by the public, and whether it was sufficient for their requirements.

The Chairman. I think it is injudicious to mention the figures, but I may say that we have plenty of working capital The amount subscribed was over £110,000.

Perfecta Seamless Tube.

The first annual meeting of the Perfecta Seamless Steel Tube Company (Limited) was held at the Queen's Hotel, Birmingham, on June 3rd, Mr. G. J. Brodie presiding. The Chairman said the vendor, when the business was taken over, guaranteed that £40,000 should be made in two years, and as a fact they had made more than that on the first year's trading. The prospects for the current year's trade were exceedingly good, and the works were going night and day; and, although they had laid down large additional plant, they were unable to overtake the orders. They had supplied the Admiralty with the tubes for 60 ships now in commission without a single complaint. They were also well in with the War Office and foreign Governments, and strong enough not to fear any competition. The report was adopted.

Peerless Metal and Martino (Limited).

Under the above title a Company has been incorporated with a share capital of £150,000 divided into 60,000 5½ per cent. cumulative preference shares and 90,000 ordinary shares of £1 each.

In addition to the fixed cumulative preference dividend of 5½ per cent., the holders of preference shares will be entitled to one-third of the profits of the Company in excess of sufficient to pay dividends at 10 per cent. per annum on the ordinary shares. They will also be entitled to a preference to capital, and the articles of association provide that no debentures or debenture stock can be created by the Company without the sanction of a resolution of the preference shareholders at a meeting especially summoned and held for the purpose.

The present issue is 60,000 5½ per cent. cumulative preference shares and 40,000 ordinary shares of £1 each.

The prospectus states that the Company has been formed to take over from the Peerless Metal Company (Limited) the old-established nickel and white-metal business for many years carried on by Mr. F. R. Martino, at Princip Street and Lower Loveday Street, Birmingham, which has recently been acquired by them; the valuable British patent under which the now well-known metal "Peerless" is manufactured; the business carried on by the "Peerless" Metal Company at 38, Parliament Street, S.W., and West Ferry Road, Millwall, E.; the valuable freehold property, comprising six acres, situate at Hollywood, and the large range of manufacturing premises erected thereon; the residences adjoining; the leasehold manufacturing premises at Millwall, covering an area of about 38,000 square feet; and also trade marks and trade secrets, formerly the property of Mr. F. R. Martino, whose business was established in the year 1876. Mr. Martino occupies a leading position in the white metal trade, and having agreed to act as director of the Company for a period of five years, it will acquire the benefit of his experience and knowledge. The profits over a long range of years of this business are certified at £3,000 per annum, and, added to this, the total profit for distribution is estimated to amount to £27,600 without taking into consideration any extra profit to be made by the rolling, tube, and drawing mills. Some of the advantages claimed for the "Peerless" metal are its cheapness, its splendid appearance, which is equal to silver, its great strength, durability, and ductability, its purity and uniformity of colour throughout, the latter being unaffected by the atmosphere or sea water, and, finally, the facility with which it adapts itself to being rolled and drawn into tubes, wire, &c. Considering the enormous opening for a first-class metal of this description for every type of fitting and component parts of vehicles, cycles, ships, railway carriages, &c., without mentioning the thousand and one small articles to which it is applicable, the calculations as to prospective profits of the directors do not seem excessive. As we have previously stated, the strength of this special metal is very remarkable, Messrs. David Kirkaldy and Sons having reported that a sheet 30 by 20 by 12 inches, I.W.G., stands a stress of 139,228 lbs. to the square inch, with an extension of 35·1 per cent. in 10 inches.

The purchase price for the business and assets of Mr. F. R. Martino, the freehold and leasehold premises before referred to, the patents, trade marks, and goodwill, has been fixed by the vendors, who are the only promoters, at £130,000, payable as to £80,000 in cash, and as to £50,000 by the allotment of fully paid ordinary shares of that amount.

The list of applications will be opened on Wednesday, June 16th, 1897, and closed on or before Friday, June 18th, 1897, at 4 p.m. for town, and on or before Saturday, June 19th, for the country and abroad.

The information which we published in our last issue regarding the decision of the French law courts against the Welch-Dunlop pneumatic tyre patents has, we notice, already begun to bear fruit, as shareholders appear to be getting very restless and anxious about the value of their property which was so glowingly set forth in the prospectus issued some time back. Some rather pertinent questions are being raised by various correspondents, and "Astley" in writing upon the subject says:—"I imagine most shareholders in the Dunlop Pneumatic Tyre Company (France) (Limited), like myself, think it high time the directors called a meeting and explained how the Company now stands as to the validity of its patents, position, and prospects in face of the recent decision in the French courts. It would also be interesting to know what the 'experts'' opinions are now worth, also the contingent claims upon 'firms who have infringed'; also if the vendors or promoters are likely to come forward and show their generosity out of their immense profits. The prospectus drew attention to the fact that profits were taken over from October, 1895, and gave one to understand they were very substantial profits—yet, in spite of this, although 20 months ago, there is no mention of even a small interim dividend. The sooner the shareholders know exactly how matters stand the better." Which appears to be reasonable. In France they do many things better than in England, and although we are sorry for the unfortunate shareholders, in this case we are inclined to think the decision of the French courts upon the "novelty" of the patents is not a very unreasonable one.

Mr. H. Swingler, of Edgehill, Derby, another correspondent, goes one step further, as he, having been in correspondence with the secretary of the Company, is anxious to act with other shareholders in insisting upon the directors calling a meeting so that they may know the position of affairs. With this object in view he is prepared to co-operate with others, as well as to subscribe towards expenses. Possibly those who were originally responsible for the issue will be able to afford some information at any meeting which may be held, and some valuable points no doubt might be gained by communicating with Mr. A. M. Broadley, at the Midland Grand Hotel, St. Pancras, who, we believe, has a good deal of inner knowledge upon most points involved at the time of the flotation of this and some kindred companies.

The Dutch-Roumanian Petroleum Company at Amsterdam has been over-subscribed 115½ times.

Messrs. M. Samuel and Co. are converting that portion of their business relating to petroleum and its storage and transport into a private limited liability company, under the name of the Shell Transport and Trading Company (Limited), with a paid-up capital in ordinary shares of £1,800,000. No shares will be offered to the public.

New Issues.

For the Month ending June 14th.

Brampton Brothers (Limited).—Share capital £200,000, divided into 15,000 six per cent. cumulative preference shares of £5 each, and 125,000 £1 ordinary shares. Formed to acquire and carry on the business of Brampton Brothers, manufacturers of cycle and motor-car chains, saddles, chain wheels, and other cycle and motor-car accessories, &c. The Company acquire the freehold and leasehold works at Oliver Street, and the freehold works at Chester Street, Birmingham. The prospectus states that the firm employ about 1,000 hands, and that recent additions to the Chester Street works will accommodate 500 more. The net profits from August 1st, 1895, to July 31st, 1896, have amounted to £27,120, and those from August 1st to April 15th last to £28,910, or at the rate of £32,798 per annum. Purchase price £181,500, payable £125,000 by the allotment of all the ordinary shares, and the balance in cash, leaving £18,500 for working capital.

The James Cycle Company (Limited).—Share capital £50,000, in £1 shares. Formed to acquire the business of Mr. Henry William James (trading as Harry James), of the James Cycle Works, Sampson Road North, Birmingham, manufacturers of the cycles known as the James Cycles, also the leasehold manufactories and premises at Birmingham and depôt at Liverpool, the goodwill, machinery, plant, stock-in-trade, and other assets. Purchase price £40,000, payable £16,666 in fully paid-up shares, and the balance of £23,334 in cash.

Brown Brothers (Limited).—Formed to acquire as a going concern the business of Messrs. Brown Brothers, general hardware, cycle parts, accessories, and fittings, lamp, tool, and machinery warehousemen, of Great Eastern Street, London, together with their branch at 24, Passage de l'Opera, Paris, and the business carried on by them at 44, St. Mary Axe, London, under the style of H. A. Knox and Co., and all the assets of their business. Share capital £250,000, divided into 20,000 preference shares of £5 each and 150,000 ordinary shares of £1 each. Purchase price £250,000, payable as to £150,000 in ordinary shares (the whole issue) and the balance in cash.

The New MacGregor Cycle and Engineering Company (Limited).—Share capital £60,000, divided into 25,000 cumulative seven per cent. preference shares, 25,000 ordinary shares, and 10,000 deferred shares of £1 each. Formed for the purpose of purchasing the MacGregor Cycle Company (Limited), now carried on at Nottingham, including freehold factory, lately erected by the vendor company at Apsley Lane, Nottingham, and surplus land, and also all the plant, machinery, and assets of the vendor company. Purchase price £45,000, payable as to £10,000 in deferred shares, and as to £35,000 at the option of the new Company, either in cash or ordinary or preference shares.

Blackpool and Fleetwood Tramroad Company.—Share capital £120,000, in £10 shares. Formed for the purpose of working, by electricity on the overhead system, a tramway from Talbot Road Station, Blackpool, to the borough boundary, and constructing, working, and maintaining a tramroad from the borough boundary to Fleetwood, and a tramway in Fleetwood—altogether over eight miles in length, held by the Company in perpetuity, except the portion in Fleetwood, which may be purchased at the expiration of 30 years, and the line in the borough of Blackpool, which will be held on 21 years' lease from the Corporation. Estimated annual profit, £14,400. Authorised borrowing powers, £40,000.

South Wales Motor-Car and Cycle Company (Limited).—Share capital £5,000, divided into 1,000 shares of £5 each. Formed in December last for the purpose of experimenting with motor vehicles and of acquiring the business of Mr. Josh. Williams. At that time £2,000 of the capital was issued. Since then two depôts have been opened—one at the Docks, and the other in High Street, Cardiff—and this issue is the remaining £3,000 capital, with the object of further extending the business. The Company has secured the sole agencies in the district for the Steam Carriage and Wagon Company (Limited), the New Beeston cycles and motors, &c.

New Companies Registered.

[Under this heading we give a full list of new Companies registered which take power to make, deal, or become interested in any manner in automotor vehicles. We shall be pleased to reply with detailed particulars to inquiries through the "Answers to Correspondents" column. All communications should be addressed to the Editor. The only stipulation which we make is that where the inquiry involves a search of the records at Somerset House—as in the case of information on the subject of the holdings of shareholders—a postal order must be enclosed to cover the Government stamp of one shilling which is charged before a search is allowed to be made.]

	Capital.
Accumulator Syndicate, Ld.	£30,000
Ames Brake Syndicate, Ld. (Guildhall, Northampton)	1,700
Bailey Bros., Ld. (53, Tenby St. North, Birmingham)	8,000
Birmingham Carriage Lamp Co., Ld. (City Lamp Works, Birmingham)	15,000
Blackpool Motor-Car Co., Ld. (Commercial Buildings, Leeds)	10,000
Brampton Brothers, Ld. (Oliver St. Wks., B'ham.)	200,000
Frank Peach & Co., Ld. (48, Holborn Viaduct, E.C.)	50,000
Hewett's Chain-Gearing Syndicate, Ld. (6, Jeffrey's Square, E.C.)	15,000
Hitching's, Ld.	50,000
Hull & Barton Cycle Manufactrg. Co., Ld. (Butt's Rd., Barton-upon-Humber, Lincolnshire)	10,000
Ideal Cycle Syndicate, Ld. (3 & 4, Crooked Lane, E.C.)	10,000
James Cycle Co., Ld. (26, Waterloo St., B'ham.)	50,000
Kear-Appleton Cycle & Engineering Co., Ld. (Redcross St., Bristol)	50,000
Masonoid Silver Syndicate, Ld.	3,000
Messrs. Cross & Mathews, Ld.	60,000
Mulliner (London) Ld. (28, Brook St., W.)	10,000
National Motor-Carriage Syndicate, Ld. (37, Walbrook, E.C.)	30,000
New Macgregor Cycle & Engineering Co., Ld. (Nottingham)	60,000
Peerless Accumulator Syndicate, Ld.	15,000
Perry & Co., Ld. (36, Lancaster St., Birmingham)	800,000
Progress Cycle Co., Ld. (Foleshill, Coventry)	50,000
Robert Bunting & Sons, Ld. (19, St. James' St., Sheffield)	85,000
Thornton Motor Co., Ld. (Worsley St., Hulme, Manchester)	1,000
White, Jacoby, & Co., Ld. (54, Bayham Place, Camden Town, N.W.)	4,000
Yorkshire Motor-Car Co., Ld. (Bradford & Harrogate)	2,500

CONTINENTAL NOTES.

THE "Société Francaise d'Automobiles pour Construire des Voitures sans Chevaux" has recently been formed with a capital of 600,000 francs. M. Gaillardet is director and chief engineer.

L'Autocar advertises for a motor-car which shall carry 1,500 kilos. at a speed of 15 kilometres for 15 hours per day, or, in other words, a motor-car is required that shall have a speed of 9·3 miles and shall carry $1\frac{1}{2}$ tons for 15 hours per day.

IT is said that owing to the death of M. Levassor the business of the Société Panhard-Levassor will be carried on by the former gentleman as sole proprietor, or a public company might be formed. The firm is very busy with orders for its type of motor-car. We are glad to hear it.

"LA SOCIÉTÉ D'ENCOURAGEMENT POUR L'INDUSTRIE NATIONALE," whose address is 44, Rue de Rennes, Paris, offers a prize of 2,000 francs for the invention of a new means for the safe employment of heavy petroleum. ·800 specific gravity safety in the use of petroleum is one of the principal objects to be attained.

A WRITER in our contemporary, *La Locomotion Automobile*, exhibits his Anglophil propensities by signing himself "O'Tom Obile." We had some difficulty at first in recalling to mind such a distinguished family name, but at last we grasped it. Not bad, is it? Next please.

A PUBLIC service of automotors is to be inaugurated from Antwerp to Brussels on lines similar to that which govern light railways in Belgium.

THE Committee of the Automobile Club of Paris has voted a medal to M. Georges Broca, director of the Paris Tramways, in recognition of the great services he has rendered to the cause of automobilism in substituting mechanical traction in place of horse traction. How different with us. Our tramway and 'bus company directors in London are marking time and are waiting, to use their own language, for the production of a "really satisfactory" motor. Everything comes to him who knows how to wait—even (as *The Engineer* would say) a "really satisfactory motor."

THE Vicomte de Champfleur has had a Panhard and Levassor motor-car for three years, and in which he and his wife have travelled more than 3,000 leagues.

IT is proposed to introduce automotor fire-engines for use in Paris. We should think so, too, after the late terrible accident, which, like our London warehouse fires, demonstrated the inutility of steam squirts drawn by horses.

A MAJORITY of Paris cyclists have adopted Saint Cloud as their patron saint in preference to Saint Germain.

THE General Council of La Charente has authorised the establishment of several services of motor-cars to facilitate communication between the various towns.

THE "Concours d'Art Industriel" has not succeeded in effecting any decided improvement in motor-cars. The Competition is, indeed, a failure so far as bringing forth any really practical types of motor-cars is concerned, and hence the three medals were not awarded. Five competitors received money prizes and mention. Really, the Concours had the effect of producing some of the most fearful and wonderful looking things on wheels it is possible to imagine, and even those machines which obtained reward and mentiou are beautiful examples of what to avoid in motor-car work.

La Locomotion Automobile illustrates, rather unkindly we think, these prize winners. M. Pierre Selmersheim obtained a special mention and 500 francs for a motor-car, which, no doubt, is efficient in affording protection to the driver and passengers, but which at the same time resembles a huge cocked hat on wheels with numerous windows—a more atrociously ugly thing it is difficult to conceive.

Four other motor-cars obtained mention and money prizes of 150 francs. That of M. Vireux resembles a four-wheeler with a clothes basket in front and a "boot" behind; that of M. Courtois is also like a four-wheeled cab with a kind of elevated coffin attached to the rear, in the upper part of which the driver sits and looks over the roof. M. Frich's car is something like a phaeton in a very early stage of development, and it carries a kind of cow-catcher in front. M. Lafore's car looks like an overturned Nautilus shell. The appearance of these cars in London would, we think, evoke that ridicule which kills. It is evident that none of these designers have considered the æsthetic element. A London omnibus or "growler" may not be as artistic as Apollo's chariot (we believe that gentleman used to take occasional carriage exercise), but they are things of beauty compared to the motor-cars in question. To use the language of the distinguished reporter to the jury they certainly are *not* calculated to arouse either enthusiasm or admiration, but we admit with him that the subject involves much difficulty.

Notwithstanding the disappointment with which Motor-car Competitions have so far resulted in, our French friends are determined to solve the problem of producing a motor-car that will replace the dray and wagon. That enterprising and patriotic body, "L'Automobile Club de France," whose efforts in the direction of automobilism we cannot sufficiently appreciate, have evidently intended that if we claim the honour of the locomotive, to France shall belong the honour of producing the "really satisfactory" (will *The Engineer* please note) motor van. To this end they have arranged for a competition for automotors and other tractors intended for heavy weight the minimum weight to be carried being one ton, either of passengers or goods. The object of the vehicles being for use either as street cars or, as we should say, railway omnibuses or as parcels vans. The competition will take place on August 5th of this year, near Paris, and is international. A competitor can enter as many vehicles as he pleases, provided they are not of the same type. Each vehicle pays an entrance fee of 200 francs, and double that if entered after the official date, June 1st. The list of engagements closes on June 25th. Since writing the above we hear that the competition has been postponed for a month, at the request of competitors. We hope that at the last minute the "L'Automobile de France" will not be disappointed as was *The Engineer.*

The Technical Commission is composed of MM. Barbet, Bourdi, Broca, de Chasseloup, Laubat, Collen, Jentaud, Lemoine, Mommerqué, Perignon, Talansier, Varennes, Hospitalier, Forestier, Panhard, Michelin, Mors, and Quesnay. M. Le Compte de Chasseloup is the organising director.

According to *Les Sports* the entries have been very numerous, but we do not hear that any English firms have entered. If we might suggest, we should say that the Liquid Fuel Company, of Cowes, and Mr. Thornycroft, of Chiswick, might enter their motor-cars with decided prospects of success. It is all very well for our contemporary *Les Sports* to decry the exhibits at the Crystal Palace Show, but we cordially recognise that even they could not approach the motor-cars which were shown at the Magasins du Louvre—in sheer ugliness. *Les Sports* says that the decision of the jury in the latter case has been most severely criticised; we should think so, indeed. The French have undoubtedly a keener artistic perception than we have, and how anyone can commend these things passes our comprehension.

Automobilism in France is evidently a matter which involves (and rightly so) a commendable attention to the inner wants of the human motor, which somehow finds in automobilism no end of excuses for the consumption of pleasant "fuel" in the shape of dinners, which, in their turn involve free "lubrication" through the valves, &c. Thus the members of the Automobile Club de France find it necessary, in order to undergo the severe mental and physical hardships involved in their search after *The Engineer's* "really satisfactory" motor, to recuperate themselves with dinners, picnics, &c. (a course of conduct of which we ourselves highly approve). On this side of the channel, however, automobilism is under a cloud at present, and hence we take our bread and cheese sadly, and *don't* ask our friends to share the repast.

MOTOR-CAR FITTINGS.

It is a significant sign of the growth of the motor-car industry when we see the leading steel makers laying down plant especially to cater for the trade. Among those who are devoting themselves to the manufacture of the various forgings, stampings, &c., used in the industry, we should mention the Kelham Rolling Mills Company, of Sheffield. This firm of ironmasters possesses plant and equipment for the rapid and accurate production of all

those parts which must be light and yet very strong. Their speciality is, however, tyres; these they make of every conceivable section and size, several rims being specially designed to take the rubber motor tyre of Mr. Jessop Browne, of 104-107, Great Brunswick Street, Dublin, one of which we illustrate herewith.

Improvements in Gas Motors.—Mr. Tremlett Carter has worked out the details of a new gas-engine cycle which he has invented. According to the *Electrician*, the principal improvements in the Otto cycle which this new cycle is directed to effect are :—(1) The useful recovery of heat wasted in the jacket and the exhaust, which in the Otto cycle is represented by some 70 to 80 per cent. of the total heat; (2) the abolition of the idle revolution, without the use of two working cylinder ends, and without the use of a pump for compressing the explosive mixture; (3) an increase in the power obtained from a given-sized cylinder; (4) prompt and efficient regulation without omission of explosions; and (5) a means of increasing the power of the engine considerably beyond the normal, to enable it to take extra heavy loads for short intervals. The consumption of gas by an engine working on the new cycle is expected to be from 50 to 60 per cent. only of the gas consumed in the Otto cycle, the thermal balance-sheet showing a thermo-dynamic efficiency of 40 per cent. for engines of moderate size.

CORRESPONDENCE.

**** We do not hold ourselves responsible for opinions expressed by our Correspondents.*

**** The name and address of the writer (not necessarily for publication) MUST in all cases accompany letters intended for insertion or containing queries.*

RUBBER TYRE PATENTS.

To the Editor of THE AUTOMOTOR AND HORSELESS VEHICLE JOURNAL.

DEAR SIR,—It has been our misfortune not to see your excellent JOURNAL until just lately, and only yesterday were we able to obtain the February number, in which we find reported on page 202, a report of the hearing of the application by the Shrewsbury and Talbot (S. T.) Cab and Noiseless Tyre Company (Limited), for prolongation of Carmont's patent, No. 703, it is therein stated that Mr. Alexander, Q.C., and Mr. Baker appeared for "various opponents," this is an error which in justice to ourselves (though late in the day) we must ask you to be good enough to correct. WE ALONE took out a caveat, entered objections, and took the very costly course of getting up a case against the application of the S. T. C. Company, by accountants, experts, and others, and by appearing by Counsel before their Lordships of the Judicial Committee of the House of Lords, when, owing to, as we are informed, our action the petition was dismissed. We should be obliged by your inserting this letter in your next issue. Kindly see enclosure.—We are, dear Sirs, yours truly,

Per pro KELHAM ROLLING MILLS COMPANY (Limited),
J. B. BOOTH, Director.

Kelham Island, Sheffield,
May 29th, 1897.

(Enclosure referred to.)

Extract from the "Sheffield Daily Telegraph," February 4th, 1897.

IMPORTANT ACTION BY A SHEFFIELD COMPANY.—The Kelham Rolling Mills Company (Limited) were successful in an important case decided yesterday. The action was one heard before the Judicial Committee of the Privy Council, including Lord Herschell (president), Lord Davey, Lord MacNaghten, and others, for the prolongation of a patent, No. 703, for the manufacture of tyres for rubber-tyred vehicles. The patent was one taken out by Mr. William Hassalwood Carmont, consulting engineer, and the Kelham Rolling Mills Company objected to the patent being prolonged. Mr. Sutton, Q.C., appeared for the Attorney-General, Mr. Cozens Hardy, Q.C., and Mr. Wilkinson for Mr. Carmont and the Shrewsbury Talbot Noiseless Cab and Tyre Company, and the Kelham Rolling Mills Company were represented by Mr. Alexander, Q.C., and Mr. Baker (instructed by Messrs. Porrett and Fawcett, Sheffield). The hearing of the action occupied a long time, and many expert witnesses were in attendance. Their Lordships finally gave judgment in favour of the Kelham Rolling Mills Company, and decided not to grant a prolongation of the patent.

THE BRITISH MOTOR SYNDICATE'S "MASTER PATENTS" AND ROOTS AND VENABLES.

To the Editor of THE AUTOMOTOR AND HORSELESS VEHICLE JOURNAL.

DEAR SIR,—Referring to the correspondence between the British Motor Syndicate's solicitors and ourselves which you inserted in the May issue, we think that the detailed contents of the No. 6 letter to which you made reference should prove of particular interest to your readers generally, as we especially wanted to draw attention to the points as follows, viz., that having written on the 17th and 25th of March each time asking for numbers and dates of the patents which it was alleged we were infringing, and still receiving no reply from Messrs. Sharpe and Parker, we then informed Messrs. Sharpe and Parker that whereas they alleged we were infringing the patent or patents of the British Motor Syndicate, we claimed that an infringement of these patents was impossible, because, firstly, our patents deal with petroleum *oil* motors, while the patents of the B.M.S. are in connection with petroleum *spirit* motors and use that dangerous spirit benzoline. Secondly, ours is the only carriage *oil* motor, and, therefore, is in another class to the *spirit* motors of the B.M.S. Thirdly, our patents are prior as to date to the B.M.S. patents. Mr. Roots made the first oil-engine, although another firm put one on the market first; our patents are therefore, the only master patents, although this has been widely claimed by the B.M.S.

So far from our infringing the B.M.S. patents, we have been authoritatively informed that the B.M.S. is infringing our patents, and we shall endeavour to obtain evidence on this point.

After then referring to the suggested use of our patent, No. 23,786, as stated by you, we then mentioned that when our Mr. Roots in 1893 sold a vehicle oil-motor to Messrs. Peugeot, he gave them permission to use this invention (No. 23,786) on that vehicle only, to which his motor was fixed, and no other, and we then asked, as appears in the subsequent letters, as to whether the Daimler carriages of the B.M.S. use this method of cooling the motor jacket water.

By inserting this letter in your next issue we shall be obliged.—Yours faithfully, ROOTS AND VENABLES.

100, Westminster Bridge Road,
London, *May 25th*, 1897.

THE MOTOR-CAR COMPETITION.

To the Editor of THE AUTOMOTOR AND HORSELESS VEHICLE JOURNAL.

SIR,—I have read with both interest and regret the leader on the above subject in *The Engineer* of the 4th inst.

The opinions and suggestions as set forth there raise such momentous questions that some further consideration of them cannot fail to be of interest.

The Engineer roughly outlines the probable conditions of service of the successful motor-car, which, as I understand them, are that it must be capable of being steered, managed, and maintained by one semi-skilled man—a man knowing about as much of engineering as the average groom or coachman knows of veterinary surgery. A discussion of the possibilities of constructing such a motor-car will probably be instructive. In my opinion—and I have had some experience of steam launch machinery run by half-skilled men—it is impossible that such a man as has been referred to could satisfactorily take care of a compound high-speed engine, water-tube boiler, and surface condenser suitable for a motor-car; but it does not follow that it is impossible to make machinery for this purpose which he could manage. It is into the peculiarities of this machinery that I propose to inquire.

The boiler must be of simple and strong construction, incapable of explosion, and yet not too heavy; it must also be capable of regulating its own water level and furnace temperature, for no one could steer a carriage in ordinary traffic and at the same time have to be constantly handling feed and fuel cocks. The only boiler which seems at all promising as likely to comply with these conditions is some form of instantaneous generator. Possibly a combination of steam tubing could be arranged to form such a generator which, if feasible, would possess the advantages of great cheapness and facility for repair.

With such a generator a pressure-piston balanced by a spring would suffice to regulate both water supply and furnace temperature. Of course, I assume that petroleum would be the fuel used, as with a suitable burner it does away with stoking and smoke, besides being under perfect control and being capable of great ranges of power. The engines of this conveyance probably present greater difficulties than the boiler. They must be able to run for very extended periods without anything but the most elementary adjustment; they must be able to do with no oil one week and half a pint per hour the next, and must be able to stand cleansing with a stable hose. This looks rather a large order, but it is not quite as extensive as it seems. Of course, it excludes anything like high-speed compounds and such-like engines, and it precludes the possibility of using the lightest possible engines, which, however, there is no necessity for; in fact, it is hardly likely that any form of double-acting engine would stand such treatment.

The most promising line of advance is in the single-acting direction. A single-actiug engine, either simple or compound, can be built which may be simplicity itself, and as it has pressure only in one direction and no bottom cylinder covers, wear in the bearings only increases the clearance, and adjustment is unnecessary for a very long time. For instance, a single-acting compound engine with two cranks at an angle of 180° can be arranged with the ports in the cylinder walls, the piston acting as slide valves, and the high-pressure cylinder exhausting direct to the low pressure. Some extra clearance would have to be provided to obviate back pressure, but the loss from this source would be amply compensated by the total absence of complication. The only valve required would be an admission valve—a tappet valve, if you like—to the high-pressure cylinder. Or, as we have a valve we can make it work full time, and by controlling the high-pressure exhaust do away with unnecessary back pressure in this cylinder.

Such an engine can be safely boxed in, and given a crank pit oil bath which will carry sufficient oil in ordinary work for a long time if the party in charge should happen to forget he has such a thing as an engine to look after. Parsons's steam turbine would be an ideal car motor; but I am informed that there is a difficulty in reducing the speed, and I believe one has to use two of them if one wishes to reverse.

As to the condenser, nothing like a circulating fan can be admitted. Our only sources of circulating energy are the waste funnel heat, as with a funnel casing, and the force of the exhaust. With a surface condenser the former is the only feasible plan, and the weight would be considerable. Some time since an engineer of high standing suggested the use of an air-jet condenser, using the exhaust steam to carry air into a condensing chamber, and in this way there is a chance of making a cheap and indestructible condenser. Some waste of water would be inevitable, but with the boiler suggested no great harm would result from filling up at the nearest pond. It may be as well to pause here to remind intending builders of motor-cars for the market that the party in charge of them is fairly certain, sooner or later, to fill them up at a horsepond. This is worth bearing in mind when designing a boiler. Along these lines it may be possible to build motor-car machinery sufficiently hardy for the public use.

Finally, I may be able to give a word of consolation to those who feel disappointed over the result of *The Engineer* competition. As a maker of petroleum burners for motor-car furnaces, I am in a position to know that some of the best firms in England, beyond those mentioned in *The Engineer* entry list, are working at the motor-car problem.

Camborne, *June 8th*. J. S. V. BICKFORD.

[We agree with our correspondent; elsewhere we have pointed out that more engineers are quietly working out the automotor problem than our contemporary is apparently aware of. We have also expressed a high opinion of the suitability of Parsons's turbine.—ED.]

A HINT TO ENTERPRISING FIRMS.

To the Editor of THE AUTOMOTOR AND HORSELESS VEHICLE JOURNAL.

DEAR SIR,—I often experience great difficulty in finding out where to get parts made for autocars, such as hinged axles, large sized ball bearings, large wheels, tubular or other frames, and other parts. I have sometimes written to a number of firms who make carriage parts, but they often decline to undertake special work for motor carriages.

If those firms who are laying themselves out for this work would advertise their names in your JOURNAL it would assist many who, like myself, are working out improvements in autocars, and it would undoubtedly be to their own advantage. I enclose my card, and remain, yours faithfully,

PATENTEE.

June 10th, 1897.

PROCEEDINGS OF SOCIETIES.

Petroleum as Steam-Engine Fuel.*

PETROLEUM as liquid fuel has been used much more largely than other oils, but gas tar, creosote oil, and green oil from gasworks have also been found to be very effective. The first experiments in Russia with petroleum were made in 1874, but it was not until 1883 that liquid fuel was used to any great extent in locomotives. Many experiments were tried in the direction of using atomisers or pulverisers for the purpose of making liquid fuel into the form of a spray, and amongst them may be mentioned those of Lentz, Artimeff, and Brandt. In 1884 a communication as to the use of liquid fuel for locomotives in south-east Russia was made by Mr. T. Urquhart to the Institution of Mechanical Engineers, and that communication contains very full information as to the way in which the work was done.

While there is little doubt that there are great advantages in the use of petroleum refuse for raising steam, either in locomotive or other boilers in a country like south-east Russia, where such fuel can easily be obtained, the difficulty of obtaining it at a reasonable price in this country has been a barrier to the introduction of liquid fuel as an article of considerable consumption, although its great convenience and adaptability render it a very desirable fuel if anything can be done in the way of ensuring a constant supply at a moderate price. Roughly speaking, the author has found that with Lancashire coal at 9s. per ton, liquid fuel ought not to cost more than 1*d*. per gallon to do equivalent work. In the south of England, where coal is dearer, the conditions are somewhat more in favour of oil. The use of oil is in some respects not unlike the use of gas in a gas-stove, as it can be turned off at once when it is not wanted, and started again at a moment's notice, thus preventing waste. The combustion can be made so perfect as to get rid of all smoke, and, if proper precautions are taken, no damage whatever is inflicted upon the fire-box plates. These no doubt have to be protected in some instances by a lining of brickwork where the spray impinges upon one spot constantly, but, on the other hand, the fire-box sides in a locomotive are relieved from the constant abrasion of the coal which tends to wear down the plates between the stays and thus reduces the life of the fire-box.

A liquid-fuel system does not necessitate the radical alteration of a boiler, as in most cases arrangements can be made:—1st, either to burn coal alone; 2nd, coal and oil in such proportions as may be convenient; and 3rd, oil alone.

The theoretical evaporative value of different kinds of oil compared with coal has been as under:—

THEORETICAL EVAPORATIVE VALUE OF PETROLEUM FROM AND AT 212° F.

	Lbs. of water per lb. of fuel.
Pennsylvanian heavy crude oil	21·48
Caucasian light crude oil	22·79
,, heavy ,, ...	20·85
Petroleum refuse	20·53
Good English coal	14·61

The methods of applying the oil-jet in a locomotive boiler have been varied a good deal, in some cases the oil being introduced through the fire-hole door, and in other cases the jet being inserted below the foundation rings; so that, as Mr. Urquhart pointed out, he was able where he burnt nothing but liquid fuel to close up the fire-hole door altogether, thus obtaining more heating surface in his fire-box.

The method adopted by Mr. Holden on the Great Eastern Railway is to put in two special openings through the fire-box casing, into which are entered the oil-jets.

There are on the Great Eastern Railway 37 locomotives, 13 stationary boilers, and 4 furnaces fitted with liquid-fuel firing at present. In the case of the locomotives, the oil-fuel is carried in two cylindical tanks placed on the tender, leaving the central space perfectly free to hold coal as before. Suitable provision is made for warming the oil in these tanks in the winter. From these tanks the oil is carried by pipes to the engine foot-plate, where, after passing through the necessary valves, it is sprayed into the fire-box by the injectors. Sections of one of these injectors are shown in the figures on next page.

An ingenious addition to this form of injector has a pipe at the end through which heated air, heated by the waste heat in the smoke-box, can be drawn through the injector, which it enters at a temperature of 300° F., and combined with the oil as it enters the fire-box. Another use which is made of this induced current where a locomotive happens to be fitted with the automatic vacuum brake, is to couple the injector up with the brake-pipes and make the fuel-injector act as an ejector for maintaining the vacuum throughout the train. Where this is done, of course the advantage of the heated air going into the fire-box is not obtained. Should oil-fuel be used alone, it is only necessary to cover the fire-bars with a thin coating of broken fire-brick so as to prevent the in-rush of too much cold air.

The consumption of fuel for doing corresponding work is stated to be, on the Great Eastern Railway, as follows:—

			Lbs. per mile.
When using coal only			35·4
,, ,, ,, and oil combined	coal	11·8	
	oil	10·5	
			22·3
,, ,, oil only...			16·5

* Excerpt of paper read before the Institution of Civil Engineers, by J. A. ASPINALL, Esq., M.I.C.E., &c.

Once the use of oil is arranged for in considerable quantities, it becomes an easier matter to supply the locomotives with their fuel than in the case of coal, as the oil can be allowed to run out of suitable tanks with great facility into the reservoirs provided upon the tender. The fuel employed on the Great Eastern Railway until recently consisted of Russian astatki, or petroleum refuse, having a specific gravity of 0·906, and an ignition temperature of 336° F., but the quantity imported to this country is not sufficient at present to make it readily obtainable. At present green oil is being used, and this is obtained from gas-works, and has a specific gravity of 1·1, and a flash-point of about 220° F.

The author has fitted several Lancashire and Yorkshire Railway Company's locomotives with oil-burning apparatus for use on the Liverpool Dock lines, the main object in this case being, not to economise in fuel, but to get rid of fire risk, on account of the emission of sparks, and also to avoid the production of smoke, which would have been most objectionable in passing some of the Liverpool streets. In this case Holden's injector was used, and the author has reason to believe that this course has been followed by the other railway companies who make use of the Liverpool Dock lines. In the case of the Liverpool engines, creosote oil has been largely used as being the cheapest fuel available, but gas-tar has been found to give very good results.

The use of liquid-fuel for the production of steam cannot be said to be in any way in the experimental stage so far as mechanical appliances are concerned, in fact, it may be called an ideal method of raising steam, the only difficulty arising being that of the question of supplying fuel at a reasonable price, a difficulty not easily surmounted in a country so far removed from the oil-fields.

HOLDEN'S LIQUID-FUEL BURNER AS USED ON THE G.E.R.

Roller-Bearings.*

THE constantly increasing application of roller-bearings to rolling stock and other purposes, and the advantages claimed from such applications, have excited so much attention, that the author feels no apology is needed for introducing this subject to the Institution.

It is certainly somewhat strange that although full knowledge of the advantages of rolling motion, when applied to tractive purposes, has existed for centuries, as illustrated by the use of wheels for transporting heavy loads, it is only within quite recent times that any serious attempt has been made to introduce the same movement between the axles or journals of such wheels and their bearings.

To realise the importance of easy traction it is only necessary to consider the vast sums of money which have been expended in producing surfaces favourable to traction by rolling motion, as exemplified by the railway, tramway, and road systems of this and other countries. It would, therefore, appear that, if by the introduction of roller-bearings to the journals of the rolling stock or to the axles of the vehicles running upon such surfaces, a further and considerable reduction in the tractive effort can be obtained, and this at a comparatively small additional expenditure, the application of such bearings would become general.

The following are the principal advantages claimed for rolling motion in bearings: reduction in starting effort, decreased tractive and revolving effort, economy in lubrication.

If these theoretical advantages are accepted as arising from the application of rolling motion to bearings, the practical question is, Can such bearings be constructed to withstand the shocks of present railway loads and speeds, as also the heavy stresses connected with modern tools and machinery, at reasonable cost?

The requirements of satisfactory roller-bearings may be summarised as follows:—(1) That the proportions of their parts and the materials of which they are constructed are suitable to withstand the stresses imposed upon them. (2) That the bearing-rollers must be kept parallel with their axle or journal, and that they must not be allowed to touch each other. (3) That the bearings must be as simple and contain as few working parts as possible, and that they must be so designed that they can be applied and adjusted by any intelligent workman. (4) That they can be produced at reasonable cost. Simple as these requirements may appear, it is probable that only those who have tried to construct such bearings know how difficult they are to obtain.

The reduction in starting effort in roller as compared with ordinary bearings, which reduction reliable experiments have proved to amount to from 50 per cent. to as much as 83 per cent., is of such importance in all cases of mechanical, electrical, or animal traction, that, if this was the only advantage, it would warrant, other things being equal, the adoption of these bearings. In the case of steam or other mechanical traction, the reduction of starting effort allows of heavier trains or vehicles being controlled by the existing locomotives or other motors than can at present be dealt with. In railway vehicles the starting effort has been found in many cases to be as low as 3 lbs. per ton of load. The following are the results of careful experiments made to ascertain the relative starting effort and running friction of tramcars fitted with ordinary and roller bearings:—

Starting Effort.—Cars weighing 4 tons 15 cwt.; ordinary bearings, 196 lbs., or 41·63 lbs. per ton; roller-bearings, 30 lbs., or 6·53 lbs. per ton.

Running Friction.—Gravity test.

A car fitted with ordinary bearings and weighing 2 tons 15 cwt. was let loose from a point 56 feet up an incline with 1 foot 6¼ inches rise. It ran down this incline and 57 feet along the level line at foot of same, or a total distance of 111 feet. The force expended was, therefore, 6,160 lbs. falling through 1·521 foot, or 9,364 foot-lbs. The average frictional resistance was 9,364 ÷ 111, or 84 lbs., equal to 30·5 lbs. per ton. A similar car fitted with roller-bearings, being let loose from the same point, ran the full length of the level line available, namely, 320 feet, and had not then quite come to rest, the total distance traversed being 376 feet. The force expended was as above, 9,364 foot-lbs. The average frictional resistance was 9,364 ÷ 376 = 29·4 lbs., or about 9 lbs. per ton of load.

In the case of animal traction any reduction would not only be of great economical value by increasing the average life of the animals employed, but would also enable them to perform their duties with much less distress than under present conditions—a result much to be desired.

The following figures are of interest, and are founded on the results of actual experiments in tramway practice:—Relative starting effort of a tramcar on a gradient of 1 in 20—ordinary bearings, 100; roller-bearings, 77; saving 23 per cent. On a gradient of 1 in 80—ordinary bearings, 100; roller-bearings, 50; saving 50 per cent. On a gradient of 1 in 140—ordinary bearings, 100; roller-bearings, 39·6; saving 60·4 per cent.—results which require no comment.

As to decrease in tractive or revolving force, as the case may be, decrease in tractive force is of great consequence in railway, tramway, and road vehicles, as it reduces the constant or "fixed charge" upon the locomotive, motor, or animal; and similarly a reduction in the force necessary to revolve shafting and other machinery is of the greatest economical value, seeing that the amount of power expended in driving the main and counter shafts in workshops has been proved to amount to as much as from 50 to 80 per cent. of the total power employed.

The reduction in the amount of lubrication required is purely an economical question; experiments have, however, shown that at least 50 per cent. saving can be effected by the use of roller-bearings. With a perfect roller-bearing no lubricant is required, but oil must be used to prevent rusting.

As to the possibility of realising the theoretical advantages of roller-bearings

* Paper read at Institution of Civil Engineers, by W. BAYLEY MARSHALL, Esq., M.I.C.E.

in practice, which is the question engineers have to consider, the results so far obtained are to the author's knowledge so satisfactory that his conviction is, that their adoption will be greatly increased in the immediate future. The following examples appear to prove that the experimental stage has been passed, and that roller-bearings have now developed into practical realities :—

The Corporation of Blackpool have had some of their tramcars fitted with roller-bearings, and these cars have been running on their electric tramway for over three years, and with results so satisfactory that they have applied similar bearings to all the new cars which have been constructed since the advantages of these bearings were established; and their consulting engineer some short time ago certified that at least 30 per cent. of energy is saved by the use of such bearings as compared with those in ordinary use.

The Liverpool Overhead Railway made their first trials with roller-bearings some two years ago, and are now gradually fitting them to the whole of their rolling stock. Mr. Cottrell, the engineer and general manager, has been good enough to send examples of the bearings after they have performed a considerable mileage.

The City and South London Electric Railway are now experimenting with roller-bearings applied to their carriages.

The engineers for the Waterloo and City Railway have specified roller-bearings for the whole of the stock ordered for this line.

A passenger train of six carriages fitted with roller-bearings throughout has been running for two years between Brighton and Kemp Town, and has shown a saving of from 12½ to 15 per cent. in the consumption of fuel, which saving has been obtained under disadvantageous circumstances, inasmuch as the engine has to be kept in steam for about 16 hours, whilst its actual running time is under seven.

The Western Railway of France are fitting a complete train with roller-bearings for experimental purposes, and the report of their engineers will undoubtedly be of great value, as investigations of this kind are carried out with great care and skill by our Continental neighbours.

Experiments are being made in some of our Colonies, as also on some of the principal railways in South America.

Roller-bearings have been fitted to many horse-cars with results most beneficial to the animals employed, and it is estimated that the use of them would so prolong the life of the horses that the reduction in their depreciation alone would show a saving of considerably over £10 per car per annum.

In general application, perhaps the most interesting is the fitting of roller-bearings to the big bell of St. Paul's Cathedral, "Great Paul," which with its headstock weighs some 25 tons, and which gave considerable trouble when mounted on ordinary bearings.

It would also appear that there is a large field for the introduction of these bearings to the thrust and ordinary bearings of propeller shafts. The foregoing illustrations of actual application of roller-bearings serve to show the importance of the question and the headway already made, and the author hopes that discussion will throw further light on this important subject.

The Application of the Compound Steam Turbine to the purpose of Marine Propulsion.*

THE manufacture of the compound steam turbine was first commenced in the year 1885 with the construction of small engines for the driving of dynamos; successive improvements were made, and larger engines constructed, but up to the year 1892, the consumption of steam was not such as to justify the application of this class of engine to the purpose of marine propulsion, though on account of its light weight, small size, and high speed of revolution, it presented great advantages over ordinary engines for certain classes of work.

In the year 1892, however, a highly developed compound turbine, adapted for condensing, was constructed for the Cambridge Electric Supply Company, and when tested by Professor Ewing, F.R.S., showed a consumption of steam equivalent to 15·1 lbs. per indicated horse-power per hour, the boiler pressure being 100 lbs., and the steam superheated to 127° F. above the point of saturation.

More recently, compound turbine engines have been constructed up to 900 horse-power, both condensing and non-condensing, and consumptions of steam as low as 14 lbs. per indicated horse-power with saturated steam, and 100 lbs. boiler pressure, have been ascertained in engines of 200 horse-power, and still lower consumptions in engines of larger size. Many of the original engines are still doing good work; some, especially the larger sizes of 500-horse and upwards, are frequently kept at work for several weeks without stopping. The returns of the Newcastle and District Electric Lighting Company show a yearly cost of up-keep of 2½ per cent. per annum, and the total horse-power of turbines now at work in England exceeds 30,000 horse-power.

In January, 1894, a syndicate was formed to test thoroughly the application of the compound steam turbine to marine propulsion, and a boat was designed for this purpose. In view of the large amount of alteration that would probably be required before a satisfactory issue was reached, and the large amount of time and expense necessarily involved, it was decided to keep the dimensions as small as possible, but not so small as to preclude the possibility of reaching an unprecedented rate of speed, should all the parts work as satisfactorily as was anticipated.

The fulfilment of these anticipations was, however, much delayed, and almost frustrated, by a difficulty which, though foreseen, proved to be of a much more serious character than was anticipated. This difficulty was that termed by Mr. R. E. Froude "The cavitation of the water," or, in other words, the hollowing out of the vacuous spaces by the blade of the screw, and this pitfall for the designers of screws for very fast vessels, though indicated by theory to exist, came upon us in the case of our very fast running screw, taxed beyond the usual extent, in its most aggravated form. When the boat and machinery were designed, the trials of the "Daring," which first drew attention to this difficulty, had not taken place.

The "Turbinia"—as the boat is named—is 100 feet in length, 9 feet beam, and 44½ tons displacement. The original turbine engine fitted in her was designed to develop upwards of 1,500 actual horse-power at a speed of 2,500 revolutions per minute. The boiler is of the water-tube type for 225 lbs. per square inch working pressure with large steam space, and large return water legs, and with a total heating surface of 1,100 square feet, and a grate surface of 42 square feet; two firing doors are provided, one at each end. The stokeholds are closed, and the draught furnished by a fan coupled directly to the engine shaft. The condenser is of large size, having 4,200 square feet of cooling surface; the circulating water is fed by scoops, which are hinged and reversible, so that a complete reversal of the flow of water can be obtained should the tubes become choked. The auxiliary machinery consists of main air pump and spare air pump, auxiliary circulating pump, main and spare feed pumps, main and spare oil pumps, also the usual bilge ejectors; the fresh-water tank and hotwell contain about 250 gallons.

* Excerpt of paper read at the recent spring meeting of the Institution of Naval Architects, by the HON. CHAS. PARSONS.

The hull is built of steel plate, of thickness varying from $\frac{3}{16}$ inch in the bottom to $\frac{1}{16}$ inch in the sides near the stern, and is divided into five spaces by watertight bulkheads. The deck is of steel plate, $\frac{1}{16}$ inch thickness.

The approximate weights are—

Main engines	3 tons 13 cwt.
Total weight of machinery and boiler, screws, and shafting, tanks, &c....	22 tons
Weight of hull complete	15 tons
Coal and water	7¼ tons
Total displacement	44½ tons

Trials were made with screws of various patterns, but the results were unsatisfactory, and it was apparent that a great loss of power was taking place in the screw.

From experiments it would appear that in all screws, of whatever slip ratio, there will be a limiting speed of blade, depending upon the slip ratio and the curvature of the back—in other words, on the slip ratio and thickness of blade; beyond this speed a great loss of power will occur; and that should the speed of ships be still further increased, the adoption of somewhat larger pitch ratios than those at present usual will be found desirable.

The boat has been run at nearly full speed in rough water, and no evidence of gyroscopic action has been observable, though such a result would be anticipated from the known small amount of these forces under actual conditions; indeed, the "Turbinia" has so far proved herself an excellent sea boat.

The oiling of the main engines is carried on automatically under a pressure of 10 lbs. per square inch by a small pump worked off the air-pump engine; a small independent duplex oil pump is also fitted as standby. The main engines require practically no attendance beyond the regulation of a small amount of live steam to pack the glands and keep the vacuum good.

The advantages claimed for the compound steam turbine over ordinary engines may be summarised as follows :—

1. Increased speed.
2. Increased economy of steam.
3. Increased carrying power of vessel.
4. Increased facilities for navigating shallow waters.
5. Increased stability of vessel.
6. Increased safety to machinery for war purposes.
7. Reduced weight of machinery.
8. Reduced space occupied by machinery.
9. Reduced initial cost.
10. Reduced cost of attendance on machinery.
11. Diminished cost of upkeep of machinery.
12. Largely reduced vibration.
13. Reduced size and weight of screw propellers and shafting.

APPENDIX.

TRIALS OF THE "TURBINIA."

In December of last year several runs were made on the measured mile, and the maximum mean speed obtained after due allowance for tide was 29·6 knots per hour, the mean revolutions of the engines being 2,550 per minute.

Since then new propellers of increased pitch ratio have been fitted.

Further trials were made on April 1st. The mean of the two consecutive runs gave a speed of 31·01 knots per hour, the mean revolutions of the engines being 2,100 per minute, the fastest run being at the rate of 32·61 knots per hour.

The utmost horse-power required to drive the boat at the speed of 31·01 knots is 946, as calculated from experiments on her model, made at Heaton Works, on the method of the late Mr. William Froude.

Assuming the ratio of thrust horse-power to indicated horse-power to be 60 per cent. (which appears to be the ascertained ratio for torpedo boats and ships of fine lines), the equivalent indicated horse-power for 31·01 knots is 1,576.

The feed-water supplied to the boiler was measured by a Siemens' water metre previously calibrated under the working conditions, and found to be substantially correct.

These measurements were made when running at a speed of 28 knots, and the consumption at 31·01 knots has been calculated from these measurements according to the known law between steam pressure and consumption, and by the observed steam pressures on the engines at the respective speeds. The consumption at 31·01 knots is approximately 25,000 lbs. per hour, or 15·86 lbs. per indicated horse-power. It should be observed that the assumption of the thrust horse-power being 60 per cent. of the indicated horse-power presupposes that the propellers are of the best form attainable, and should those now fitted be superseded by others of higher efficiency, as is possible, and, indeed, probable, then the figures of consumption per indicated horse-power will be correspondingly improved, and the speed of the boat increased.

The consumption of steam at 11·4 knots speed has been measured by meter, and found to be 2,700 lbs. per hour, or equivalent to a coal consumption of about 24·6 lbs. per knot.

CONDITIONS OF RUNNING OF "TURBINIA" AT 31·01 KNOTS SPEED.

Mean revolutions of engines	2,100
Steam pressure in boiler	200 lbs.
Steam pressure at engines	130 lbs.
Vacuum at exhaust of engines	13¼ lbs.
Speed of boat	31·01 knots.
Calculated thrust horse-power	946
Calculated indicated horse-power	1,576
Consumption of steam, reduced to basis of 31·01 knots	25,000 lbs.
Consumption of steam per indicated horse-power per hour...	15·86 lbs.
Total weight of machinery, including boiler, condensers, engines, auxiliaries, shafting, propellers, tanks, water in boiler, and hotwell, in working order	22 tons.
Indicated horse-power per ton of total machinery	72·1 tons.

Owing to adverse weather these trials have been much delayed, and had finally to be made under unfavourable circumstances. They are, however, believed to be substantially accurate.

The Value and Scope of Inland Navigation.*

To arrive at a just opinion of the "Value and scope of Inland Navigation in England" is more difficult than in many other countries, owing to the lack of statistics on the subject.

In Germany and in the United States, and especially in France, the Government supply very complete and useful information on this, as on many other matters of general and commercial interest which are not so fully dealt with by the British Government.

The Board of Trade publishes annually statistics of railways, tramways, shipping and building societies, &c., but not of inland navigation. The canals were anterior to the age of statistics, and had hitherto managed to evade the duty of supplying them to the Board of Trade.

The only attempt at an exhaustive return was made in 1888, and this, owing to its novelty and other circumstances, proved to be very defective.

Whenever opportunity offered I have referred to the insufficiency of this return, and as the question has been at last taken up by many Chambers of Commerce, I look forward to another return being called for on an improved form, and hope that the information sent by the various companies will be carefully sifted, so that the return when published may be useful to traders, carriers, and the public generally.

The importance of inland navigation has been lost sight of in this country for many years, but the time seems to be coming when it will receive greater attention. Sixty years ago, and for many previous years, transport in England cost less than elsewhere, thanks to the sea and the system of inland navigation.

It appears that the rate of freight for perishable goods was 3*d*., for imperishable 2½*d*. per ton per mile, and that this was about half the cost of conveyance by road.

Before the advent of railways, the British canal system of nearly 4,000 miles was without doubt the best in the world, and at this period the average cost of transport in Europe was probably upwards of 8*d*. a ton a mile.

How much the average cost of transport by rail amounts to in England, it is hard to say, as the returns deal only with weight and not with tons per mile, as they do in many other countries.

The *Journal des Economistes* states that in England it costs 1·4*d*. a ton a mile; in Italy, 1·25*d*.; Russia, 1·2*d*.; France, 1·1*d*.; Germany, 0·82*d*.; Belgium, 0·8*d*.; Holland, 0·78*d*.; United States of America, 0·4*d*.; so that Englishmen pay more than their competitors; 75 per cent. more than the Belgians, and 350 per cent. more than the Americans.

Good and cheap transport is essential to manufacturing and mercantile prosperity. The railways are good, but it is clear they are not cheap, and for merchandise they are distinctly dear.

The average charge per ton of minerals is 1*s*. 6½*d*., of goods 5*s*. 1*d*. The receipts from 200,275,270 tons of the former amounted to £15,414,154 as compared with £20,703,007 for 80,048,772 tons of the latter in 1895. The author is not prepared to endorse many of the figures put forward by out-and-out advocates of canals, but there are palpable advantages which have only to be used aright, to enable water-carriage to compete efficiently with railways. One of these is cheapness of construction compared with capacity for traffic.

The average cost of railways in England was never less than £34,000, and is now upwards of £47,000 a mile. The Bridgewater Canal cost from £4,000 to £5,000 a mile, and allowing another £5,000 to have been spent in improving it and making it fit for steamers, the cost per mile becomes £10,000, rather more than one-tenth the average cost of a railway.

The traffic passing over a portion of this water-way, which has a depth of only 4 feet 6 inches, amounts to 1,300,000 tons per annum.

The maintenance of way and works is heavier on a railway than on a canal, and increases more uniformly with an increase of traffic. The life of permanent way is largely dependent on the volume of traffic carried over it, whereas on a canal the additional cost entailed by an increase of traffic is trifling. Expensive arrangements for signalling are not needed on canals. The outlay on canal vessels for an equal tonnage is less than on railway trucks and locomotives, while the number of men employed on a good-sized barge canal is the same approximately, ton for ton, as on a railway.

In facilities for loading and discharging along the route, canals have also an advantage, and the expense of terminal arrangements is much less than on railways. A steam barge 90 feet long will carry 300 tons; a mineral train to carry this would be 550 feet long, an ordinary goods train more than double that length.

A well-managed railway must always have the advantage as regards speed, but there is an immense amount of traffic for which high speed is unnecessary. Regularity is very desirable, and this can be obtained on canals if the system is properly organised.

The American railway rates are the lowest in the world, but this does not prevent the use and improvement of canals.

In 1691 the freight rate for wheat per bushel of 60 lbs. from Chicago to New York was, by rail, 15 cents; by lake and rail, 6·5 cents; by lake and canal, 5·9 cents; the latter was reduced to 5·6 cents in 1892. In order to stimulate competition the State of New York has voted £1,800,000 to improve the Erie Canal and two of its branches, so that the available depth may be increased from 7 feet 6 inches to 9 feet 6 inches, and a considerable length has been taken in hand during the past winter.

The great interest taken, and the expenditure which has been incurred of late years in America, France, and Germany shows the high value put upon inland navigation among the leading competitors of England for the trade of the world.

For twenty years the French have been aiming at making their canals available for craft of 300 tons, and in 1892 there were 2,500 miles of this capacity, and while so doing they have added 81 per cent to the traffic. The improved canals carry two-thirds of the tonnage in weight, and the work done on them amounts to four-fifths of the total ton mileage, carried over nearly 8,000 miles. The mean length of voyage is 91 miles as against 82 miles by rail; a portion of the St. Quentin Canal carries 4½ million tons annually.

Six million tons of goods enter Paris by water as against 15,000,000 tons by rail. Berlin is supplied to the extent of one-half its imports by canal.

In the United States 27½ per cent. of the traffic is waterborne, in France 30 per cent., and in Germany 23 per cent., whereas in the United Kingdom it is less than 11 per cent.

The dead weight carried on French canals amounted in 1892 to 26,000,000 tons; this compares with 34,375,000 tons carried in England in 1888. It is, therefore, evident that the traffic in this country is well worth providing for; but how little has been done to improve the position of navigations is proverbial.

Of the 3,520 miles navigable, 1,264 miles are in the hands of railway companies. There are about 130 different canals under 100 different ownerships. Consequently there is little or no organisation of traffic possible, and a great deal of unnecessary expense is incurred.

The improvement in the permanent way and equipment of railways has been most marked. Locomotives of four tons and rails of 35 lbs. had given place to locomotives of 50 tons and rails of 103 lbs., whereas over nine-tenths of the water-ways no change has been made for a century.

There are undoubtedly certain lines of communication which would pay well for adequate improvement, and, as the attempt to obtain a reduction of railway rates at the hands of Parliament has proved unsuccessful, this appears to be the only means left by which the mercantile and manufacturing community can obtain relief from a state of things which is very detrimental to the commercial position of this country. The cost of internal transport is of such great importance that unless it is materially reduced, I believe the public will ere long become as alarmed on this question as it has been in recent years at our neglect of technical education, and then the nation would be hurried into a wasteful expenditure of capital. In the author's opinion a good system of canals would do much to avoid this, and he considers, therefore, that the value and scope of inland navigation is very apparent.

Specifications Published.

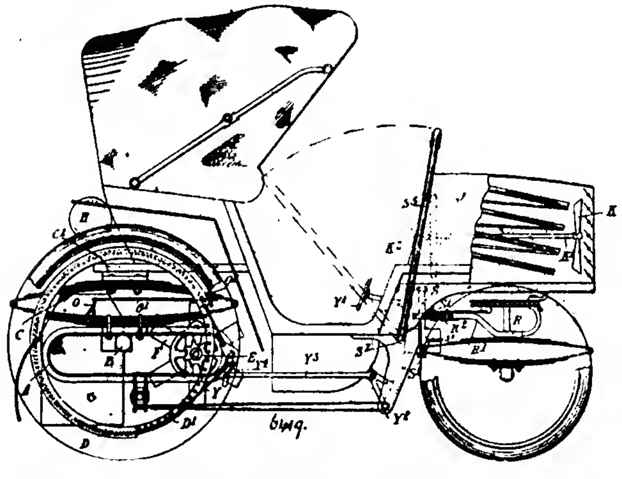
6,419. Self-Propelled Vehicles. Herbert Churchill Capel, 168, Dalston Lane, Middlesex, and Thomas Clarkson, Grove Villa, Carshalton Grove, Sutton, Surrey. March 23rd, 1896.

Relates to:—1st. The mounting of the apparatus upon or in immediate connection with one of the axles, preferably the back axle of the vehicle, so that an existing vehicle can be easily converted.

2nd. An improved system of steering, whereby the fore-carriage usually employed in horse vehicles may be retained and utilised for the new requirements.

3rd. The increasing of the efficiency of the condenser by employing a fan or equivalent driven by the exhaust steam from the engine, so that the speed of the air-propeller may vary according to the quantity of the steam used, and, so far as the motive power is concerned, complete duplication of the whole system.

Two frames, A, are securely attached to the axle, B, of the road wheels, and are conveniently shaped so that the motor and driving mechanism, with or without the fuel tank, and also the boiler if the motor is steam-driven, may be attached to them and enable all these parts to be mounted upon or in immediate connection with, and to be supported by, the axle, B. The latter is non-rotating, and attached, either directly or through the framing, A, to the springs, C, which are connected to the ordinary framing, C¹, of the body of the vehicle. The driving-wheels, D, run loose upon the axle, B, and each carries



on its inner face an internally toothed annulus, D¹, with which engages a pinion, E, carried upon a shaft, E¹, driven directly by the engines. Each of the shafts, E¹, runs in bearings carried by the framing, A, and is provided with an independent motor, F. This arrangement of duplicate shafts and motors enables differential gear to be dispensed with, and also permits of the road wheels being arranged out of the vertical plane, as is commonly the practice.

The motors, F, are preferably operated by steam, and are of the multi-cylinder type, with the cylinders radiating. The boiler, which is of the water-tube type, is enclosed in a casing, G, attached to the frames, A. The tank, H, containing the liquid fuel for the boiler may be placed, as shown, behind the hood of the vehicle, or may be arranged in more immediate connection with the boiler.

A condenser is carried upon the fore-carriage in a casing, J, the front of which is provided with louvres to permit of free access of air. Immediately at the back of these louvres is arranged a fan, K, mounted on a light shaft, K¹, and adapted to be driven by a turbine operated by the exhaust steam from the engine. A casing enclosing the turbine receives the steam from the latter, and either returns it through suitable tubes to the boiler direct, or takes it to the condenser and general circulating system.

The boilers are preferably in duplicate.

The steering device adopted so as to utilise the usual fore-carriage may be arranged in the following manner:—To the framing, R, of the fore-carriage and preferably to the existing shaft receptacles, R¹, is attached a toothed arc, R², the fore-carriage being turned round so as to bring this toothed arc upon the side nearest to the body of the vehicle. In suitable bearings mounted upon the framing of the vehicle is arranged a vertical shaft, S, which carries a pinion, S¹, engaging with the toothed arc, R², and also carries the drum, S². Around the latter passes a cord, S³, either endless or with its ends attached to the drum in such a manner that by pulling the cord one way or the other the drum, S², is rotated, and consequently the fore-carriage turned. The cord, S³, passes from the drum round pulleys and through the tubular sides, S⁵, of a frame which is pivoted at S⁷, so that it can be moved from the position shown in full lines into that indicated by dotted lines. The tubular sides, S⁵, are connected by a cross-bar, the cord passing round pulleys at the corners, and across from one side to the other of the frame. The portion of the cord lying between the pulleys is exposed to the grip of the driver, so that by drawing this portion one way or the other across the vehicle the fore-carriage can be turned in the manner described.

The vehicle is provided with a hand brake, the band, Y, preferably operating upon the exterior of the toothed annulus, D¹, a foot lever, Y¹, pivoted at Y², and connected by a link, Y³, with the lever, Y⁴, affording means of putting the brake into operation. An improved construction of boiler and method of mounting the motor are also described.

6,659. Motive Fluid Engines. Robert Christian John Dicken, of 21, Weltje Road, Ravenscourt Park, Middlesex, and George Dicken, of Rose Villa, Melbourne Road, West Bridgford, Nottingham. March 26th, 1896.

In order to prevent steam or other motive fluid from being wasted in the cylinder of a steam or motive fluid engine on account of the length of the ports between the interior of the cylinder and the valve face, the latter is made curved and concentric with the internal surface of the cylinder, the slide-valve being suitably formed to fit thereon.

The invention also relates to improved means for distributing steam to and from engine cylinders.

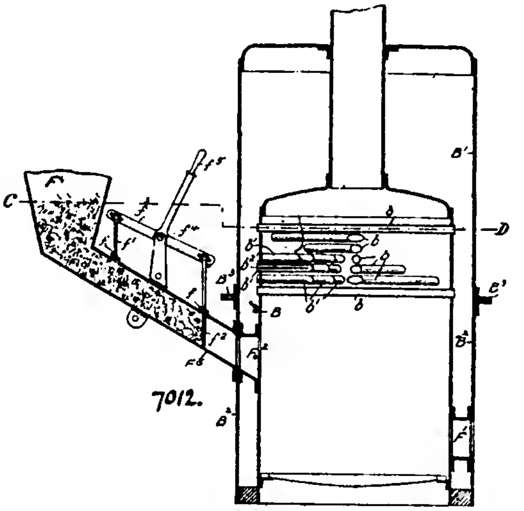
The slide-valve comprises a hollow body, the ends of which are made concave to fit the convex surface of the valve face of the cylinder on which they work, and are provided with ports adapted to be brought alternately into correspondence with the cylinder-ports so as to allow live steam to pass from the interior of the valve into the cylinder. In the portion of the body of the valve remote from the cylinder there fits a hollow plug or tubular piece, which works against a seat on the inner side of the cover of the valve-chest, and by means of which the interior of the body of the valve is kept in constant communication with a steam-inlet in the said cover. This hollow or balance plug is of such dimensions that it and the valve body will be pressed against the cover and valve face respectively with no more than the requisite amount of force to keep them thereon, so that unnecessary wear will be avoided and the power necessary to actuate the valve will be reduced. A spring is provided between the valve body and hollow plug for keeping the plug against the valve face when the engine is not under steam. In exhausting, the steam issues from the cylinder past the ends of the valve into the valve-chest and escapes therefrom through a suitable outlet. The cylinder may advantageously be turned externally and fit into a casing adapted to form both the valve-chest and a steam jacket. Modifications are described.

7,012. Steam Generators and Motors. George Francois Gabriel des Vignes, Teddington, Middlesex, and Stephen Harding Terry, M. Inst. C.E., 17, Victoria Street, London. March 31st, 1896.

Relates to steam generators and motors for self-propelled road carriages.

The boiler is of the vertical type with internal closed firebox. The firebox, B, is fitted in its upper part with a number of superposed cross water-tubes, b, b, of the full diameter of the box which radiate at different angles or spirally from the vertical centre line of the box one above another at suitable vertical intervals apart. In the same horizontal plane as each of these full diameter cross-tubes, b, b, is a number of radial or centripetally disposed closed ended water-circulating tubes, b^1, b^1, of the same or less diameter than said cross-tubes, each having preferably (or where its diameter admits) an internal circulating diaphragm plate, such as illustrated at b^2, in one tube, b^1, extending from the expanded or fixed end of the tube, b^1, for a suitable distance towards its closed end. The uptake may be arranged as usual at or near the top of the box and passing through the crown of the shell as shown, or laterally therethrough as most convenient. The boiler shell is made in two parts, B¹, B², with a central bolted flange, B³, for affording access to the firebox and tubes when required for cleaning, repairing, and the like. In the boiler we prefer to employ two fire holes, one, F^1, about the grate level for lighting up, cleaning out, and so forth, and adapted to be closed up during work; the other, F^2, at a much higher level and preferably at the opposite side of the box as illustrated for firing purposes. The fuel is preferably fed automatically to the upper hole, F^2, by a shoot such as F^3, having an inclination slightly superior to the angle of the rest of the fuel, which is contained in an upper hopper, F^4. In this shoot two suitably formed "cut-off" slides, f^1, f^2, with knife-edged bases work in slots f, f, and are connected by a lever, f^3 fulcrummed at f^4, and having a hand lever such as f^5, or other convenient operating device. The arrangement is analogous to that of the measuring necks of old-fashioned shot pouches, and by it, on oscillation of the lever, f^3, the measured quantity of coal always lying between the slides, f^1, f^2, will be discharged into the furnace as will be readily seen, and afterwards a fresh charge will take its place.

The boiler is connected to the motor, which may consist of a half-speed, self-lubricated engine of the closed compound type, preferably tandem or double-crank, with two separate eccentric rods for the slide valves of the high and low-pressure cylinders, and the novelty of our improvement in such a motor is that we use and arrange the high-pressure valve gland and sometimes the low-pressure valve gland so as to be always exposed to view, for in a completely closed engine experience has shown that it is with these glands and especially the high-pressure gland that trouble by unseen leakage always occurs.



The condensing apparatus consists of a novel kind of combined surface and jet condenser, by which also the feed water for the boiler and the air supply to its furnace are heated, and by which all water of condensation is recovered, whereby great economy and efficiency accrue.

10,781. Application of Electricity to Vehicles Driven by Mechanical Means. Herbert John Dowsing, 24, Budge Row, London, E.C. May 19th, 1896.

This invention relates to apparatus for the production, storage, and utilisation of electricity in connection with vehicles driven by mechanical means, and it is particularly applicable to motor-cars or other vehicles in which petroleum, benzine, or other explosive vapours are used to drive the engine.

An electric generator or dynamo of the continuous current type is fixed on the vehicle and properly geared to the engine, so that the surplus power given off from the engine when driving the vehicle is utilised in driving the dynamo, the current so produced being stored in a secondary battery provided for the purpose. This current may be utilised for firing the engine, or producing light or motive power. The connections between the dynamo and battery can be so arranged that when the speed of the machine falls below the normal and electricity is produced at a lower pressure than that of the storage battery, the current from the battery flows through the machine which then becomes an electro-motor producing mechanical power.

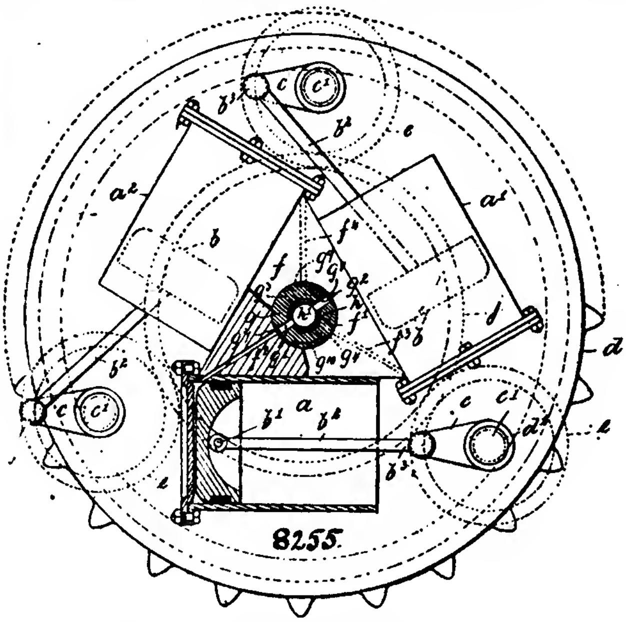
The power of the motor is transmitted by means of belting or other gearing to the engine which it aids to overcome its load, or if the engine is at rest, the power transmitted from the electro-motor will start it. When the engine generates sufficient power to drive the electro-motor at its full speed electricity is again generated, and the pressure being greater than that given off from the battery, storage again takes place.

The connection between the dynamo or motor and battery can be varied or broken either by hand or other means. Automatic contrivances can be employed for making or breaking connection according to the varying speed or current and these may be worked by electro magnetic or mechanical means.

The most suitable dynamo to use for the double purpose of dynamo and motor is a machine of the shunt wound type, as the direction of rotation is the same when generating or using the current.

8,255. Motors Driven by Steam, Compressed Air, Mixtures of Gas and Air, Petroleum and Air, or other Explosive Mixture. James Osmonde Dale, Glendene Grove Lane, Handsworth, Stafford. April 20th, 1896.

a, a^1, a^2, are three trunk cylinders, having pistons, b, reciprocating within them and each having jointedly connected to them at b^1, a piston rod, b^2, whose outer end, b^3, is likewise jointedly connected to a crank, c, mounted upon a countershaft, c^1, passing through a



bearing, d^1, formed in the walls of a plate or carrier wheel, d, and having made fast to its opposite end a spur pinion or driving toothed wheel, e. The cylinders which comprehend or are arranged in the planes of an equilateral triangle are bolted to and carried by a bed, bracket, or boss, f, coming upon or within, the said carrier wheel, d, and with the central hole or bearing, f^1, taking over and working upon a concentrically arranged valve or plug, g, having supply passages, g^1, g^2, and exhaust passages, g^3, g^4, leading respectively from the supply entrance, h^1, and exhaust exit, h^2, of the hollow spindle, h, to the supply ports, g^7, g^8, and exit ports, g^9, g^{10}, whilst directed radially from the central hole, f^1, in the cylinder bed are passages, f^2, f^3, f^4, leading respectively to the cylinders, a, a^1, a^2, and acting in proper sequence and coming alternately over the supply and exhaust ports of the valve as the said bed is bodily rotated, with the cylinders, driving plate and cognate parts of them around the valve as a centre. The driving plate or wheel, d, which may have sprocket teeth upon its periphery for communicating the motion of the motor by chain to a driven shaft, or may be in the form of a drum and have its motion transmitted by a band, carries a brake drum, i, around the periphery of which a braking hand or other like frictional or retarding device comes for the purpose hereinafter described, whilst the spur pinion, e, which, as shown, have each 16 teeth, intergear with the principal toothed wheel, j, having 32 teeth, and being made fast upon the hollow spindle, h^1, carried in end bearings, mounted in suitable supports, and provided with a brake drum, which is normally held fast (when the other part of the motor is at work) by the application of a brake band or other friction or retarding device.

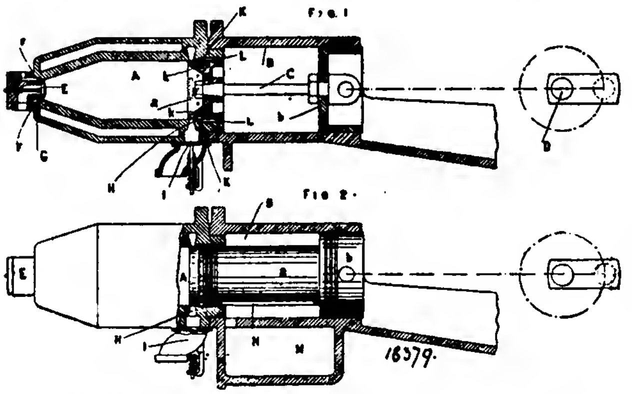
The means for successively exploding the charges of the cylinders of a gas or similar engine is as follows:—

The explosion chamber in the back cover of the cylinder is fitted with a small insulated spring buffer, or equivalent arrangement, against which a projection on the back of the piston comes and makes a contact every time the said piston completes its back stroke. This buffer or spring contact is in connection by a lead wire with a brush of which a number corresponding to the number of cylinders in the engine are mounted upon an insulating ring made fast to and rotating with the driving part of the motor, and these brushes are arranged to wipe over a commutator made fast on the spindle, so that the said brushes come successively upon and make electrical contact with a plate, covering only a small portion of the circumference of the commutator and proceeding from a complete ring, with which the spring tongue or terminal of the electric circuit is in constant connection. A wire leads from one pole of the induction coil or battery the other pole of which is coupled to any suitable part of the engine.

On the piston nearly completing its back stroke, the projection and spring buffer come together, and on the forward stroke being commenced they are again separated, an electric spark passes between them and the charge is fired.

18,379. Improvements in Gas and Petroleum Engines. John Johnston, Engineer. July 1st, 1896.

This invention relates to gas and petroleum engines. Fig. 1 is a longitudinal vertical section. Fig. 1 is an open ended cylinder of two diameters, A, B. The inner cylinder, A, is the smaller one, and it serves as the power cylinder. The outer cylinder, B, is a larger one and acts as a pump.



Two pistons, *a* and *b*, connected rigidly together by the piston rod, C, work their respective cylinders, A and B. These pistons, *a* and *b*, are connected in the usual manner to a crank shaft, D, as shown diagrammatically at Fig. 1. The larger piston, *b*, on its outstroke creates a partial vacuum between itself and the smaller piston, *a*. This vacuum is utilised to charge the power end, A, of the cylinder by first sucking out the exhaust gases left after the working stroke, and then drawing in a charge of gas and air. The inlet gas and air valve, E, is of the ordinary conical seated type and the seat is provided with holes, F, F, opening into an annular channel, G, connected to the gas supply.

The cycle of operation of this engine is as follows:—Assume the double piston, *a*, *b*, to move out after compression and explosion under a power impulse; then at the out end of the stroke a groove, K, in the piston, *a*, communicating with the cylinder, A, by means of a number of holes, *k*, *k*, over-runs the first port, H, controlled by the conical-seated lift valve, I, opening outwards, and the expanded gases discharge to atmosphere. On the further movement of piston, *a*, the groove, K, over-runs the annular port or groove, L, thus putting the front end, B, of the cylinder into communication with the back end, A. Simultaneously with this movement the back end of the piston, *a*, covers the port, H, thus cutting off communication between the cylinder, A, and the atmosphere.

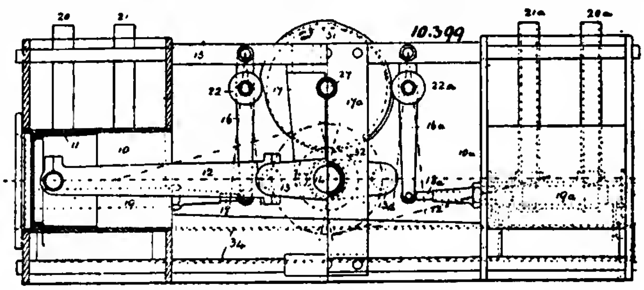
This particular position of the double piston in the cylinder is shown clearly at Fig. 1, and as there is a vacuum existing between the two pistons, *a*, *b*, the exhaust gases are drawn from A into B by way of the holes, *k*, groove, K, and annular port, L; while simultaneously the automatic gas and air valve, E, opens and a charge is drawn into the cylinder, A. On the return stroke compression of the mixture takes place, at the same time the exhaust is discharged as soon as the outer end of the piston, *a*, over-runs the port, H, slight compression of these gases taking place until this occurs. This cycle of operation thus gives an explosion for every revolution of the crank shaft.

Ignition of the mixture when compression is complete is arranged for in any known manner, preferably by means of a hot igniting tube.

Fig. 2 shows a modification of the double pistons, *a*, *b*. Instead of connecting the two pistons by a rod such as C, Fig. 1, a trunk piston is formed by a reduced prolongation of *b*; in which case a reservoir, M, is provided of sufficient volume in conjunction with the annular cylinder space, B, to enable the act of exhausting the cylinder end, A, and similarly drawing in the necessary charge of gas and air through the valve, E, to be performed. To exhaust from B on the return stroke, a port, N, runs along the trunk and up to the piston rings, so that the gases may be discharged through the exhaust valve, I, by way of the ports, N and H.

10,399. Gas, Oil, and Spirit Engines. Thomas James Bennett, 160, Walton Street, Oxford, and Walter Frederick Thomas, 37, Bloomsbury Street, Birmingham. May 15th, 1896.

This invention relates to improvements in gas, oil, and spirit engines, and its object is to provide a combination and arrangement of mechanism whereby such engines may be capable of being worked either upon a single or non-compressive cycle, or upon the com-



pressive (or Otto) cycle; also means by which the engine may be started upon the non-compressive cycle, and then at will transferred to the compressive (or Otto) cycle; also means whereby the engine, when in full work, being upon the compressive cycle, the act of stopping returns the mechanism to the single cycle, ready for restarting; also the combination and arrangement with such engines of a combustion chamber which is common to two opposite cylinders for simultaneous explosion, thus neutralising the shock and preventing vibration; also the combination with such engines of two sets of cams for the different cycles and reversing purposes.

10, 10ª, are cylinders forming a pair, which are opposite to each other, each having their respective pistons, 11, and connecting rods, 12, connected up to cranks, 13, 13ª, placed at an angle of 180° on the shaft, 14. These cylinders are strongly tied together by tie-rods, 15, which also serve as fixtures to which and from which the levers, 16, 16ª, may be carried, and also the brackets or frames, 17, 17ª, are connected thereto. 18, 18ª, are the valve rods, to which preferably piston valves of suitable type are attached, and which are arranged for inlet and exhaust openings to and from the cylinders, such valves being situated at 19, 19ª, the exhaust ports being shown at 20, 20ª, and the air and gas supply ports being shown at 21, 21ª. Other forms of valve may be used if found necessary. The lower ends of the levers, 16, 16ª, are coupled to the valve rods, 18, 18ª. Upon these levers are rollers, 22, which are acted upon by cams, 23. These cams are secured upon a shaft, 27, which is capable of an endway sliding motion.

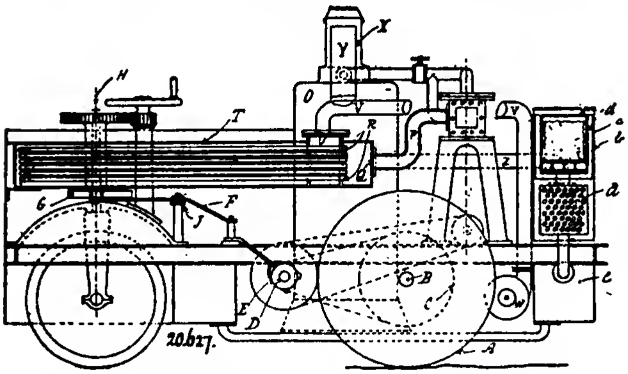
This cam shaft is rotated by means of suitable gearing, the proportion of which is preferably one revolution of cam shaft to two revolutions of main crank shaft.

The valve, 19, is employed to supply and exhaust from both cylinders of one pair, and the valve, 19ª, is independently used for a second pair of cylinders, that is the valve, 19, may be used for the two cylinders, 10, 10ª, while the valve, 19ª, may be used for similar cylinders on the other side.

The cams 23, act diametrically upon each valve rod.

20,627. Road Locomotives. Thomas Ballard Marchant, Verney Wharf, Verney Road, Rotherhithe New Road, Surrey. September 18th, 1896.

The figure shows a side elevation of a road motor propelled by steam power. A are the two driving road wheels, revolving each upon the axle ends, B. Affixed to the said wheels, A, are their respective driving-chain or toothed wheels, C, by which the road wheels are driven, the said chain or cog-wheels deriving their rotary motion in either direction from the countershaft, D, and upon each end of the said shaft, D, is placed a friction clutch shown at E, and



these clutches are each moved in or out of gear by suitable levers, applying motion and force to the clutches independently of each other, so that by controlling these levers marked, F, or their equivalents, the said clutches are in or out of gear with their respective road wheels which they drive, and the said control is given to the levers, F, by their attachment to the double cam, G, which cam is mounted upon the centre spindle of the steering mechanism, H, and this double cam is so designed that when the steering road wheel is in its central position the larger portions of the cam are holding out at their widest limit the ends of the said clutch levers, F, and where, as in this instance, the levers are pivoted at some intermediate point in their length, as at J, it is clear that both of the clutches are being forcibly held in contact with the countershaft, and are consequently transmitting the required power to rotate the two wheels, A, and thus to propel the motor in a straight line, as shown. Now, when the motor is required to turn around a curved path the person steering the machine will rotate the spindle, H, and with it its steering road wheel, and likewise the cam, G, and at a required point the said cam in revolving will present to the lever end, F, the portion of its circumference, K, which is removed, and in consequence the one lever (according to the direction of rotation of the cam) will be liberated, and with it its clutch, and of course its respective driving-wheel, A, and under these conditions the whole of the motive power is then being transmitted to the particular driving road wheel which is required to traverse the outside of the circular path in which the motor has to travel, and it will now be apparent that this automatic mechanism will materially lessen the loss of motive power usually wasted in turning corners, and will entail absolutely no thought upon the person actuating the same; slight modifications will have to be made to suit engines of different constructions. The levers, F, are guided and connected by a sliding grooved frame in which the clutch levers, F, can move as far as required in either direction.

The condensing apparatus is as follows:—Steam for motive power is generated in a boiler, O, which steam is passed to the cylinder of a steam-engine in the usual manner. When the said steam emerges from the said cylinder or cylinders by an exhaust pipe and passage, P, it is conveyed preferably first into a chamber, Q, and from which are taken a number of thin small tubes, R, which said tubes convey the exhaust steam along them until they terminate in a second chamber, S. Around the tubes, R, is constructed an air-tight casing, T, and into this casing at one end or other, and through one of the openings, U, is fixed a pipe, V, which conveys atmospheric air from a blower or pump, or fan. When the said air has been compelled to traverse the casing surrounding the said tubes, R, it is, if necessary to combustion of fuel, directed under the grate or ash-pan of the boiler, and if not necessary for that purpose it is allowed to escape to an annular space, X, where it escapes to open air, together with the products of combustion from the chimney, Y, of the boiler. The steam remaining uncondensed is carried through a pipe, Z, into one end of a water surface condenser, *a*, preferably sending the steam through the interior of the condenser tubes as is usual. When the steam has passed through the surface condenser, *a*, and it has not yet been totally liquefied, or its resultant water is of too high a temperature, a further cooling effect is brought to bear upon it as follows.

Fitted in a convenient part of the machine, preferably over the water surface condenser last described, is a chamber, *b*, made to store ice, *c*, in any convenient form, usually in the form of artificially formed blocks, as it is of course mostly required in warm weather when the combined cooling effect of the air cooling current and the water surface condenser might not of themselves be sufficient. The cooling effect of the ice is brought to bear upon the condensing steam to ensure perfect condensation and the required vacuum.

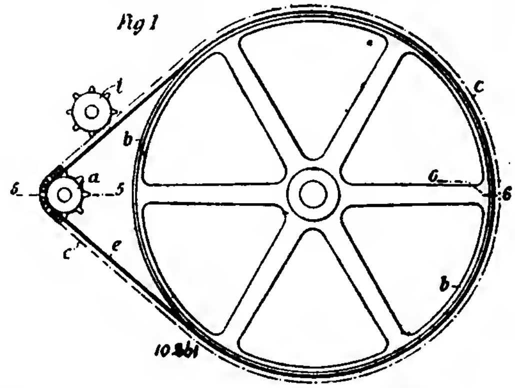
The said ice receptacle is made with hollow walls, thus leaving a surrounding space, *d*, in which may be placed non-conducting substances to prevent radiation, and loss of ice, or it may be surrounded with cold water on its way from the cold water tank, *b*, to the surface of the tubes of the condenser, *a*, and which is being driven by a circulating water-pump in the usual way in surface condensing steam-engines.

10,861. Driving Mechanism for Road Carriages. Chaimsonovitz Prosper Elieson, Broad Street Avenue, London. May 19th, 1896.

The object is to obtain all the advantages of belt transmission as regards the provision for slipping with the advantages of chain transmission in so far as regards non-slipping upon the motor-shaft. To effect this end, a combined belt and chain transmitter is used—that is to say, a belt having a chain fixed to it and moving therewith. The pulley on the motor shaft is provided with teeth adapted to engage with the chain, whilst the pulley on the driven shaft or travelling axle is plain. With this arrangement it will be understood that no slip can take place between the pulley on the motor shaft and the belt, whilst the belt is free to slip upon the pulley of the travelling axle.

a is the sprocket pinion on the driving shaft, and *b* is the belt-wheel or pulley on the driven shaft; *c* is the driving chain which runs around the pulley, *b*, and is in engagement with the teeth of the sprocket pinion, *a*, so that the said chain is positively driven. Pins project from the sides of the chain, the said pins being of a length approximately corresponding with the width of the driven pulley. These pins carry leather bands or belts, e, *e*, the said bands being secured to the pins by any suitable means in such a manner that they will run in contact with the surface of the wheel, *b*. The said bands are secured to the pins by means of small sockets, into which the pins are inserted, and which are secured to the said bands by rivets. In order to keep the bands, e, e, taut upon the pulley, the sprocket wheel, *a*, is made wide enough to allow of the said band running around the same, or loose pulleys may be used for the purpose.

With the arrangement hereinbefore described it will be obvious that the motion of the driving shaft will be communicated through the sprocket wheel, *a*, to the combined chain and belt without any liability of the latter slipping thereon; whilst as the pulley, *b*, is



plain, that is to say, unprovided with sprocket teeth, it will be obvious that the power which is transmitted from the driving pinion through the chain will be received by the driven wheel through the band which is free to slip upon the surface of the said driven wheel. The driven wheel, *b*, is recessed on the periphery at that part adjacent to which the chain, *c*, runs; however, such recessing is not essential.

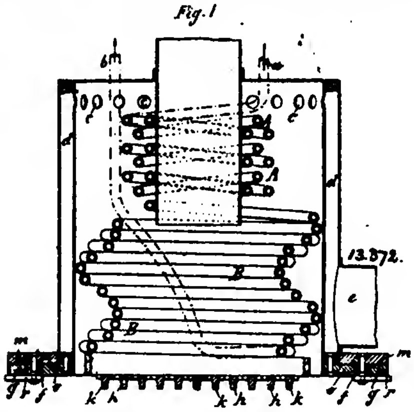
In order to retain the transmitter at the required tension, there may be combined therewith a loose sprocket wheel, such as that indicated at *i*, which is adapted to be moved at will towards or away from the transmitter, to give the latter more or less grip upon the pulley as required.

18,372. A Boiler for Steam-driven Velocipedes or like Vehicles. Eugène Labitte, 177, Boulevard Pereire, Paris, France. June 17th, 1896.

Relates to a light and compact construction of boiler, presenting large heating surface and capable of rapidly generating and superheating steam for driving a velocipede or like vehicle.

The upper coil, A, which is supplied at *a* with the feed water is connected at its lower end with the superheating coil, B, which consists of straight parts connected by bent parts, each convolution

Fig. 1



forming a triangle which is turned partly round relatively to the next, so that between the successive convolutions there are narrow passages for the flame and combustion gases, which play upon both the inner and the outer surface of the coil. From the lowest convolution of B, the superheated steam is led to the steam engine by a pipe, *b*, which ascends through the combustion chamber, as indicated by the dotted lines.

The combustion gases pass through holes, *c*, at the top of the chamber into the annular space, *d*, within the casing, and descend to the outlet, *e*, leading to the chimney.

The fire grate consists of two sets of bars, *h* and *k*, which alternate and are carried on two rings, *f* and *g*, respectively. The ring, *f*, is attached to a ring, *m*, which rests by segments, *n*, on a flange, o, fixed to the base of the boiler casing. This flange has segments, *p*, cut out of it to allow the segments, *n*, to pass up, these being then turned partly round so as to be held in the manner of a bayonet joint. The ring, *g*, which carries the bars, *k*, is held outside the ring, *f*, by turn buckles, *r*, pivoted on *f*. Other brackets, *t*, serve to hold the ring, *g*, up to *m*. When it is desired to shake out ash or small cinders, the ring, *m*, is turned a little to and fro between suitable stops, thus shaking the grate. In order to clear the grate from larger pieces the brackets, *t*, and the turn-buckles, *r*, are disengaged, and the ring, *g*, with the bars, *k*, is lowered, thus leaving larger spaces between the bars, *h*. Fuel descends by the central tube, the shake of the vehicle ensuring its descent.

Between the boiler and the engine may be arranged a slide-valve by which the steam is directed either to the cylinder or to the escape pipe, or partly to each according to the engine power required. In case very little or no power is required as in descending a slope, the feed may be cut off, and as there is no longer exhaust in the chimney the fire becomes deadened.

6,573. Gas Engines. Herbert John Dowsing, 35, Queen Victoria Street, London, and Henry Sheehy Keating, Queen's Gate Mansions, Queen's Gate, Kensington, London. March 25th, 1896.

The object of this invention is to ensure more perfect combustion and thereby obtain increased power from a given charge of combustible.

For this purpose an ozonising apparatus of any suitable known kind is combined with the engine and through this is passed the air which is to form part of the combustible charge, thereby converting its oxygen or a portion thereof into ozone, which acts more effectually in combustion than oxygen itself does.

As, in ozonising air, considerable heat is absorbed, it is preferred to heat the air either before or after it is ozonised, for which purpose it may be passed through the cylinder jacket or through or along tubes or other extended surfaces heated by the exhaust products of combustion from the cylinder. By ozonising the air in contact with the cylinder, the heat of the cylinder may to some extent be reduced.

THE AUTOMOTOR AND HO LESS VEHICLE JOURNAL

A RECORD AND REVIEW OF APPLIED AUTOMATIC LOCOMOTION.

Circulates amongst Makers and Users of Motor-Cars, Cycles, etc., in the United Kingdom, the Colonies and the Continent.

VOL. I. No. 10. JULY 15TH, 1897. PRICE SIXPENCE.

CONTENTS.

THE AUTOMOTOR INDUSTRY.

A Visit to Messrs. New and Mayne's Works at Woking.

LONG before that oracular utterance, "There is no motor-car industry," was pronounced by a contemporary to an astonished public, we had arranged to give in each issue of the AUTOMOTOR an account of the industry as carried on in the principal centres. We commence with a description of the automotors, &c., manufactured by Messrs. New and Mayne (Limited), of Woking and London. Woking in Surrey is not exactly a Birmingham, but is, nevertheless, the home of several industries connected with automobilism. Messrs. New and Mayne's premises are extensive and straggling, owing to the number of separate industries in which the firm is engaged. Steps are, however, being taken to locate all the purely engineering and constructive works under one roof. The automotors manufactured by Messrs. New and Mayne are the result of a long investigation of the properties of various internal combustion-engines, supplemented by an equally long and costly series of experiments. How very expensive scientific investigation is, may be gathered from the fact that in perfecting their various appliances used in their automotor industry, Messrs. New and Mayne have spent no less than £50,000. In their oil motor which we illustrate, Messrs. New and Mayne have succeeded in effecting many improvements whereby the general efficiency is increased. Figs. 1 and 2 are respectively an end and side elevation, while Fig. 3 is a part sectional elevation; the scale is a quarter of the full size. It will be seen that the motor is of the twin cylinder vertical, enclosed crank type; the cylinders are 2½ inches diameter by 6 inches stroke. The cylinders form in themselves a really very special feature, and in this design is ample evidence of the proper application of science to practice which, in our opinion, alone constitutes real engineering. The cylinder of a gas-engine has to bear the stresses not unlike those set up in a gun, although, of course, of much less intensity. Hitherto it has been the practice to make the cylinders of gas-engines of fine-grade cast iron, and where weight and space are of little account and low first cost essential this practice is good and proper. For automotor work, whether for land or water, we wish to associate the maximum of strength and the minimum of weight with also small cost. To this end Messrs. New and Mayne decided to employ a steel of a similar specification to that used in the manufacture of quick-fire ordnance; this steel has an ultimate strength of about 65,000 lbs. per square inch and is exceedingly tough and ductile. As will be seen by Fig. 3 the cylinders are thickened at their rear ends so as to provide ample strength to withstand the stresses set up by the explosions; the initial pressure being about 260 lbs. per square inch. The cylinders are jacketed by the outer casing. The engine works on the "Otto" cycle, but the essential features, however, of the New and Mayne motors, and which differentiate them from others, are the inlet spraying valve and the electric and self-firing ignition device. Whilst being able to use any kind of petroleum, either light or heavy oil, or coal gas, they also possess the great merit of starting almost immediately and without any previous heating up of tubes, &c., by lamps. There is no vaporiser, carburiser, or similar device. The engine is altogether simpler, stronger, and more easy to manage. Owing to the perfect combustion the exhaust is almost colourless.

The *inlet spraying valve*, unlike those used in most engines, is a positive action one, and hence does not require delicate adjustment of the spring which retains it in its seat. This positive action also enables the velocity at which the mixture of oil and air enters the cylinder to be adjusted to a nicety; the compression on the return stroke to be varied and set accurately;

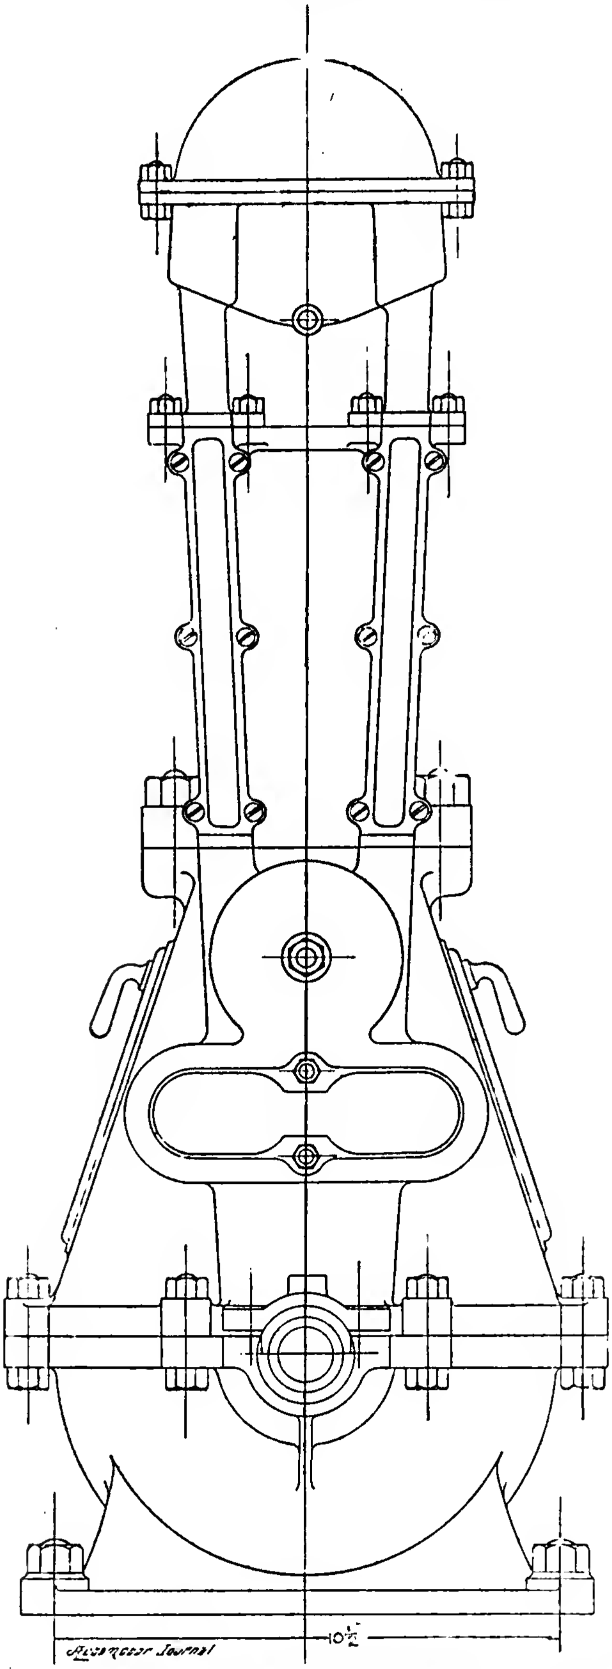

FIG. 1.—NEW & MAYNE'S TWO-CYLINDER VERTICAL OIL-ENGINE End View.)

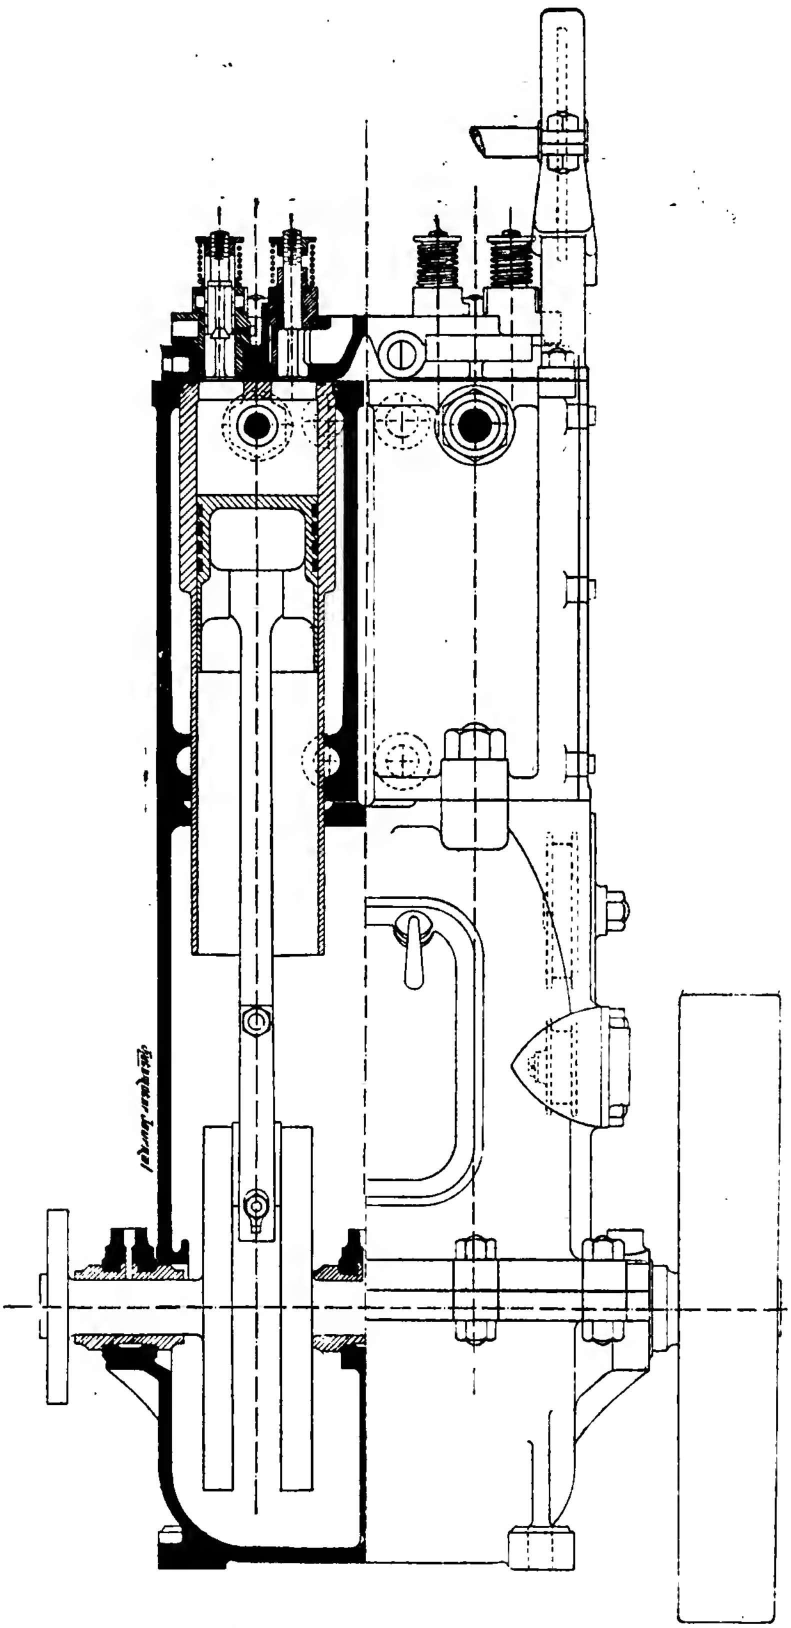

FIG. 3.—NEW & MAYNE'S TWO-CYLINDER VERTICAL OIL-ENGINE (Side View.)

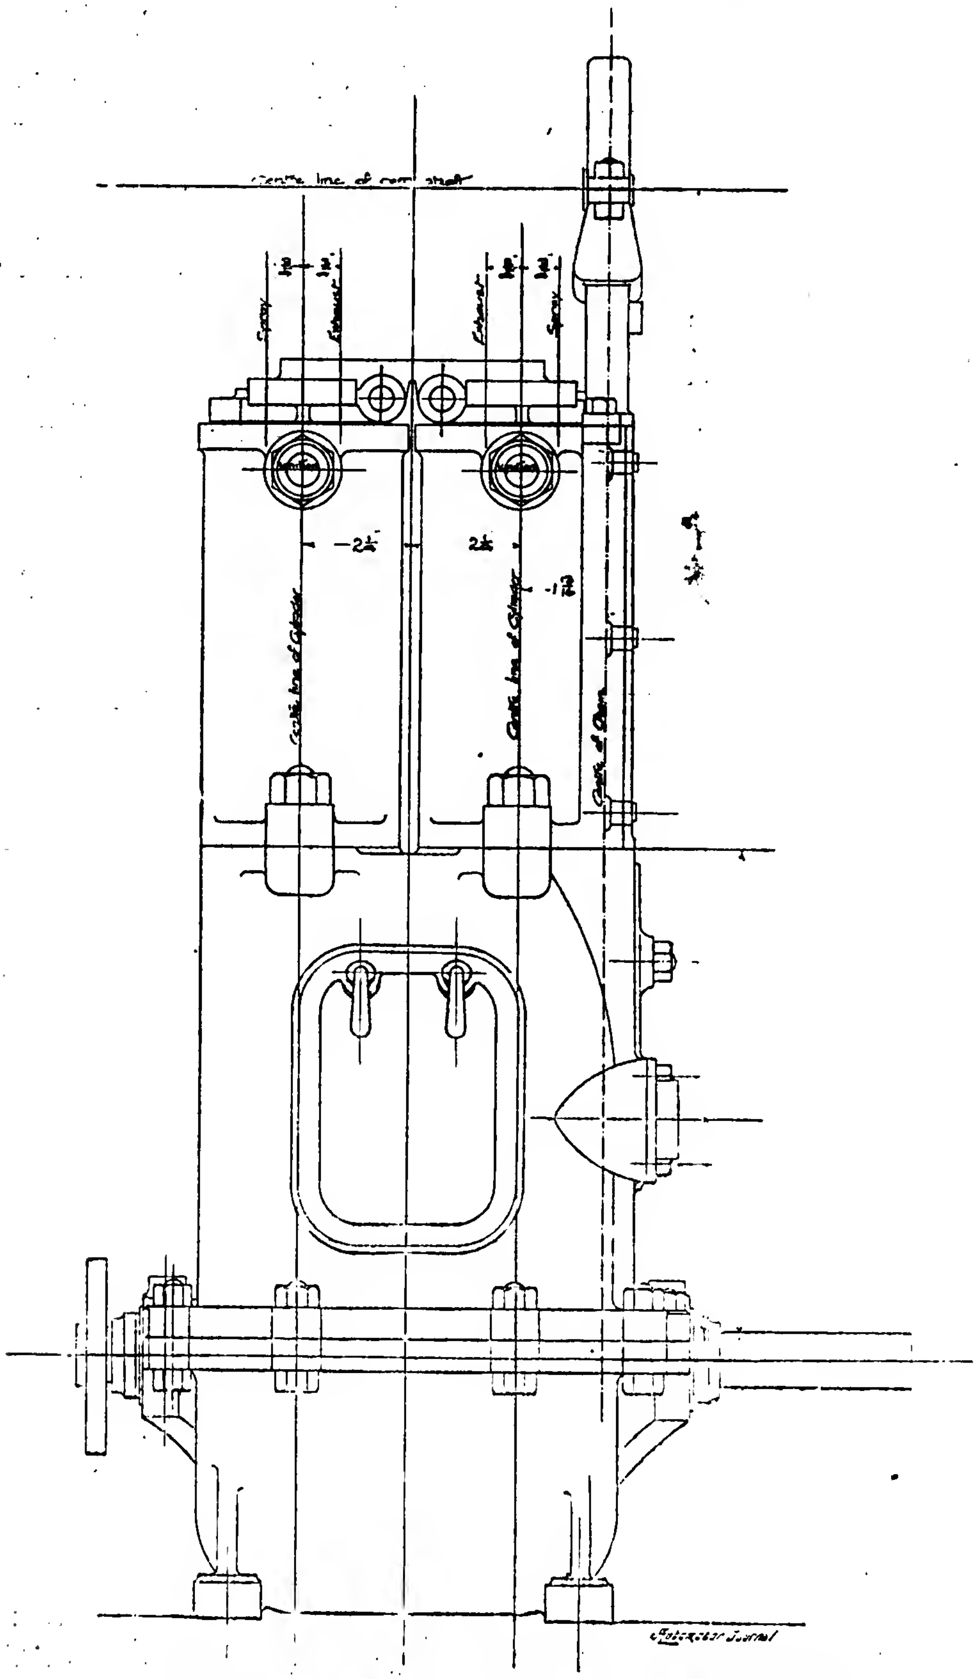

FIG. 2.—NEW AND MAYNE'S TWO-CYLINDER VERTICAL OIL-ENGINE (Elevation).

and the amount and proportion of oil and air to be varied to requirements, or to be automatically controlled by the governor.

The valve is actuated by means of a cam, in a similar manner to that employed (in nearly all similar engines) for the exhaust valve. This cam is made in such a manner that it can be adjusted to open the inlet valve earlier or later in the cycle of the engine, and to close it earlier or later.

of detail in these engines as made, but these two parts are chiefly dealt with in the numerous patent applications held by Messrs. New and Mayne.

Referring to the current required to render the ignition tube incandescent, Messrs. New and Mayne make the carriage of a battery of accumulators a part of their system of automobilism.

Fig. 4.—Arrangement of New and Mayne's Direct Coupled Engine and Dynamo (Side Elevation).

for such a short time that quite a small battery of secondary cells suffices for a long period. On passing the current for a few seconds, the ignition tube becomes red hot. The engine can then be started immediately, and after it has run for a minute or so the electric current is switched off, and not required again until the motor has been stopped and is again wanted to work. The firing of the mixture in the cylinder is, after starting, effected automatically, because the sleeve is kept sufficiently hot by the constant explosions. This sleeve not only serves the purpose of automatic igniter, but is essential even for starting, as it shields the ignition tube from the inrushing cold mixture of air and vapour, and thus prevents it from being chilled, as it otherwise would be. There are other minor points

They maintain that the advantages of this combined oil and electric system are:—(1) That the oil-engine can be automatically started, without any labour, by using the dynamo as a motor from the accumulators. (2) That the engine always has a "full load," and hence runs more quietly and free from vibration. (3) That for extra power required for short periods (such as for hills) the accumulators *assist* the engine. (4) That electric current is always available for lighting and the other numerous conveniences for which it is so especially applicable.

It will be seen that all the valves are worked off the main shaft by a chain. The cranks are placed at 180° apart, and are balanced. There is also a heavy fly-wheel; there is thus very little vibration. In the smaller sizes the connecting-rods are made so as to permit a slight increase or decrease in their length, with a view to obtaining greater or less compression of the firing charge. Large bearing surfaces are provided for all the motion parts, and, the cranks being enclosed, ample and efficient lubrication for long periods without attention is ensured. Altogether the workmanship in these motors is of a very superior character.

With the increased use of high-speed reciprocating engines of late years, a phenomenon somewhat akin to hysterisis in electro-

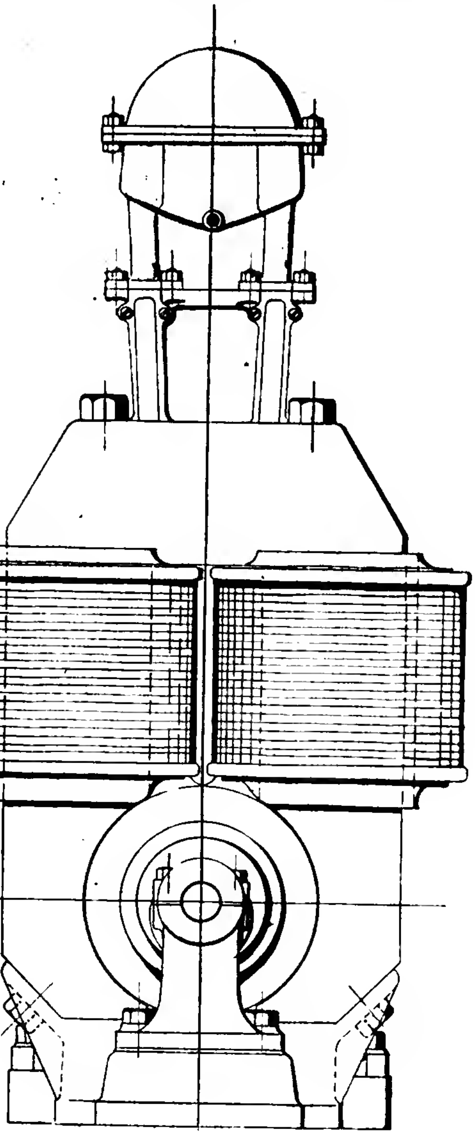

FIG. 5.—ARRANGEMENT OF NEW AND MAYNE'S DIRECT COUPLED ENGINE AND DYNAMO (End Elevation).

dynamics is often noticeable. In other words, each engine seems to have some critical speed or speeds at which synchronism is maintained in all parts of the machinery; at other speeds the parts are out of place and vibration results. In oil-engines this hysterisis manifests itself by checking the flow of oil to the cylinders; that is, when the admission valve is opened for oil, unless the pipe, &c., is synchronising with the motion of the engine, the result is either an acceleration or retardation in the flow of oil to the cylinder, with, of course, great variations in the power. In order to get over this difficulty, Messrs. New and Mayne have devised an exceedingly ingenious automatic valve. The oil is made to pass into a chamber, not unlike the vacuum chamber of an aneroid barometer. Any relative motion between the two ends is transmitted by a stalk to a tiny bell crank lever which actuates the needle valve, which is kept in its place by a small coiled spring; should the oil be forced forward the needle tends to close, and *vice versâ*. This arrangement has been found to answer its purpose very effectively.

These motors are made either with single, double (as illustrated), or with four cylinders, two on each side of the shaft. The following table contains the principal data relating to them:—

Number of Cylinders.	Diameter of Cylinders.	Stroke.	Revolutions.	B.H.P.	Over-all Dimensions.	Weight, with casing, &c., in cwts.
1	2½″	6″	800	1	33″ × 13″ × 9″	1½
2	2½″	6″	800	2	33″ × 13″ × 13″	2
4	2½″	6″	800	4	33″ × 13″ × 15″	2¾
1	4″	8″	500	3½	42″ × 15″ × 12″	3¾
2	4″	8″	500	7	42″ × 15″ × 14″	4¾
4	4″	8″	500	14	42″ × 15″ × 22″	6

These weights are considerably reduced by employing aluminium which, while equally strong, is so much lighter than cast iron that the saving effected varies proportionally from ½ cwt. in the case of the one H.P. motor to 1½ cwt. in the 14 H.P. Expressed in terms of weight per H.P., these motors run out at about 72·8 lbs. per B.H.P. for cast iron, and at 54·2 lbs. per B.H.P. when of aluminium.

The consumption of petroleum (ordinary paraffin) is about 1½ pints per B.H.P. per hour in the smallest size, and very much less in the larger ones. The larger sizes of these motors have been very successfully applied for the propulsion of light vans, carriages, &c., while in a somewhat modified design the smaller sizes are used for bicycles and tricycles. For the latter purpose two fly-wheels are attached, one on each side, to the spindle of the driving-wheel, but while the latter revolves freely on the spindle the fly-wheels are rigidly keyed to it. To the ends of the axle are fixed the cranks of the motor. Suitable gearing, such as a sun or planet wheel motion or differential gearing, is used to transmit the energy, with the object of enabling the axle to revolve at a greater speed than the driving-wheels.

An interesting application of the New and Mayne two-cylinder motor is shown on Figs. 4 and 5, which show the motor coupled direct to the dynamo, thus forming a very compact plant, very suitable for country house, shop, or ship lighting. The dynamo as shown gives at 800 revs. 12 ampères at 100 volts; this is equal to 20 16 C.P. or 40 8 C.P. lamps.

As regards electric traction, we illustrate in Figs. 6, 7, and 8 Messrs. New and Mayne's char-à-banc, which carries, including driver and conductor, 24 persons. These drawings are self-explanatory, and show the arrangement of the various parts. The most interesting parts are, however, the change and differential gear (Hardingham's patent) shown in Fig. 9. It will be seen that the electro motor carried underneath the rear of the car drives, by means of a raw hide pinion, the friction wheel, P, of the drum, R, which is keyed on to the boss of the pinion, N, which revolves on the sleeve or hollow shaft, B; A being the main shaft. Keyed on to shaft, B, is the arm, D, which carries the planet wheel, M, on the spindle, H′, this pinion, M, gearing with the internal teeth, E, of the drum, L. When the brake-wheel, K, is held, the wheel, E, drives the arm, C, by means of three intermediate pinions, F, of which only one is shown, which revolve around the fixed wheel, J; this gives an increased speed between the wheel, R, and the sleeve, B, and is the full speed gear.

When the wheel, L, is held by the wide brake, the arm, D, is driven round by the wheel, N, through three intermediate pinions, M, which roll round the internal rack, L. This gives a diminished speed between the wheel, P, and sleeve, B.

The power is then transmitted by the sleeve, B, to the

2 D 4

differential gear, the outer case of which revolves, carrying three bevel pinions, T, on the three armed forging, V.

The driving shaft is divided into two portions, the division

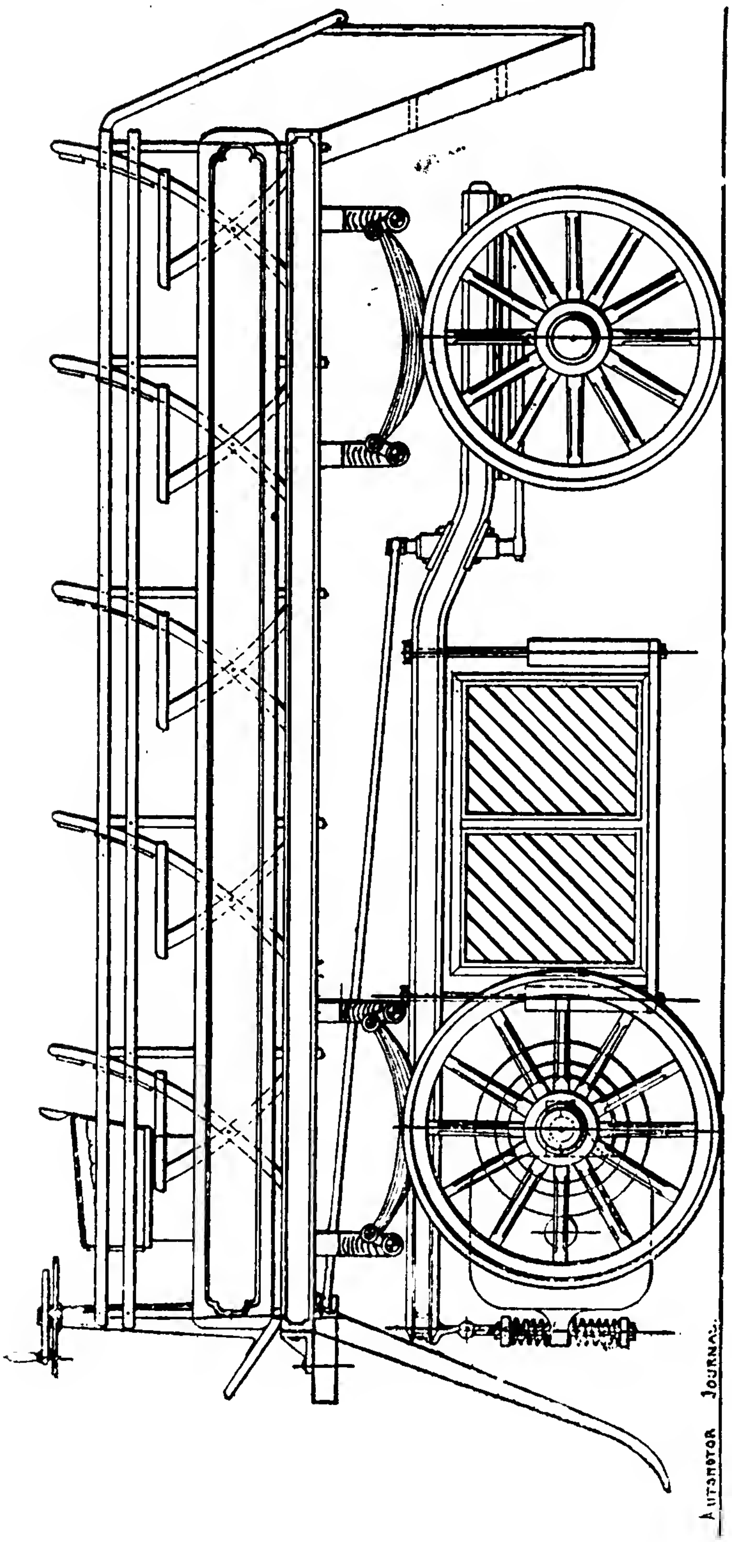

FIG. 6.—NEW AND MAYNE'S ELECTRIC CHAR-À-BANC (Side Elevation).

being on the centre line of the bevel pinions. To each portion of the shaft is keyed a bevel wheel, Y and S. When the motion of the car is straight ahead, the two wheels, Y and S, are carried round by the pinion, T, which then do not revolve on their pins, Y. When going around corners, either wheel can remain stationary in the well known way. The brake on the differential gear case is merely used to retard the motion of the vehicle.

Another automotor speciality designed and manufactured by Messrs. New and Mayne is their "Motor-trailer." This apparatus consists of a specially designed electric motor, in which all the necessary gearing for the reduction of the speed of the moving and driving part is self enclosed. In appearance (*see* Fig. 10) it resembles a pulley or drum mounted on a shaft. If the shaft is held the drum rotates when the machine is supplied with an electric current, and may then be connected by a belt with any machinery which it is intended to drive, or may be fitted with a rubber, leather, or other tyre, and used for driving direct on to a road; in this latter case it is assumed that it is fixed to the vehicle in a suitable position and manner, preferably between the main driving wheels and in the centre of the carriage. For vehicle driving it possesses the special advantages of saving a great portion of the friction loss in the reduction of speed, which is always necessary, owing to the fact that the driving wheel itself is small; saving weight and space, and also being absolutely dust proof; and, lastly, that of being readily attached to existing vehicles without serious alteration in their structure.

As regards the efficiency of this trailer, the particular electric motor used in it being an experimental one and only having an efficiency of about 70 per cent., we give a few figures obtained from recent trials, and it will be seen that the real efficiency is very high, and it forms a thoroughly reliable apparatus at small cost of production. A similar machine is also constructed by New and Mayne (Limited), with an oil machine as the driving power, and in this case a variable gear is used instead of the fixed gearing mentioned above, but the application is similar :—

TESTS OF MOTOR-TRAILER.

Volts.	Ampères.	Revolutions.	Miles per hour.	E.H.P.	B.H.P.	Efficiency = $\frac{\text{B.H.P.}}{\text{E.H.P.}}$

115	18	230	13·1	2·77	1·36	49·2

In another branch of automobilism Messrs. New and Mayne have attained considerable notoriety and success. The River Thames at this time of the year, especially in the upper reaches, presents a good deal of variety in the way of all sorts and descriptions of craft. From the scientific, nautical, and pleasure points of view no craft are more interesting than electrically-propelled launches. In most boats there is usually much space which should be utilised for ballast, and unless a boat *is* properly ballasted, and especially a pleasure boat, in which there will often be people who *will* stand up and who *will* crowd to one side, there is great risk of a capsize, owing to what is scientifically known as an insufficient metacentric height, or, as the vulgar have it—topheaviness. The use of secondary or storage cells is then emphatically the proper thing for small craft, so long as they ply within range of a central station. Deriving power from storage cells is, of course, no new thing. It is in the arrangement of the motor and propeller that Messrs. New and Mayne have made a radical departure, and one which at first sight startles the seaman and naval architect.

The apparatus, a drawing of which appeared in the April number of the AUTOMOTOR, consists of an electric motor, specially constructed in the shape of a small torpedo, to which the necessary conductors are conveyed from the yoke or tiller bar through the supporting tube which forms part of its construction. The rudder is fitted with an adjustable frame, which enables it to be attached to any boat without in any way altering its construction or making any special provisions. The yoke or tiller bar and the adjustable frame are easily detached from the motor, as also is the propeller, thus enabling the machine to be fitted with a small pulley wheel, and to be used for other purposes in winter, such as driving a sewing machine, lathes, or other light machinery. The rudder is provided with rudder lines, which terminate in metal plugs, and these fit into

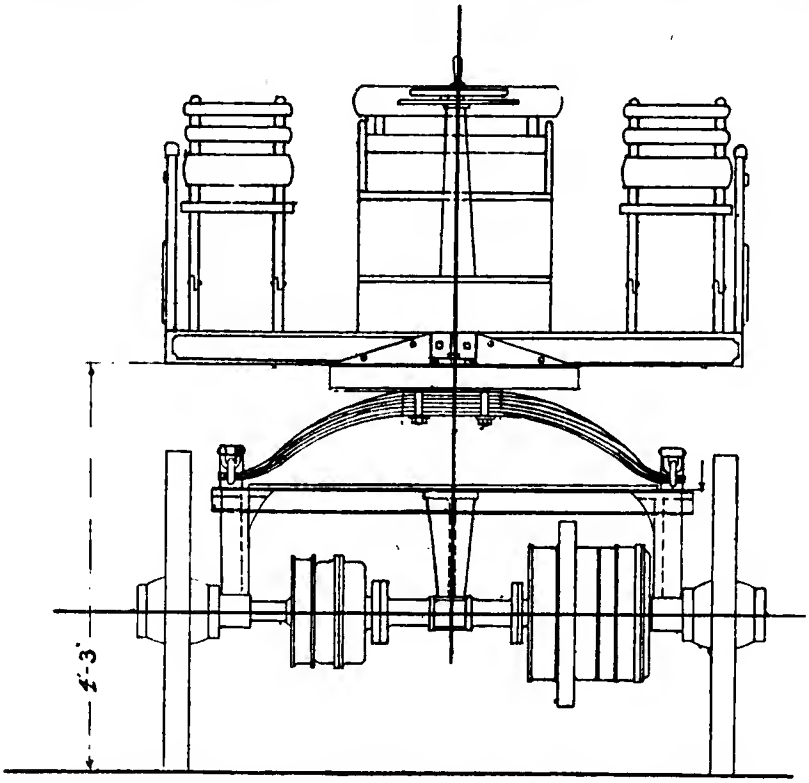

Fig. 7.—New and Mayne's Electric Char-à-Banc (End View).

Fig. 8.—New and Mayne's Electric Char-à-Banc (Plan).

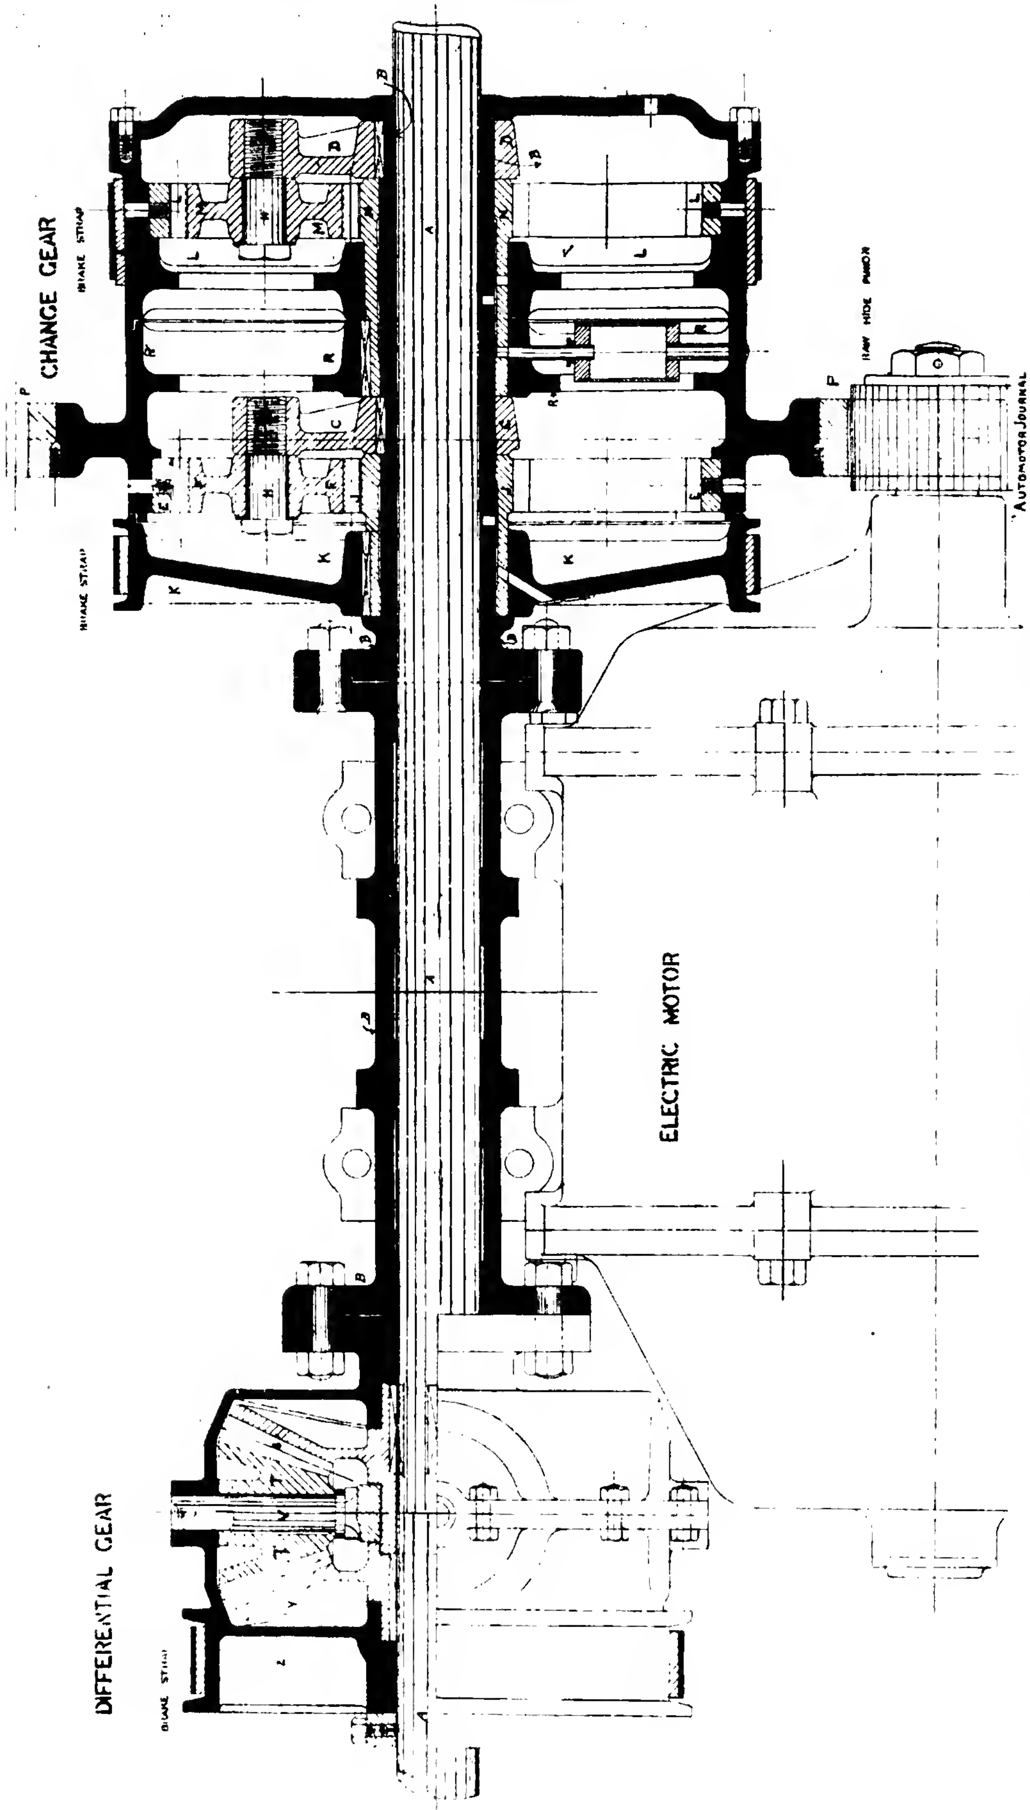

Fig. 9.—New and Mayne's Differential and Change Gear.
(Hardingham's Patent.)

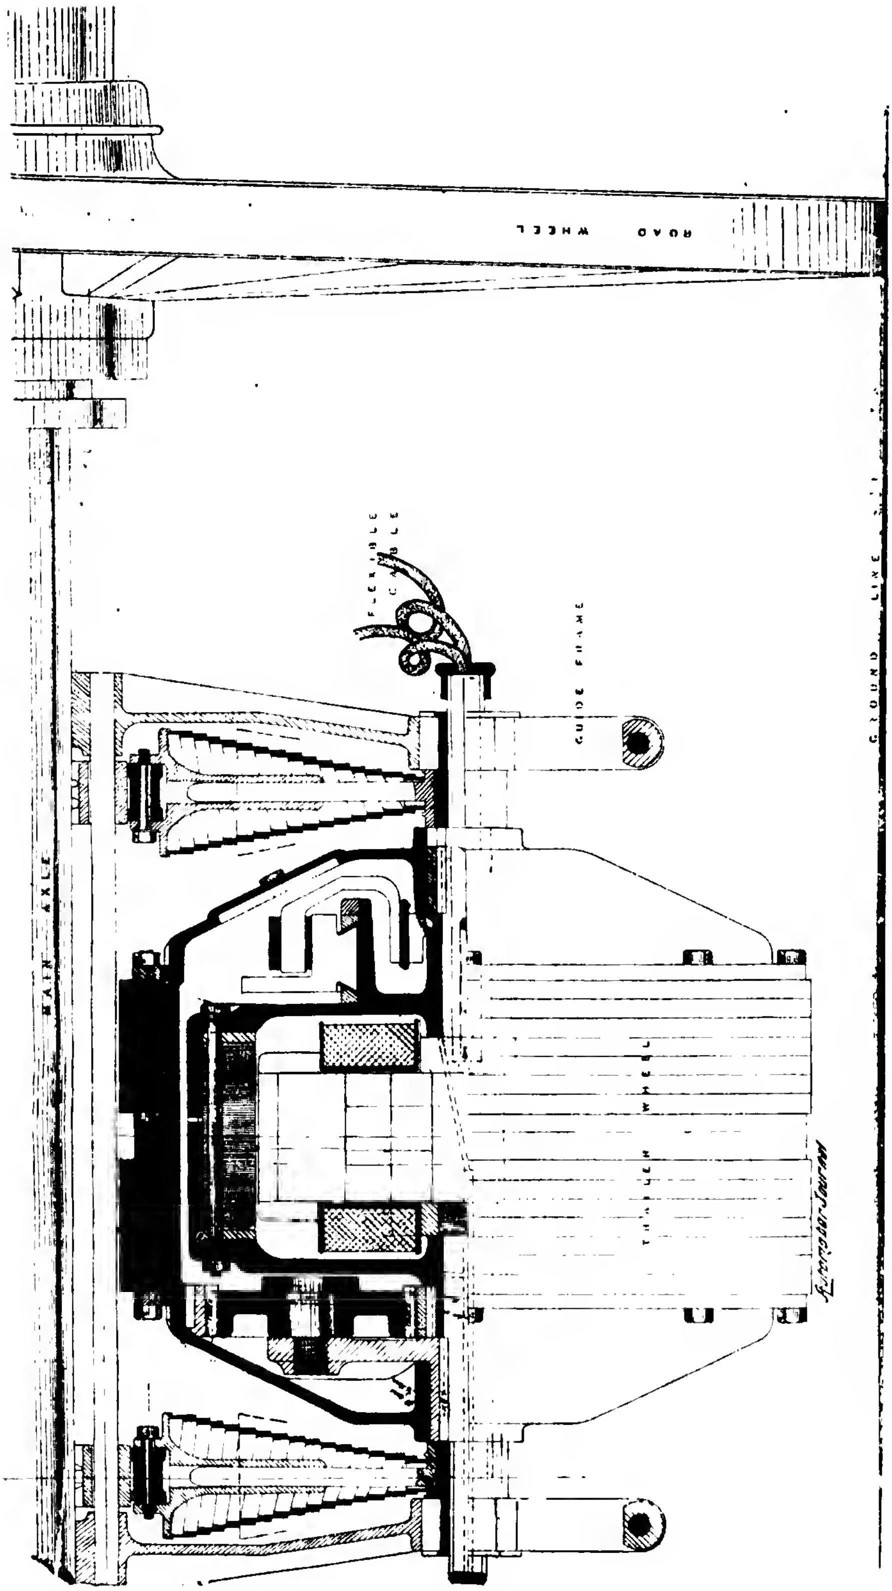

FIG. 10.—NEW AND MAYNE'S ELECTRIC TRAILER WHEEL.

sockets provided on the switch inside the boat; these lines not only serve for steering as in the ordinary way, but also make the necessary electrical connection between the switch and the motor. A small propeller is fitted on a projecting shaft at the end of the torpedo, and when in place on the stern of the boat lies close up to the keel. This propeller revolves at a very high speed when current is supplied to the motor. The motor is also fitted with a thin metal fin, which enables the rudder to be used in the ordinary way when sailing or rowing. The pivoted point of the motor is where the supporting tube passes through the frame to the yoke, and this takes an ample bearing in the frame. The frame is fitted with two thumbscrews, which press small pads against the stern of the boat and hold it perfectly rigid. Owing to the fact that the propeller moves with the motor, extremely sensitive steering is obtained when the motor is running, and thus the most complete control and manœuvring power to the operator is secured. The battery consists of a number of accumulator cells which are fitted into compact boxes, these boxes being of convenient size and weight for portability. The battery supplied with each set is capable when fully charged of supplying current to run the motor at full speed for five to six hours. The boxes are all fitted with sockets, into which the necessary connecting wires and plugs fit, making complete electrical connection. The connections and sockets are marked, so that it is impossible to make any mistake.

The regulation of the current and speed is effected by a switch which enables any one to regulate the speed of the motor from rest to half or full speed, in either direction. This is effected by the movement of a single handle, which is free to move rapidly or slowly from one position to another; an indicating pointer attached to it denotes its position at any time. This switch is also arranged in the smaller sizes in such a way that in one of its positions all necessary connections are automatically made for re-charging the accumulators. The connections and switching arrangements are shown in Fig. 11.

In the following table we give particulars of this motor and battery as we think there is a considerable field for its use:—

H.P. of Motor.	Volts.	Charging Ampère.	Cells.	Total Plates.	Weight of Rudder Motor.	Weight of cells.	Weight of Switch.
					lbs.	lbs.	lbs.
½	24	20	12	108	55	320	14
1	48	20	24	216	110	640	14
2	48	35	24	360	200	1,080	20
3½	96	35	48	720	550	2,160	20

Needless to say Messrs. New and Mayne manufacture many other things besides those described above. Indeed, as indicated elsewhere, the automotor industry as carried on at Woking is quite subsidiary to their more important one, that of electric lighting machinery manufacturers. As, however, this branch is beyond our province we do not describe it. A visit to Woking is, however, to the student of automobilism something in the nature of a liberal education.

Here, then, we take leave of Messrs. New and Mayne. We have in this sketch amply justified our contention that not only is there a legitimate automotor industry in this country, but that it is also one which is, and must be, in the hands of such firms as that whose works we have attempted to describe—progressive.

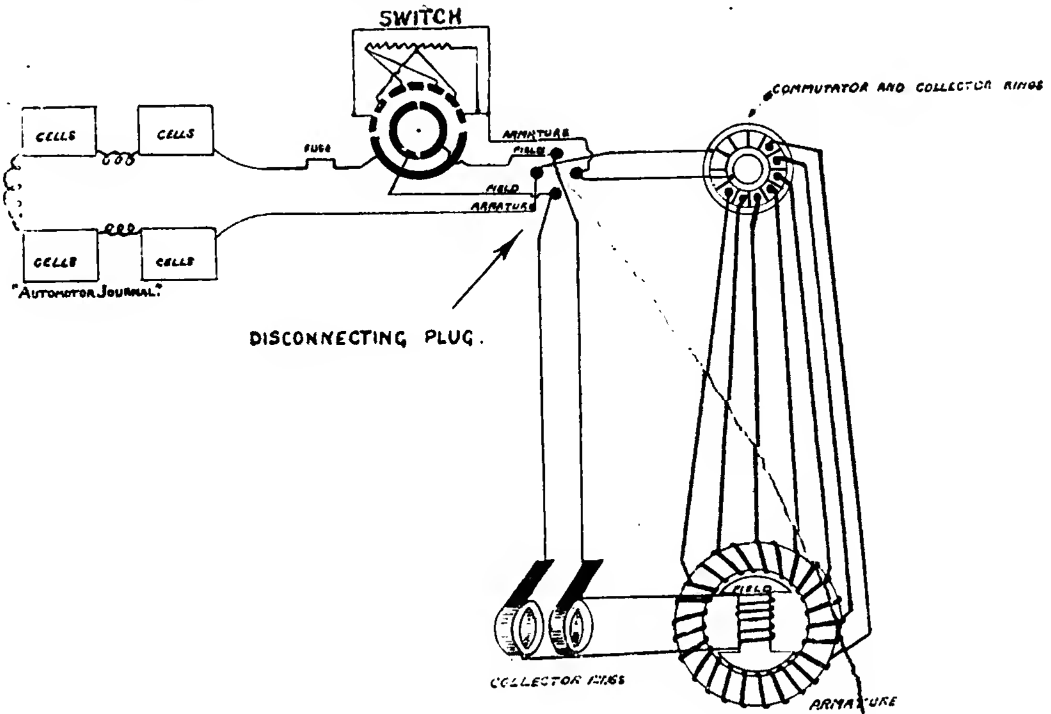

FIG. 11.—NEW AND MAYNE'S RUDDER-MOTOR CONNECTIONS.

WHEN computing the horse-power of a steam-engine, and you have multiplied together the piston area, the mean effective pressure, the double stroke, the revolutions per minute, and all that, if you divide by 44,236, instead of by 33,000, you will have your power expressed in kilowatts instead of in horses. A kilowatt is 1,000 watts. One horse-power is equal to 746 watts. If kilowatts must be had, and some people want them, it may save labour to get the horse-power in the old-fashioned way, and then multiply by ·746. Having the power in kilowatts, multiplying by 1·34, or more accurately by 1·3404825 +, gives the horse-power.

PROCEEDINGS OF SOCIETIES.

Liquid Fuel.*

THE writer's experiences with this form of fuel has principally been with petroleum residues on board of steamships, and the contents of this paper may, therefore, be taken as applying more particularly to its use in this direction. The application of liquid fuel for the purpose of raising steam in boilers is now no longer in the experimental stage, a large number of boilers, both on board ship and ashore, being fired with this fuel, and there is no doubt that as the numerous oil-fields in the various parts of the world develop, its application will rapidly extend. In addition to the oil wells of Southern Russia and Pennsylvania, oil has been found in varying quantities in most countries all over the globe. The late Mr. B. G. Nichol, in his paper on this subject before this Institution in 1886, mentions the countries in which petroleum had then been discovered. Since that time several of these oil fields have been developed, and are now producing petroleum in considerable quantities, especially those of Peru, Burmah, Sumatra, and Beluchistan. The principal source of fuel oil is Russian petroleum residuum or "astatki": this is the oil remaining in the distillery apparatus after the lighter naphthas and paraffins have been distilled over. Russian crude petroleum yields a very much smaller percentage of burning oils than American crude oil, as is shown in Table 1, but fuel oil in Russia, where astatki is used for this purpose, is cheaper than in America, where crude oil is used.

The percentages of the various oils that, with the perfected process of distillation now used, could be obtained from Caucasian naphtha are as follows:—

TABLE I.

—		Density at 17° Centigrade.	Percentage.
Light oils ...		0·725	3
Illuminating oil...	Kerosene ...	0·822	30
	Solar oil ...	0·863	14
Lubricating oils...	Spindle oil ...	0·895	10
	Machine oil ...	0·908	16
	Cylinder oil ...	0·915	5
Oil fuel ...		0·93	17
Loss ...		—	5
			100

American oils contain a very much higher percentage of burning oils, about 80 to 90 per cent., instead of only about 50 per cent., as above.

The first steamer to use liquid fuel was the s.s. "Constantine" on the Caspian Sea in 1870, and in America it was used on the steamer "Thoroughfare" in 1885. The first steamer to cross the Atlantic burning oil as fuel was the s.s. "Baku Standard" in January, 1894.

* Excerpt of paper read before the North-East Coast Institution of Engineers and Shipbuilders in South Shields, by R. WALLIS, Wh. Sc.

In addition to the petroleum oils the following oils have also been used as fuels:—Shale oil, blast furnace oil, creosote, green, and other tar oils.

On the table are examples of Russian astatki, American crude petroleum; crude petroleum, which has been exposed in a lake to the influence of the atmosphere for twelve months; creosote oil; heavy and light tar oils.

Comparing the value of coal and oil as fuel, it will be found to vary considerably according to the quality of the fuel and the circumstances under which each are burnt, oil doing from 1½ to 2½ times the work of an equal weight of coal; taking the average conditions, the results of extended experience with astatki and crude petroleum show that these oils will be found to do twice the work of coal.

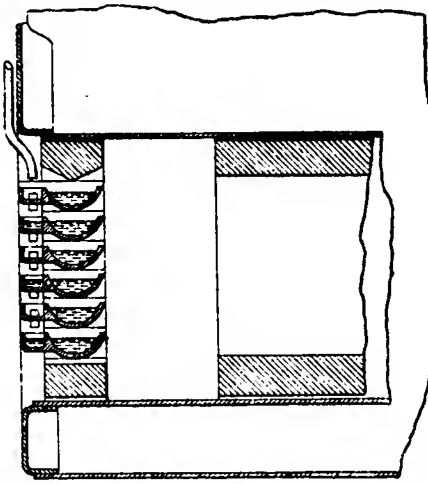

FIG. 1.—CUP FURNACE.

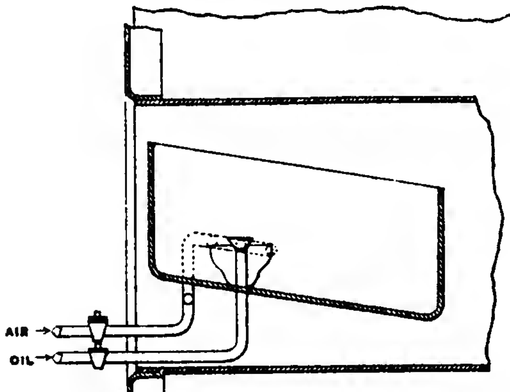

FIG. 2.

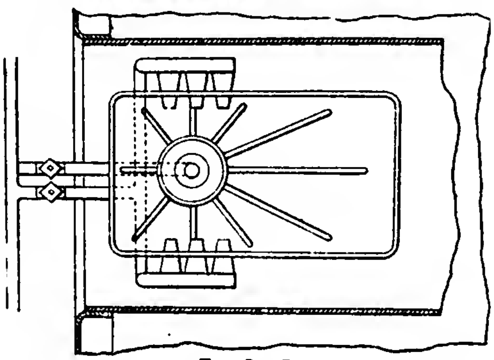

FIG. 3.—PLAN.

FIGS. 2 & 3.—BIDLE PAN FURNACE, 1862.

Table II shows the analyses of various oils and coals, together with their calculated calorific and evaporative values. This shows a value for oil of only 1½ times that of coal, and, therefore, some cause other than that of comparative heat value must be looked for to account for the result of a value of two to one in favour of oil fuel, which is found in practice. This difference may be accounted for to a great extent by the following causes.

Fig. 15.—Kauffmann.

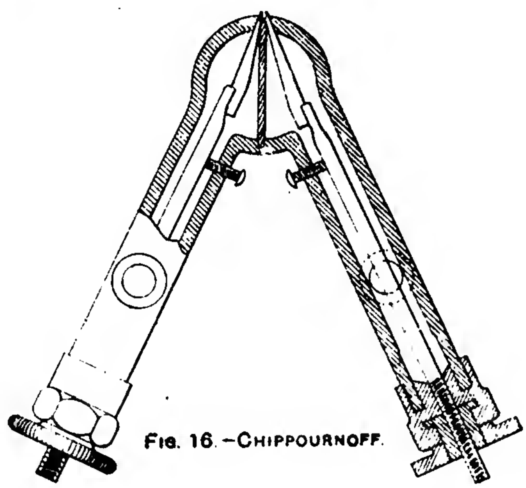

Fig. 16.—Chippournoff.

1. The combustion of the liquid fuel is complete, whereas that of coal is not, consequently in the former case there is no lost heat in smoke or soot.

2. There are no ashes or clinkers, and consequently no fires to clean, with the accompanying loss of heat and drop in the steam pressure—the steam pressure and revolutions of the engines being maintained at one point throughout the voyage.

3. The boiler tubes are always free from soot and clean, and therefore always in the best condition for transmitting the heat from gases passing through them to the water of the boiler.

4. The temperature of the escaping gases may be considerably lower than is required to create the necessary draught for coal firing. With coal the air has to be drawn through the bars and the fire in the furnaces; by natural draught this requires a temperature of the escaping gases about 600° to 700° F. But in the case of liquid fuel there are no bars or thick fire for the air to force its way through, and the required amount of air can be drawn through the furnaces by a much lower uptake temperature—about 400° to 450° F. being in most cases sufficient.

5. The admission of air to the furnace being under complete control, and the fuel being burnt in fine particles in close contact with the oxygen of the air, only a very small excess of air above that actually necessary for the complete combustion of the fuel is required. With coal, in order to ensure as complete combustion as possible, a very much larger excess of air is required.

In addition to its higher calorific value, liquid fuel has many other advantages, especially on board ship.

STOWAGE.—A ton of coal will occupy about 45 cubic feet of bunker space, and a ton of oil will require about 40 to 45 cubic feet. Assuming that both coal and oil will require the same bunker space per ton, then, since one ton of oil fuel is equal to two tons of coal, the bunker space necessary to steam the same distance at the same speed is only one-half. In addition to this, there is no lost space caused by the projection of frames, stringers, or beams. Also, portions of the ship which, if used as coal bunkers would be inaccessible, can be utilised for the stowage of oil.

TRIMMING.—This is altogether dispensed with, the oil being run or pumped into the fuel tanks through a deck connection, and beyond the opening and closing of the distributing valves, no other attention or labour is necessary for the shipment of the fuel; this makes a considerable reduction in the labour cost and the time occupied. When at sea the oil either gravitates to the furnaces, if the tanks are above them, or is pumped up if below, and no trimmers are required.

STOKING.—The sprayers require very little attention after they are once adjusted, and one man can attend to a large number of furnaces, and there being no ashes or dirt to remove the stokehold staff can be reduced to a single man for each watch in any ordinary vessel, or in a small vessel the sprayers can be attended to by the engineer on watch in the engine-room, as is done in many of the vessels on the Caspian Sea.

There are also no firing tools to repair, or firebars and floor-plates to renew, and the absence of smoke and dust enables the ship to be kept cleaner.

Regarding the various methods which have been adopted for the burning of liquid fuel these may be divided into three systems:—

(1) Furnaces into which the oil is run or dropped and burnt without gasifying or spraying.
(2) Furnaces in which the oil is first wholly or partially gasified.
(3) Furnaces into which the oil is sprayed.

1. This is the oldest form of burning oil, and is illustrated by the following examples:—

Fig. 1 shows the step or cup form of furnace, and is the latest form of a very old method of burning oil. Figs. 2 and 3: the pan furnace of Biddle used in North America in 1862. Fig. 4: Richardson furnace, patented in 1864. The bottom of this furnace is covered with ordinary slacked lime, which is kept saturated with the oil to be burned. Fig. 4A: Audouin furnace, first tried in 1865, consists of a large number of small tubes, from which the oil is constantly dripping, and is carried into the furnace and burnt by the draught through the openings in the front. The furnaces of St. Claire-Deville, 1868, Wagenknecht, 1870, Kamenske, 1869, MacKine, 1865, Verstraët, 1868, and Paterson, 1878, are all similar to one or the other of the above furnaces. The defect in all these is that the air is not brought in close contact with the burning fuel, with the result of imperfect combustion, accompanied by dense black smoke.

2. Fig. 5 illustrates Shaw and Lintou's gas furnace, patented in America in 1862. Fig. 6; Dorsett and Blythe gas furnace, tried in England in 1868 on board the steamer "Retriever." It may be observed that the disadvantage of all gas furnaces is that when using heavy residual oils the tarry deposits rapidly stop up the passages and pipes.

3. The furnaces into which the fuel is sprayed can be divided into three distinct classes:—(A) Flat slit sprayers. (B) Sprayers in which a jet of steam or air meets a jet of oil at an angle. (C) Circular sprayers.

(A) FLAT SPRAYERS.

Fig. 7 shows the first sprayer, which was constructed by Lenz in 1870, who commenced experimenting with oil as a fuel in 1868. Fig. 8 shows the later form of Lenz sprayer. Fig. 9: Korting's flat-mouthed sprayer of 1872. Fig. 10: Artemeff sprayer, 1878. A large number of these sprayers are used in ships on the Caspian Sea and the Volga. Figs. 11 and 12: Karapetoff sprayer, 1880. Fig. 13: Brandt's flat sprayer, 1880. The openings for both steam and oil in this sprayer are circular; it was designed for use in locomotive boilers, and was placed in the centre of the firebox at the level usually occupied by the firebars. Fig. 14: Bloomer and Korebutt-Dachkeveich, 1886. Fig. 15: Kauffmann's flat sprayer. Fig. 16: Chippournoff's sprayer. Fig. 17: Berseneff's sprayer, 1891. This very much resembles Brandt's sprayer (Fig. 13), with the addition of a second steam opening.

(B) JET SPRAYERS.

Fig. 18: The sprayer of Wise, Field, and Aydon was patented in 1865, and is one of the oldest methods of spraying fuel oils. It was first used on a Cornish boiler in 1866 in South Lambeth. Admiral Selwyn also experimented with this sprayer. Fig. 19: Aydon and Selwyn, 1867. This sprayer was tried by the Admiralty in 1868 at Greenwich, heavy tar oil being used as fuel and the steam superheated. Fig. 20: Benkston, 1874. This sprayer consists of two pipes flattened at one end, the oil pipe being bent over, and is the most simple form of sprayer. Fig. 21: Korting, 1876. This sprayer shows an attempt to carry in air with the steam jet before it reached the oil jet, but the spraying was found to be imperfect. Since 1880 Korting has used a sprayer very closely resembling that of Aydon and Selwyn (Fig. 19). Dickey's jet sprayer, 1878, is illustrated in the paper by the late Mr. B. G. Nichol.

(C) CIRCULAR SPRAYERS.

Fig. 22: Spakovski, 1870. This sprayer was fitted to the boilers of the steamship "Ivan," on the Caspian Sea, in 1870. Fig. 23: Lenz, 1872. Fig. 24: The first sprayer used by Urquhart in 1874. Fig. 28 shows his sprayer of 1832, and is the form now used so extensively on the Russian railways. Fig. 25: Salisbury,

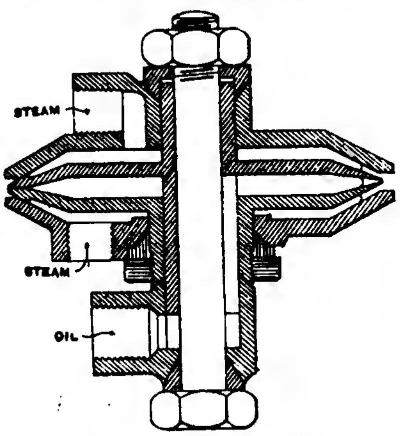

FIG. 17.—BERSENEFF, 1891.

1878. Fig. 26: Brandt circular sprayer, 1880. Fig. 27: Korting, 1881. Fig. 29: D. Aliest, 1885. D. Aliest carried out a large number of experiments, principally on board ship, using compressed air and steam for spraying the oil, and also with artificial draught. Sadler's, 1884, and Smith's, 1886, sprayers are illustrated

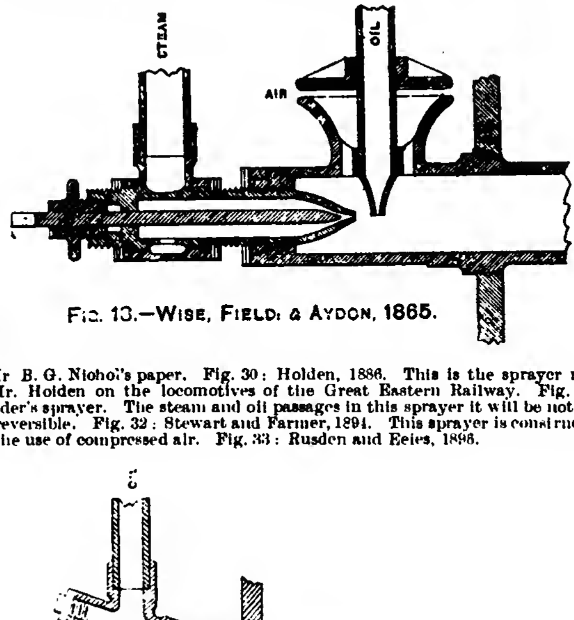

FIG. 18.—WISE, FIELD & AYDON, 1865.

in Mr B. G. Nichol's paper. Fig. 30: Holden, 1886. This is the sprayer used by Mr. Holden on the locomotives of the Great Eastern Railway. Fig. 31: Dunder's sprayer. The steam and oil passages in this sprayer it will be noticed are reversible. Fig. 32: Stewart and Farmer, 1894. This sprayer is constructed for the use of compressed air. Fig. 33: Rusden and Eeles, 1896.

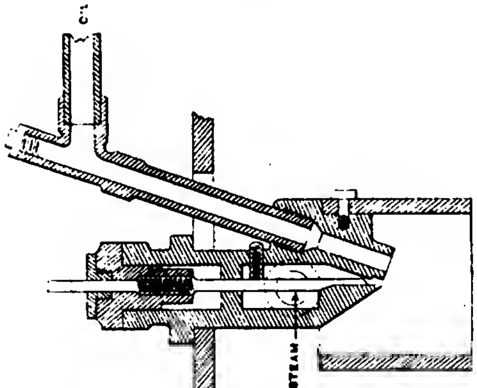

FIG. 19.—AYDON & SELWYN, 1868.

Several attempts have been made to spray the oil by other means than that of the steam jet, in order to overcome the difficulty of making up the fresh water drawn from the boilers in the form of steam. Air under pressure, especially if heated, has been found to give good results, but the flame is shorter, giving a more intense heat for a short distance than the flame from a steam sprayer, More air than steam is required for the spraying of the oil, and the air jets are more noisy than the steam. The danger of an explosion of oil gas in the furnace and combustion chamber when lighting up, especially if the furnace has been stopped for a short time only, is very much greater with air than with steam sprayers.

Comparing the economy of air and steam sprayers (notwithstanding the drawback of having to make up the water lost in steam used by the sprayers), the steam sprayers appear to be the most economical, and are certainly the

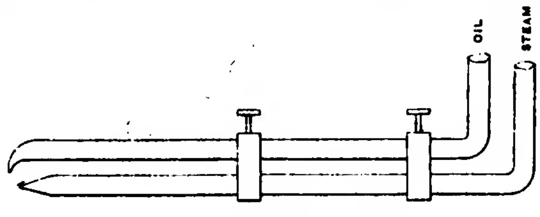

FIG. 20 —BENKSTON. 1874.

type mostly in use. The arrangement of the whole of the steam sprayer installation is exceedingly simple and not liable to derangement or breakdown, whereas the compressed air system is complicated and the risk of breakdown increased by the addition of the air compressor.

The essential requirements in a sprayer are :—

1. The oil and steam openings must be so arranged that the oil can be sprayed in the finest particles possible.
2. The steam consumption of the burner must be as low as possible.

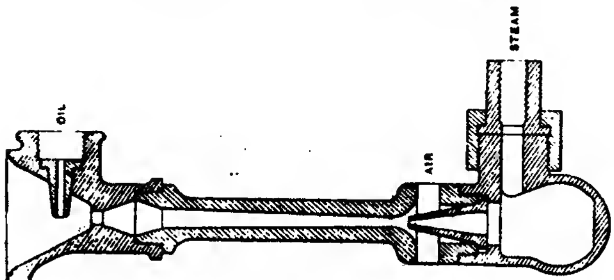

FIG. 21.—KORTING. 1876.
